Important note: Medical knowledge is ever-changing. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may be required. The authors and editors of the material contained herein have consulted sources believed to be reliable in their efforts to provide information that is complete and in accord with the standards accepted at the time of publication. However, in view of the possibility of human error by the authors, editors, or publisher of the work herein, or changes in medical knowledge, neither the authors, editors, publisher, nor any other party who has been involved in the preparation of this work, warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this publication is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Some of the product names, patents, and registered designs referred to in this book are in fact registered trademarks or proprietary names even though specific

CONTRIBUTORS

Naomi A. Abel, M.D.
Electrodiagnostics

Siviero Agazzi, M.D., M.B.A.
Management of vestibular schwannomas
Blunt cerebrovascular injury

Amir Ahmadian, M.D.
Cavernous malformations

Norberto Andaluz, M.D.
Carotid stenosis & endarterectomy
Emergency carotid endarterectomy
Totally occluded carotid artery

Ali A. Baaj, M.D.
Moyamoya disease

Magdalena Banasiak, M.D.
Medulloblastomas & PNETs

Enrico M. Camporesi, M.D.
Introduction to neuroanesthesia
Awake craniotomy

Rafael F. Cardona, M.D.
Bone graft materials

Elias Dakwar, M.D.
CSF fistulas

Armen Deukmedjian, M.D.
Dandy Walker malformation

Angela Downes, M.D.

Spontaneous subdural hematoma

Edward A. M. Duckworth, M.D.
Update on aneurysms, 6ed

Sarah J. Gaskill, M.D., F.A.C.S., F.A.A.P.
Periventricular-intraventricular hemorrhage of the newborn

Shannon Hann
Neurocutaneous melanosis
Treatment of status epilepticus

Michael C. Huang, M.D.
EC/IC bypass
Angiographic pointers

Rashid M. Janjua, M.D.
Peripheral nerve

Tsz Y. Lau, M.D.
Spinal cord stimulators

Shih-Sing Liu, M.D.
Cavernous malformations
Neurofibromatosis von Hippel Lindau disease

Ali R. Malek, M.D.
Stroke

Devanand Mangar, M.D., FCCP
Awake craniotomy

Jotham Manwaring, M.D.
X-linked hydrocephalus

Greg Morris, C.R.N.A., M.S.
Neuroanesthesia

Tann A. Nichols, M.D.
Trigeminal neuralgia, 6ed

Glen A. Pollock, M.D., D.V.M.
PRES
Endovascular neurosurgery

Edwin Ramos, M.D.
Hypothalamic hamartomas

Jaypal Reddy, M.D.
Sagittal balance

Eric Sauvageau, M.D.
Cavernous malformations
Endovascular neurosurgery

Joseph Serrone, M.D.
Pleomorphic xanthoastrocytomas

Juan S. Uribe, M.D.
Bone graft materials
Lhermitte-Duclos disease

Rohit Vasan, M.D.
Subgaleal shunt
Syncope

Justin Whitlow, M.D.
Asymptomatic carotid stenosis

Ashraf Samy Youssef, M.D., Ph.D.
Treatment algorithm for vasospasm, 6ed
Treatment of pineal region tumors

"Seize the moment of excited curiosity on any subject to solve your doubts; for if you let it pass, the desire may never return, and you may remain in ignorance." - William Wirt

DEDICATION

The seventh edition of the Handbook of Neurosurgery is dedicated to my family. To my wonderful wife, Debbie, who's loving support has made this book worthwhile; to my father, Louis Greenberg, for everything he has given me; and to my children, Michael, Leah, Alexa and Shaina.

THE COVER

The scalpel, and more recently, the vascular introducer sheath, are the keys that open the gate to gain access to the nervous system. Illustration by the author. © 2010.

CONVENTIONS

Cross references: the terms "*see below*" and "*see above*" are normally used when the referenced item is on the same page, or at most on the following (or preceding) page. When further excursions are needed, the page number will usually be included.

Σ | Paragraphs with this symbol summarize or synthesizes information from the associated text.

EVIDENCE BASED MEDICINE

The configuration shown below is used to call attention to evidence-based guidelines developed by authoritative committees. The definitions employed are in accordance with generally accepted current usage. The relevant document will be cited. This does not preclude selective deviation from recommendations to individualize care for specific and unique circumstances of a particular case. A standard of care is not implied. For an upto-date listing of some guidelines, visit www.guidelines.gov. If a Level other than I or A is given, this implies that a higher level recommendation could not be made. In some instances, the strength of the data will be mentioned e.g. as (Class II). For a listing of evidence-based guidelines contained in this book, see the *Index* under *practice guideline*.

PRACTICE GUIDELINE: DEFINITIONS	
Strength of recommendation	**Description**

Level I, II, III*	Level A, B, C, D†	
Level I High degree of clinical certainty	**Level A**	Based on consistent Class I evidence (well-designed, prospective randomized controlled studies)
	Level B	Single Class I study or consistent Class II evidence or strong Class II evidence especially when circumstances preclude randomized clinical trials
Level II Moderate degree of clinical certainty	**Level C**	Usually derived from Class II evidence (one or more well-designed comparative clinical studies or less well-designed randomized studies) or a preponderance of Class III evidence
Level III Unclear clinical certainty.	**Level D**	Generally based on Class III evidence (case series, historical controls, case reports and expert opinion). Useful for educational purposes and to guide future research

* as used in the Guidelines for the Management of Severe Traumatic Brain Injury, 3rd edition (Brain Trauma Foundation: Introduction. **J Neurotrauma** 24, Suppl 1: S1-2, 2007).

† as used in the Guidelines for the Surgical Management of Cervical Degenerative Disease (Matz P G, et al.: Introduction and methodology. **J Neurosurg: Spine** 11 (2): 101-3, 2009).

Booking the Case

These sections appear under certain specific operations to help when scheduling that surgery. Default information appears below, for example, a specific type of anesthesia will only be mentioned if something other than general anesthesia is typically used. A list of operations addressed by this means can be found in the index under “Booking the case”. 

Default values: (these details are not repeated in each section).

1. position: (depends on the operation)
2. pre-op:
   A. NPO after midnight the night before except meds with sips of water
   B. antithrombotics: discontinue Coumadin® ≥ 3 days prior to surgery, Plavix® 5-7 d pre-op, aspirin 7-10 d pre-op, other NSAIDs 5 d pre-op
3. cardiology/medical clearance as needed
4. anesthesia: default = general anesthesia, unless otherwise specified
5. equipment: special devices such as ultrasonic aspirator, image guidance…
6. instrumentation: standard surgical instrument trays for a specific operation are assumed. Special instrumentation resident in the hospital will be listed

7. implants: this usually requires scheduling with a vendor (manufacturers representative/distributor) to provide
8. neuromonitoring: will be listed if typically required
9. post-op: default care is on the ward (ICU is typically needed after craniotomy)
10. blood availability: specified if recommended
11. consent (these items use lay terms for the patient - not all-inclusive):
★ Disclaimers: **informed consent** for surgery requires disclosure of risks and benefits that would substantively affect a normal person's decision to have the operation. It cannot and should not attempt to include every possibility. The items listed in this section are included as memory joggers for some items for various procedures, but are not meant to be all inclusive. The omission of information from this memory aid is not to be construed as implying that the omitted item is not important or should not be mentioned.
   A. procedure: the typical operation and some possible common contingencies
   B. alternatives: non-surgical (AKA "conservative") treatment is almost always an option
   C. complications:
      1. risks of general anesthesia include: heart attack, stroke, pneumonia
      2. infection: a risk with any invasive procedure
      3. usual **craniotomy** complications include: bleeding intra-op and postop, seizure, stroke, coma, death, hydrocephalus, meningitis, neurologic deficit related to the area of surgery including (for applicable locations) paralysis, language or sensory disturbances, coordination impairment
      4. usual **spine surgery** complications include: injury to nerve or spinal cord with possible numbness, weakness or paralysis, failure of the operation to achieve the desired result, dural opening which may cause a CSF leak which occasionally needs to be surgical repair. Hardware complications (when used) include: breakage, pull-out, malposition. Although a rare complication, it is serious enough that it bears mentioning in cases positioned prone with possible significant blood loss (> 2 L): blindness (due to PION - *see page 450*)

ACKNOWLEDGMENTS

I would like to acknowledge all the sources used for the material in this book. This includes the many people involved in my medical and neurosurgical training. Special appreciation is expressed to John M. Tew, Jr., M.D., under whose guidance I received my neurosurgical training. It also includes those who generously granted permission to use figures and tables previously published.

I would also like to thank my colleagues and the residents in the neurosurgery program at the University of South Florida from whom I learn every day. Special thanks to our chairman, Dr. Harry van Loveren, for his advice and for inspiring excellence in neurosurgery.

Many thanks to Kay Conerly, executive editor at Thieme Publishers, for her unfaltering support and cheerleading.

ABBREVIATIONS

Abbreviations used only locally are defined in that section using boldface type. Numbers following entries below indicate the page number for the relevant section.

a.	artery (aa. = arteries)
AA	anaplastic astrocytoma - 595
ABC	aneurysmal bone cyst - 728
Abx.	antibiotics
AC	arachnoid cyst - 222
ACA	anterior cerebral artery
ACAS	asymptomatic carotid artery stenosis - 1147 *or* Asymptomatic Carotid Atherosclerosis Study - 1149
ACDF	anterior cervical discectomy & fusion - 462
ACE	angiotensin-converting enzyme
ACh	acetylcholine (neurotransmitter)
AChA	anterior choroidal artery
ACoA	anterior communicating artery
ACTH	adrenocorticotropic hormone (corticotropin) - 111
AD	autosomal dominant
ADH	antidiuretic hormone - 111
ADI	atlantodental interval - 957
ADPKD	autosomal dominant polycystic kidney disease - 1057
ADQ	abductor digiti quinti (or minimi)
AED	anti-epileptic drug (anticonvulsant)- 407
AFP	alpha-fetoprotein - 721
Ag	antigen
AHCPR	Agency for Health Care Policy and Research (of the U. S. Public Health Service)
AICA	anterior inferior cerebellar artery - 104
AIDP	acute inflammatory demyelinating polyra-diculoneuropathy - 67
AIDS	acquired immunodeficiency syndrome - 364
AIN	anterior interosseous neuropathy - 807

AD	autosomal dominant (inheritance)
AFO	ankle-foot-orthosis - 821
AKA	also known as
ALIF	anterior lumbar interbody fusion - 195
ALARA	As Low As Reasonably Achievable - 127
A-line	arterial line
ALL	anterior longitudinal ligament
ALS	amyotrophic lateral sclerosis - 65
AMS	acute mountain sickness - 916
AN	acoustic neuroma - 620
ANA	antinuclear antibodies
AOD	atlantooccipital dislocation - 951
AOI	atlantooccipital interval - 953
AP	antero-posterior
APAG	antipseudomonal aminoglycoside
APAP	acetaminophen - 46
APD	afferent pupillary defect - 831
APTT	(or PTT) activated partial thromboplastin time
ARDS	adult respiratory distress syndrome
ASA	American Society of Anesthesiologists *or* aspirin (acetylsalicylic acid)
ASAP	as soon as possible
AT	anterior tibialis (tibialis anterior)
AT/RT	atypical teratoid/rhabdoid tumor - 688
ASHD	atherosclerotic heart disease
AVM	arteriovenous malformation - 1098
AVP	arginine vasopressin - 111
Ax-LIF	axial lumbar interbody fusion - 195
ß-hCG	beta-human chorionic gonadotropin - 721
BA	basilar artery
BBB	blood-brain barrier - 109
BC	basal cisterns - 909
BCP	birth control pills (oral contraceptives)

BCVI	blunt cerebrovascular injury - 982
BG	basal ganglia
BI	basilar impression/invagination - 138
BMD	bone mineral density - 992
BMP	bone morphogenic protein - 198
BOB	benign osteoblastoma - 736
BP	blood pressure
BR	bed rest (activity restriction)
BSF	basal skull fracture - 887
BSG	brainstem glioma - 607
Ca	cancer
CA	cavernous angioma - 1106
CAA	cerebral amyloid angiopathy - 1122
CABG	coronary artery bypass graft
CAD	coronary artery disease
CAT	(or CT) computerized (axial) tomography
CBF	cerebral blood flow - 1010
CBV	cerebral blood volume
CBZ	carbamazepine - 411
CCB	calcium-channel blocker
CCF	carotid-cavernous (sinus) fistula - 1113
CCHD	congenital cyanotic heart disease
CD	Cushing's disease - 638
CEA	carotid endarterectomy - 1150 *or* carcinoembryonic antigen - 721
CECT	contrast enhanced CT
cf	(Latin: confer) compare
cGy	centi-Gray (1cGy = 1 rad)
CHF	congestive heart failure
CI	confidence interval (statistics)
CIDP	chronic inflammatory demyelinating polyra-diculoneuropathy - 68
CIP	critical illness polyneuropathy - 794
CJD	Creutzfeldt-Jakob disease - 361

CM	cavernous malformation - 1106
CMAP	compound motor action potential (EMG)
$CMRO_2$	cerebral metabolic rate of oxygen consumption - 1010
CMT	Charcot-Marie-Tooth - 793
CMV	cytomegalovirus
CNL	chemonucleolysis - 447
CNS	central nervous system
cCO	continuous cardiac output
CO	cardiac output *or* carbon monoxide - 277
CPA	cerebellopontine angle
CPM	central pontine myelinolysis - 11
CPN	common peroneal nerve - 820
CPP	cerebral perfusion pressure - 866
Cr. N.	cranial nerve(s)
CRH	corticotropin-releasing hormone - 111
CRP	C-reactive protein
CRPS	complex regional pain syndrome - 576
CSM	cervical spondylotic myelopathy - 486
CSO	craniosynostosis - 228
CSW	cerebral salt wasting - 13
CTA	CT angiogram - 128
CTP	CT perfusion - 128
CTS	carpal tunnel syndrome - 808
CVA	cerebrovascular accident (stroke) - 1010
CVP	central venous pressure
CVVT	cerebrovascular venous thrombosis - 1166
CVR	cerebrovascular resistance - 1010
CVS	cerebral vasospasm - 1045
CXR	chest x-ray
DACA	distal anterior cerebral artery
DAI	diffuse axonal injury - 853
DBM	demineralized bone matrix - 199

D/C	discontinue
DDAVP	1-deamino-8-D-arginine vasopressin (desmopressin) - 17
DDx	differential diagnosis - 1185
DBS	deep brain stimulation - 532
DI	diabetes insipidus - 15
DIND	delayed ischemic neurologic deficit - 1045
DIG	desmoplastic infantile astrocytoma and ganglioglioma - 612
DISH	diffuse idiopathic skeletal hyperostosis - 506
DKA	diabetic keto-acidosis
DLC	disco-ligamentous complex - 968
DLIF	direct lateral lumbar interbody fusion - 194
DOC	drug of choice
DM	diabetes mellitus
DMZ	dexamethasone
DNT	(or DNET) dysembryoplastic neuroepithelial tumors - 591
DOE	dyspnea on exertion
DOMS	delayed onset muscle soreness - 478
DPL	diagnostic peritoneal lavage
DREZ	dorsal root entry zone lesion - 575
DSA	digital subtraction angiogram
DSD	degenerative spine - 474
DST	dural sinus thrombosis - 1166
DTs	delerium tremens - 275
DTT	diffusion tensor tractography MRI - 134
DVT	deep-vein thrombosis - 42
DWI	(or DWMRI) diffusion-weighted imaging (MRI) - 132
EAC	external auditory canal
EAM	external auditory meatus
EAST	Eastern Association for the Surgery of Trauma
EBRT	external beam radiation therapy
EBV	Epstein-Barr Virus
ECM	erythema chronicum migrans - 368
EDC	electrolytically detachable coils - 1059

EDH	epidural hematoma - 894
EHL	extensor hallicus longus
ELISA	enzyme-linked immunosorbent assay
ELST	endolymphatic sac tumors - 668
EM	electron microscope (microscopy)
ENG	electronystagmography - 624
ENT	ear, nose and throat (otolaryngology)
EOM	extra-ocular muscles - 834
EOO	external oculomotor ophthalmoplegia
ESR	erythrocyte sedimentation rate
EST	endodermal sinus tumor - 692
EtOH	ethyl alcohol (ethanol)
ET tube	endotracheal tube
ETV	endoscopic third ventriculostomy - 315
EVD	external ventricular drain (ventriculostomy)
FCU	flexor carpi ulnaris
FDP	flexor digitorum profundus]
FIM	Functional Independence Measure - 1184
FLAIR	fluid-attenuated inversion recovery (on MRI) - 129
FM	face mask
FMD	fibromuscular dysplasia - 79
FSH	follicle stimulating hormone - 111
F/U	follow-up
FUO	fever of unknown origin
GABA	gamma-aminobutyric acid
GBM	glioblastoma (multiforme) - 596
GBS	Guillain-Barré syndrome - 66
GCA	giant cell arteritis - 74
GCS	Glasgow coma scale - 279
GCT	granular cell tumor - 641 *or* germ cell tumor - 692
GD	Graves' disease
GFAP	glial fibrillary acidic protein - 720

GGT	gamma glutamyl transpeptidase
GH	growth hormone - 111
GH-RH	growth hormone releasing hormone - 111
GMH	germinal matrix hemorrhage - 1131
GNR	gram negative rods
GnRH	gonadotropin-releasing hormone - 111
GSW	gunshot wound
GTC	generalized tonic-clonic (seizure)
H/A	headache - 57
H&H	Hunt and Hess (SAH grade) - 1039
H&P	history and physical exam
HBsAg	hepatitis B surface antigen
HCD	herniated cervical disc - 461
hCG	human chorionic gonadotropin - 721
HCP	hydrocephalus - 307
HDT	hyperdynamic therapy - 1052
HGB	hemangioblastoma - 667
Hgb-A1C	hemoglobin A1C
hGH	human growth hormone
HH	hypothalamic hamartomas - 226 *or* homonymous hemianopsia
HHT	hereditary hemorrhagic telangiectasia - 1106
HIV	human immunodeficiency virus
HLD	herniated lumber disc - 442
HLA	human leukocyte antigen
H.O.	house officer
HNP	herniated nucleus pulposus (herniated disc) - 442
HNPP	hereditary neuropathy with liability to pressure palsies - 793
HOB	head of bed
HPA	hypothalamic-pituitary-adrenal axis
HSE	herpes simplex encephalitis - 358
HTN	hypertension
IAC	internal auditory canal

IASDH infantile acute subdural hematoma - 899

ICA internal carotid artery

ICG indocyanine green

ICH intracerebral hemorrhage - 1118

IC-HTN intracranial hypertension (increased ICP)

ICP intracranial pressure - 866

ICU intensive care unit

IDDM insulindependent diabetes mellitus

IDET intradiscal endothermal therapy - 448

IEP immune electrophoresis

IG image guidance (intraoperative)

IGF-1 insulin-like growth factor-1 (AKA somatomedin-C) - 111

IIH idiopathic intracranial hypertension (pseudotumor cerebri) - 713

IIHWOP idiopathic intracranial hypertension without papilledema - 714

IJV internal jugular vein

IMRT intensity modulated radiation therapy

INO internuclear ophthalmoplegia - 834

INR international normalized ratio - 39

IPS inferior petrosal sinus

IPA idiopathic paralysis agitans (Parkinson's disease) - 59

ISAT International Subarachnoid Hemorrhage Aneurysm Trial - 1059

IT intrathecal

ITB intrathecal baclofen - 539

IVC intraventricular catheter *or*
inferior vena cava

IVH intraventricular hemorrhage - 1228

IVP intravenous push (medication route) *or*
intravenous pyelogram (x-ray study)

JPS joint position sense

LBP low back pain - 428

LDD Lhermitte-Duclos disease - 593

LE lower extremity

LFTs liver function tests

LGG low-grade glioma - 590

LH	leuteinizing hormone - 111
LH-RH	leuteinizing hormone releasing hormone - 111
LMD	low molecular weight dextran
LMN	lower motor neuron - 786
LMW	low-molecular-weight (e.g. heparins)
LOC	loss of consciousness
LOH	loss of heterozygosity
LP	lumbar puncture - 201
LSO	lumbo-sacral orthosis
MAC	mycobacterium avian complex - 381
MAOI	monoamine oxidase inhibitor
MAP	mean arterial pressure
MAST®	military anti-shock trousers
MB	medulloblastoma - 686
MBEN	medulloblastoma with extensive nodularity - 686
MBI	modified Barthel index - 1183
MBS	medulloblastoma - 686
MCA	middle cerebral artery
mcg	(or μg) microgram
MCP	mean carotid pressure *or* metacarpal phalangeal
MDCTA	multidetector CT angiography
MDMA	methylenedioxymethamphetamine - 60
mg	milligram
MI	myocardial infarction
MIB-1	monoclonal anti-Ki-67 antibody - 720
MIC	minimum inhibitory concentration (for antibiotics)
MID	multi-infarct dementia
MISS	minimally invasive spine surgery
mJOA	modified Japanese Orthopedic Association scale - 487
MLF	medial longitudinal fasciculus
MLS	midline shift - 909
MM	myelomeningocele - 248 *or* multiple myeloma - 740

MMD	moyamoya disease - 1170
MMN	multifocal motor neuropathy - 1188
MMPI	Minnesota Multiphasic Personality Inventory
mos	months
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine - 60
MRA	MRI angiogram - 133
MRS	MRI spectroscopy - 133
MRSA	methicillin resistant *staphylococcus aureus*
MS	microsurgery *or* multiple sclerosis - 61
MSO_4	morphine sulfate
MTP	metatarsal phalangeal
MTT	mean transit time (on CT perfusion) - 128
MUAP	motor unit action potential - 270
MVA	motor vehicle accident
MVD	microvascular decompression - 559
MW	molecular weight
n.	nerve (nn. = nerves)
Na	(or Na^+) sodium
N_2O	nitrous oxide - 2
NAA	N-acetyl aspartate - 133
NAP	nerve action potential - 789
NASCET	North American Symptomatic Carotid Endarterectomy Trial - 1150
NB	(Latin: *nota bene*) note well
NC	nasal cannula
NCCN	National Comprehensive Cancer Network
NCD	neurocutaneous disorders - 722
NCV	nerve conduction velocity
NEC	neurenteric cyst - 227 *or* necrotizing enterocolitis
NEXUS	National Emergency X-Radiography Utilization Study - 938
NF	(or NFT) neurofibromatosis - 722
NF1	neurofibromatosis type 1 - 723

NF2	neurofibromatosis type 2 - 724
NG tube	nasogastric tube
NGGCT	non-germinomatous germ cell tumors - 692
NIHSS	NIH Stroke Scale - 1014
NMBA	neuromuscular blocking agent - 25
NMO	neuromyelitis optica (Devic disease) - 1187
NPH	normal pressure hydrocephalus - 329
NPS	neuropathic pain syndrome - 564
NS	normal saline
NSAID	non-steroidal anti-inflammatory drug - 44
NSCLC	non-small-cell cancer of the lung - 704
NSF	nephrogenic systemic fibrosis - 130
NSM	neurogenic stunned myocardium - 1054
NTP	nitroprusside - 19
N/V	nausea and vomiting
NVB	neurovascular bundle
OAD	occipital atlantal dislocation, see atlantooccipital dislocation - 951
OALL	ossification of the anterior longitudinal ligament - 506
OC	occipital condyle
OCB	oligoclonal bands (in CSF) - 65
OCF	occipital condyle fracture - 954
ODG	oligodendroglioma - 609
OEF	oxygen extraction fraction
OFC	occipital-frontal (head) circumference
OGST	oral glucose suppression test (for growth hormone) - 648
OMO	open-mouth odontoid (C-spine x-ray view)
OMP	oculomotor (third nerve) palsy
ONSF	optic nerve sheath fenestration - 718
OP	opening pressure (on LP) - 202
OPLL	ossification of the posterior longitudinal ligament - 504
ORIF	open reduction/internal fixation
OS	overall survival
OTC	over the counter (i.e. without prescription)

PACU post-anesthesia care unit (AKA recovery room, PAR)

PADI posterior atlantodental interval - 495]

PAN poly- (or peri-) arteritis nodosa - 77

PBPP perinatal brachial plexus palsy - 802

$p_{Bt}O_2$ brain tissue oxygen tension - 874

PC pineal cyst- 691

PCA pilocytic astrocytoma - 603 *or*
posterior cerebral artery

PCB pneumatic compression boot

PCC prothrombin complex concentrate - 41

PCI prophylactic cranial irradiation

PCN penicillin

PCNSL primary CNS lymphoma - 672

P-comm posterior communicating artery

PCV procarbazine, CCNU, & vincristine (chemotherapy)

PCWP pulmonary capillary wedge pressure

PDA patent ductus arteriosus

PDN painful diabetic neuropathy - 548

PDR Physicians Desk Reference®

peds pediatrics (infants & children)

PEEK poly-ether-ether-ketone (graft material)

PET positron emission tomography (scan)

p-fossa posterior fossa

PFS progression-free survival

PFT pulmonary function test

PHN postherpetic neuralgia - 564

PHT phenytoin (Dilantin®) - 409

PICA posterior inferior cerebellar artery - 103

PIF prolactin release inhibitory factor - 111

PIN posterior interosseous neuropathy - 817

PION posterior ischemic optic neuropathy - 450

PIVH periventricular-intraventricular hemorrhage - 1131

PLAP placental alkaline phosphatase - 693

PLEDs	periodic lateralizing epileptiform discharges
PLIF	posterior lumbar interbody fusion
PM	pars marginalis - 85
PMA	progressive muscular atrophy - 65 *or* pilomyxoid astrocytoma - 606
PMH	pure motor hemiparesis
PML	progressive multifocal leukoencephalopathy - 364
PMMA	polymethylmethacrylate (methylmethacrylate)
PMR	polymyalgia rheumatica - 77
PMV	pontomesencephalic vein
PNET	primitive neuroectodermal tumor - 686
POD	post-operative day
PPV	positive predictive value: in unselected patients who test positive, PPV is the probability that the patient has the disease
PR	per rectum
PRES	posterior reversible encephalopathy syndrome - 73
PRF	prolactin releasing factor - 111
PRIF	prolactin (releasing) inhibitory factor - 111
PRN	as needed
PRSP	penicillinase resistant synthetic PCN
PSNP	progressive supra-nuclear palsy - 61
PSR	percutaneous stereotactic rhizotomy (for trigeminal neuralgia) - 553
PSW	positive sharp waves (on EMG) - 270
pt	patient
PT	physical therapy *or* prothrombin time
PTC	pituicytoma - 641
PTR	percutaneous trigeminal rhizotomy
PTT	(or APTT) partial thromboplastin time
PUD	peptic ulcer disease
PVP	percutaneous vertebroplasty - 994
PWI	perfusion-weighted imaging (MRI) - 132
PXA	pleomorphic xanthoastrocytoma - 592
q	(Latin: *quaque*) every (medication dosing)
RA	rheumatoid arthritis

RAPD	relative afferent pupillary defect - 831
RASS	Richmond agitation-sedation scale - 23
RCVS	reversible cerebral vasoconstrictive syndrome - 1035
rem	roentgen-equivalent man
REZ	root entry zone
RFR	radiofrequency rhizotomy - 553
rFVIIa	recombinant (activated) factor VII
RH	recurrent artery of Heubner
rhBMP	recombinant human BMP - 199
R/O	rule out
ROM	range of motion
RPA	recursive partitioning analysis
RPDB	randomized prospective double-blind
RPLS	reversible posterior leukoencephalopathy syndrome (see posterior reversible encephalopathy syndrome - 73)
RPNB	randomized prospective non-blinded
RTOG	Radiation Therapy Oncology Group
RTP	return to play (sports) - 851
rt-PA	recombinant tissue plasminogen activator (AKA tissue plasminogen activator)
RTX	(or XRT) radiation therapy - 770
S/S	signs and symptoms
SAH	subarachnoid hemorrhage - 1034
SBE	subacute bacterial endocarditis
SBO	spina bifida occulta - 247
SBP	systolic blood pressure
SCA	superior cerebellar artery
SCLC	small-cell lung cancer - 703
SCD	sequential compression device
SCI	spinal cord injury - 930
SCM	sternocleidomastoid (muscle)
SD	standard deviation
SDE	subdural empyema - 356
SDH	subdural hematoma - 896
SE	status epilepticus (for seizures) - 402)

SEA	spinal epidural abscess - 376
SEP	(or SSEP) somatosensory evoked potential
SG	specific gravity
SIAD	syndrome of inappropriate antidiuresis - 10
SIADH	syndrome of inappropriate antidiuretic hormone (ADH) secretion - 10
SIDS	sudden infant death syndrome
SIH	spontaneous intracranial hypotension - 305
SIRS	septic inflammatory response syndrome
$SjVO_2$	jugular venous oxygen saturation - 874
SLAD	surgical laser aiming device
SLE	systemic lupus erythematosus
SLIC	subaxial injury classification - 968
SMC	spinal meningeal cyst - 509
SMT	spinal manipulation therapy - 438
SNAP	sensory nerve action potential (EMG) - 270
SNUC	sinonasal undifferentiated carcinoma - 1230
SOMI	sternal-occipital-mandibular immobilizer - 979
SON	supraorbital neuralgia - 562
S/P	status-post
SPAM	subacute progressive ascending myelopathy - 1000
SPECT	single positron emission computed tomography (scan)
SPEP	serum protein electrophoresis
sPNET	supratentorial primitive neuroectodermal tumor - 686
SQ	subcutaneous injection
SRS	stereotactic radiosurgery - 773
SRT	stereotactic radiotherapy - 775
SSEP	(or SEP) somatosensory evoked potential
SSPE	subacute sclerosing panencephalitis - 266
SSRI	selective serotonin reuptake inhibitors
SSS	superior sagittal sinus
STA	superficial temporal artery
STICH	Surgical Trial in Intracerebral Haemorrhage - 1129

STIR	short tau inversion recover (MRI image)
STN	subthalamic nucleus
STSG	Spine Trauma Study Group
SUNCT	short-lasting unilateral neuralgiform H/A with conjunctival injection and tearing - 549
SVC	superior vena cava
SVM	spinal vascular malformations - 507
SVR	systemic venous resistance
SVT	supraventricular tachycardia
Sz.	seizure - 394
T1WI	T1 weighted image (on MRI) - 129
T2WI	T2 weighted image (on MRI) - 129
TAL	transverse atlantal ligament - 92
TBA	total bilateral adrenalectomy - 850
TBI	traumatic brain injury - 654
TCA	tricyclic antidepressants
TCD	transcranial doppler - 1048
TDL	tumefactive demyelinating lesions - 64
TE	time to echo (on MRI) - 129
TEE	transesophageal echocardiogram
TEN	toxic epidermal necrolysis
TENS	transcutaneous electrical nerve stimulation
TGN	trigeminal neuralgia - 551
T-H lines	Taylor-Haughton lines - 87
TIA	transient ischemic attack - 1010
TICH	traumatic intracerebral hemorrhage (hemorrhagic contusion) - 893
TIVA	total intravenous anesthesia
TLIF	transforaminal lumbar interbody fusion - 193
TLISS	thoracolumbar injury severity score - 990
TLJ	thoracolumbar junction - 986
TLSO	thoracolumbar-sacral orthosis
TM	tympanic membrane
TMB	transient monocular blindness (amaurosis fugax) - 1144
t-PA	tissue plasminogen activator

TR	time to repetition (on MRI) - 129
TRH	thyrotropin releasing hormone; AKA TSH-RH - 111
TS	transverse sinus
TSC	tuberous sclerosis complex - 725
TSH	thyroid-stimulating hormone (thyrotropin) - 111
TSV	thalamostriate vein
TTP	thrombotic thrombocytopenic purpura
TVO	transient visual obscurations - 715
Tx.	treatment
UBOs	unidentified bright objects (on MRI)
UE	upper extremity
UMN	upper motor neuron - 786
UTI	urinary tract infection
URI	upper respiratory tract infection
U/S	ultrasound
VA	vertebral artery *or* ventriculoatrial
VB	vertebral body
VBI	v]ertebrobasilar insufficiency - 1158
VEMP	vestibular evoked myogenic potential = 624
VHL	von Hippel-Lindau (disease) - 667
VMA	vanillylmandelic acid
VP	ventriculoperitoneal
VS	vestibular schwannoma - 620
VZV	(herpes) varicella zoster virus
WBC	white blood cell (count)
WBXRT	whole brain radiation therapy - 770
WFNS	World Federation of Neurosurgical Societies (grading SAH) - 1040
WHO	World Health Organization. For tumor grading, e.g. WHO II indicates WHO grade II
wks	weeks
WNL	within normal limits
w/o	without
WRS	word recognition score - 623
W/U	work-up (evaluation)

XLIF	extreme lateral lumbar interbody fusion - 194
XRT	(or RTX) radiation therapy - 770

1. Neuroanesthesia

1.1. General information

For issues related to intracranial pressure (ICP), cerebral perfusion pressure (CPP), intracranial constituents, etc., *see page 867*. For cerebral blood flow **(CBF)** and cerebral metabolic rate of oxygen consumption ($CMRO_2$), *see page 1010*.

Parameters of primary relevance to neurological surgery that can be modulated by the anesthesiologist:

1. blood pressure: one of the factors that determines CPP. May need to be manipulated (e.g. reduced when working on an aneurysm, or increased to enhance collateral circulation during cross clamping). Measurement by arterial line is most accurate and depending on the patient's presentation and the planned procedure, often should be placed prior to induction of anesthesia. For intracranial procedures, the arterial line should be calibrated at the external auditory meatus to most closely reflect intracranial blood pressure
2. jugular venous pressure: one of the factors that influences ICP
3. arterial CO_2 tension ($PaCO_2$): CO_2 is the most potent cerebral vasodilator. Hyperventilation reduces $PaCO_2$ (hypocapnea) which decreases CBV but also CBF. Goal is generally end tidal CO_2 ($ETCO_2$) of 25-30 mm Hg with a correlating $PaCO_2$ of 30-35. Use with care for stereotactic procedures to minimize shift of intracranial contents when using this method to control ICP[1]
4. arterial O_2 tension
5. hematocrit: in neurosurgery it is critical to balance oxygen carrying capacity (decreased by anemia) against improved blood rheology (impaired by elevated Hct)
6. patient temperature: mild hypothermia provides some protection against ischemia by reducing the cerebral metabolic rate of oxygen ($CMRO_2$) by ≈

7% for each 1° C drop

7. blood glucose level: hyperglycemia exacerbates ischemic deficits[2]
8. $CMRO_2$: reduced with certain neuro-protective agents and by hypothermia (*see above*) which helps protect against ischemic injury
9. in cases where a lumbar drain or a ventricular drain has been placed: CSF output
10. elevation of the head of the patient: lowering the head increases arterial blood flow, but also increases ICP by impairing venous outflow
11. intravascular volume: hypovolemia can impair blood flow in for neurovascular cases. In surgery in the prone position, excessive fluids may contribute to facial edema which is one of the risk factors for PION (*see page 450*)
12. positioning injuries: during the procedure, the patient's position may change and be unnoticed due to draping. Careful and frequent examination of the patient's position may prevent injuries associated with prolonged malpositioning
13. post operative nausea and vomiting (PONV): may adversely affect ICP and may negatively impact recent cervical surgical procedures. Avoidance of anesthetic agents known to cause PONV or pretreatment to prevent PONV may be prudent

1.2. Drugs used in neuroanesthesia

INHALATIONAL AGENTS

Most reduce cerebral metabolism (except nitrous oxide, *see below*) by suppressing neuronal activity. These agents disturb cerebral autoregulation and cause cerebral vasodilatation which increases cerebral blood volume **(CBV)** and can increase ICP. With administration > 2 hrs they increase CSF volume which can also potentially contribute to increased ICP. Most agents increase the CO_2 reactivity of cerebral blood vessels. These agents affect intraoperative EP monitoring (*see page 4*).

nitrous oxide (N_2O) **DRUG INFO**

A potent vasodilator that markedly increases CBF and minimally *increases* cerebral metabolism. Contributes to post-op N/V.

Nitrous oxide, pneumocephalus and air embolism: The solubility of nitrous oxide **(N_2O)** is ≈ 34 times that of nitrogen[3]. When N_2O comes out of solution in an airtight space it can increase the pressure which may convert pneumocephalus to "tension pneumocephalus". It may also aggravate air embolism. Thus caution must be used especially in the sitting position where significant post-op pneumocephalus and air embolism are common. The risk of tension pneumocephalus may be reduced by filling the cavity with fluid in conjunction with turning off N_2O about 10 minutes prior to completion of dural closure. See *Pneumocephalus* on page 890.

Halogenated agents:

Agents in primary usage today are shown below. All suppress EEG activity and may provide some degree of cerebral protection.

isoflurane (Forane®) DRUG INFO

Can produce isoelectric EEG without metabolic toxicity. Improves neurologic out-come in cases of incomplete global ischemia (although in experimental studies on rats, the amount of tissue injury was greater than with thiopental[4]).

desflurane (Suprane®) DRUG INFO

A cerebral vasodilator, increases CBF and ICP. Decreases $CMRO_2$ which tends to cause a compensatory vasoconstriction.

sevoflurane (Ultane®) DRUG INFO

Mildly increases CBP and ICP, and reduces $CMRO_2$. Mild negative inotrope, cardiac output not as well maintained as with isoflurane or desflurane.

Intravenous agents

Induction

Agents generally used for induction:

1. propofol: exact mechanism of action unknown. Short half life with no active metabolites May be used for induction ans as a continuous infusion during total intravenous anesthesia **(TIVA)**. Causes dose dependent decrease in mean arterial blood pressure (MAP) and ICP. For information other than use in induction *see page 3*). Is more rapidly cleared than, and has largely replaced, thiopental
2. barbiturates: produce significant reduction in $CMRO_2$ and scavenge free radicals among other effects (*see page 1063*). Produce dose-dependent EEG suppression which can be taken all the way to isoelectric. Minimally affect EPs. Most are anticonvulsant, but methohexital (Brevital®) can *lower* the seizure threshold (*see page 24*). Myocardial suppression and peripheral vasodilatation from barbiturates may cause hypotension and compromise CPP, especially in hypovolemic patients
   - sodium thiopental (Pentothal®): the most common agent. Rapid onset, short acting. Minimal effect on ICP, CBF and $CMRO_2$
3. etomidate (Amidate®): a carboxylated imidazole derivative. Anesthetic and amnestic, but no analgesic properties. Sometimes produces myoclonic activity which may be confused with seizures. Impairs renal function and should be avoided in patient's with known renal disease. May produce adrenal insufficiency. For information other than use in induction, *see page 3*
4. ketamine: NMDA receptor antagonist. Produces a dissociative anesthesia. Maintains cardiac output. May slightly increase both heart rate and blood pressure.

Narcotics in anesthesia

Increase CSF absorption and minimally reduce cerebral metabolism. They slow the EEG but will <u>not</u> produce an isoelectric tracing. ✖ All narcotics cause dose-dependent respiratory depression which can result in hypercarbia and concomitant increased ICP in non-ventilated patients. Often contribute to post-op N/V

Morphine: does not significantly cross the BBB.

✖ Disadvantages in neuro patients:

1. causes histamine release which
   A. may produce hypotension
   B. may cause cerebrovascular vasodilation → increased ICP[5] (p 1593)
   C. the above together may compromise CPP
2. in renal or hepatic insufficiency, the metabolite morphine-6-glucuronide can accumulate which may cause confusion

Meperidine (Demerol®): has negative inotropic effects, and its neuroexcitatory metabolite nor-meperidine can cause hyperactivity or seizures (*see footnote, page 49*). Also causes histamine release, increased ICP and tachycardia.

Synthetic narcotics

These do not cause histamine release, unlike morphine and meperidine.

⋆ **Remifentanil** (Ultiva®): (*see page 24* for details) reduces $CMRO_2$, CBV and ICP. Large doses may be neurotoxic to limbic system and associated areas. May be used for awake craniotomy (*see page 151*).

Fentanyl: crosses the BBB. Reduces $CMRO_2$, CBV and ICP. May be given as bolus and/or as a continuous infusion.

Sufentanil: more potent then fentanyl. Does not increase CBF. ✖ Raises ICP and is thus often not appropriate for neurosurgical cases.

Alfentanil: the most rapid onset and the shortest duration of the narcotics. ✖ NB: raises ICP.

MISCELLANEOUS DRUGS IN NEUROANESTHESIA

Benzodiazepines: These drugs are GABA agonists and decrease $CMRO_2$. They also provide anticonvulsant action and produce amnesia. See *page 51* for agents and reversal.

Etomidate: Used primarily for induction (*see page 2*). Initial hopes for use as a cerebral protectant were abandoned based on experimental studies[6] and a drop in $p_{Bt}O_2$ with temporary MCA clipping[7]. A cerebrovasoconstrictor, it reduces CBF and ICP. Does not suppress brainstem activity. Suppresses cortisol production with prolonged administration, and may induce seizures.

Propofol: A sedative hypnotic. Useful for induction (*see page 2*). Reduces cerebral metabolism, CBF and ICP. Has been described for cerebral protection (*see page 1064*) and for sedation (*see page 24*). Short half life permits rapid awakening which may be useful for awake craniotomy (*see page 151*). Not analgesic.

Lidocaine: Given IV, suppresses laryngeal reflexes which may help blunt ICP elevations that normally follow endotracheal intubation or suctioning. Anticonvulsant at low doses, may provoke seizures at high concentrations.

Esmolol: Selective beta-1 adrenergic antagonist, blunts the sympathetic response to laryngoscopy and intubation. Less sedating than equipotent doses of lidocaine or fentanyl used for the same purpose. Half life: 9 minutes. For dosing, etc., *see page 20*.

Dexmedetomidine (Precedex®): Alpha 2 adrenergic receptor agonist, used for control of hypertension post operatively as well as, for it's sedating qualities during awake craniotomy either alone or in conjunction with propofol (*see page 151*). Also used to help patients tolerate endotracheal tube without sedatives/narcotics to facilitate extubation.

PARALYTICS FOR INTUBATION

Paralytics (neuromuscular blocking agents **(NMBA)**): administered to facilitate tracheal intubation and to improve surgical conditions when indicated. Administration of paralytics ideally should always be guided by neuromuscular twitch monitoring. Also see *Sedatives & paralytics*, page 23. In addition to paralytics, all conscious patients should also receive a sedative to blunt awareness.

Paralytics should not be given until it has been determined that patient can be ventilated manually, unless treating laryngospasm (may be tested with thiopental). Use with caution in non-fixated patients with unstable C-spine.

Due to long action, pancuronium (Pavulon®) is not indicated as the primary paralytic for intubation, but may be useful once patient is intubated or in low dose as an adjunct to succinylcholine (*see below*).

succinylcholine (Anectine®) DRUG INFO

The only depolarizing agent. May be used to secure airway for emergency intubation, but due to possible side effects (*see page 26*), should not be used

acutely following injury or in adolescents or children (a short acting nondepolarizing blocker is preferred). May transiently increase ICP. Prior dosing with 10% of the ED95 dose of a non-depolarizing muscle relaxant reduces muscle fasciculations.

Rx Intubating dose: 1-1.5 mg/kg (supplied as 20 mg/ml → 3.5-5 cc for a 70 kg patient), onset 60-90 sec, duration 3-10 min, may repeat same dose **x** 1.

rocuronium (Zemuron®) **DRUG INFO**

Intermediate acting, aminosteroid, non-depolarizing muscle relaxant. The only nondepolarizing neuromuscular blocking agent approved for rapid sequence intubation. Duration of action and onset are dose dependent. ***Rx*** *see page 26*.

vecuronium (Norcuron®) **DRUG INFO**

Aminosteroid with activity similar to that of rocuronium, however, does not cause histamine release and is not approved for rapid sequence intubation. ***Rx*** *see page 26*.

cisatracurium (Nimbex®) **DRUG INFO**

Metabolized by Hoffman degradation (temperature dependent), intermediate acting, no significant increases in histamine. ***Rx*** *see page 4*.

1.3. Anesthetic requirements for intraoperative evoked potential monitoring

For details of intraoperative evoked potential **(EP)** monitoring itself, *see page 267*.

All volatile anesthetics produce dose-dependent reduction in SSEP peak amplitude and an increase in peak latency. Adding nitrous oxide increases this

sensitivity to anesthetic agents.

Anesthesia issues related to intraoperative evoked potential **(EPs)** monitoring:

1. induction: minimize pentothal dose (produces ≈ 30 minutes of suppression of EPs), or use etomidate (which increases both SSEP amplitude and latency[8])
2. total intravenous anesthesia (TIVA) is ideal
3. nitrous/narcotic technique is a second choice
4. if inhalational anesthetic agents are required:
   A. use < 1 MAC (minimum alveolar concentration), ideally < 0.5 MAC
   B. avoid older agents such as Halothane
5. nondepolarizing muscle relaxants have little effect on EP (in monkeys[9])
6. propofol has a mild effect on EP: total anesthesia with propofol causes less EP depression than inhalational agents at the same depth of anesthesia[10]
7. benzodiazepines have a mild-to-moderate depressant effect on EPs
8. continuous infusion of anesthetic drugs is preferred over intermittent boluses
9. SSEPs can be affected by hyper- or hypothermia, and changes in BP
10. hypocapnia (down to end tidal CO_2 = 21) causes minimal reduction in peak latencies[11]
11. antiepileptic drugs: phenytoin, carbamazepine and phenobarbital do not affect SSEP[12]

1.4. Malignant hyperthermia

Malignant hyperthermia **(MH)** is a hypermetabolic state of skeletal muscle due to idiopathic block of Ca^{++} reentry into sarcoplasmic reticulum. Transmitted by a multifactorial genetic predisposition. Total body O_2 consumption increases **x** 2-3.

Incidence: 1 in 15,000 anesthetic administrations in peds. 1 in 40,000 adults. 50% had previous anesthesia without MH. Frequently associated with administration of halogenated inhalational agents and the use of succinylcholine (fulminant form: muscle rigidity almost immediately after succinylcholine, may involve masseters → difficulty intubating). Initial attack and recrudescence may also occur post-op. 30% mortality[13].

Presentation

1. earliest possible sign: <u>increase</u> in end-tidal pCO_2
2. tachycardia (early) and other arrhythmias
3. with progression:
   A. coagulation disorder (DIC) (bleeding from surgical wound and body orifices)
   B. ABG → increasing metabolic acidosis & decreasing pO_2
   C. pulmonary edema
   D. elevated body temperature (may reach ≥ 44° C (113° F) at rate of 1° C/5-min) (normal patients become hypothermic with general anesthesia)
   E. limb muscle rigidity (common, but late)
   F. rhabdomyolysis → elevated CPK & myoglobin (late)
4. terminal:
   A. hypotension
   B. bradycardia
   C. cardiac arrest

Treatment

1. eliminate offending agents (stop the operation, D/C inhalation anesthesia and change tubing on anesthesia machine)
2. **dantrolene** sodium (Dantrium®) 2.5 mg/kg IV usually effective, infuse until symptoms subside, up to 10 mg/kg
3. hyperventilation with 100% O_2
4. surface and cavity cooling: IV, in wound, per NG, PR
5. bicarbonate 1-2 mEq/kg for acidosis
6. IV insulin and glucose (lowers K^+, glucose acts as energy substrate)
7. procainamide for arrhythmias
8. diuresis: volume loading + osmotic diuretics

Prevention

1. identification of patients at risk:
   A. only reliable test: 4 cm viable muscle biopsy for in-vitro tests at a few regional test centers (abnormal contracture to caffeine or halothane)
   B. family history: any relative with syndrome puts patient at risk

C. related traits: 50% of MH patients have heavy musculature, Duchenne type muscular dystrophy, or scoliosis

D. patients who exhibit masseter spasm in response to succinylcholine

2. in patients at risk: avoid succinylcholine (nondepolarizing blockers preferred if paralysis essential), may safely have non-halogenated anesthetics (narcotics, barbiturates, benzodiazepines, droperidol, nitrous…)
3. prophylactic oral dantrolene: 4-8 mg/kg/day for 1-2 days (last dose given 2 hrs before anesthesia) is usually effective

2. Neurocritical care

Neurocritical care topics covered in other sections of the book are shown in *Table 2-1*:

Table 2-1 Neurocritical care topics covered outside this chapter (followed by page number where the item may be found)

Intracranial pressure (ICP) monitoring - 868
Treatment of elevated ICP - 876
Adjuncts to ICP monitoring (jugular venous oxygen, brain tissue oxygenation, microdialysis…) - 874
Neurogenic stunned myocardium - 1054
Status epilepticus - 402
Vasospasm (including triple-H therapy) - 1045

2.1. Fluids and Electrolytes

2.1.1. Electrolyte abnormalities

2.1.1.1. Sodium

HYPONATREMIA

Key concepts:

- definition: serum $[Na^+] < 135$ mEq/L
- minimum W/U: ✔ serum $[Na^+]$, ✔ serum osmolality, ✔ urine osmolality, ✔ clinical assessment of volume status. if volume status is high or low ✔ urinary $[Na^+]$
  - SIADH: hypotonic hyponatremia (effective serum osmol < 275 mOsm/L) with inappropriately high urinary conentration (urine osmol > 100 mOsm/L) and euvolemia or hypervolemia
  - cerebral salt wasting **(CSW)**: similar to SIADH but with extracellular fluid volume <u>depletion</u> due to renal sodium loss (urinary [Na} > 20

mEq/L)

- treatment: based on acuity, severity, symptoms & etiology (see SIADH (*page 11*) or CSW (*page 14*) as appropriate)
- risk of overy rapid correction: osmotic demyelination (including central pontine myelinolysis - CPM)

Classification:

$[Na^+]$ < 135 mEq/L = mild, < 130 = moderate, < 125 = severe hyponatremia.

Hyponatremia in neurosurgical patients is chiefly seen in:

- syndrome of inappropriate antidiuretic hormone secretion (**SIADH**, *see below*): dilutional hyponatremia with normal or elevated intravascular volume. The most common cause of hyponatremia[1]. Usually treated with fluid restriction. May be associated with numerous intracranial abnormalities (*see Table 2-2*) and following transsphenoidal surgery
- cerebral salt wasting **(CSW)**: inappropriate natriuresis with volume depletion. Treated with volume replacement (opposite to SIADH) and sodium (symptoms from derangements due to CSW may be *exacerbated* by fluid restriction[2], *see page 13*). Etiology of 6% of cases of hyponatremia following aneurysmal SAH[3]

Other etiologies of hyponatremia

- renal failure
- volume overload (e.g. as in congestive heart failure)
- **pseudohyponatremia**: osmotically active solutes (e.g. glucose, mannitol, marked hyperlipidemia, or hyperproteinemia (which can occur in multiple myeloma)[4]) draw water from cells and also reduce the water fraction of plasma and produce artifactually low sodium values (an artifact of indirect lab techniques). For every 100 mg/dl increase of glucose, serum [Na] decreases by 1.6-2.4 mEq/L. It is necessary to measure serum osmolality to rule-out pseudohyponatremia

Evaluation

Figure 2-1 shows an algorithm for evaluating the etiology of hyponatremia[5] which drives treatment decisions.

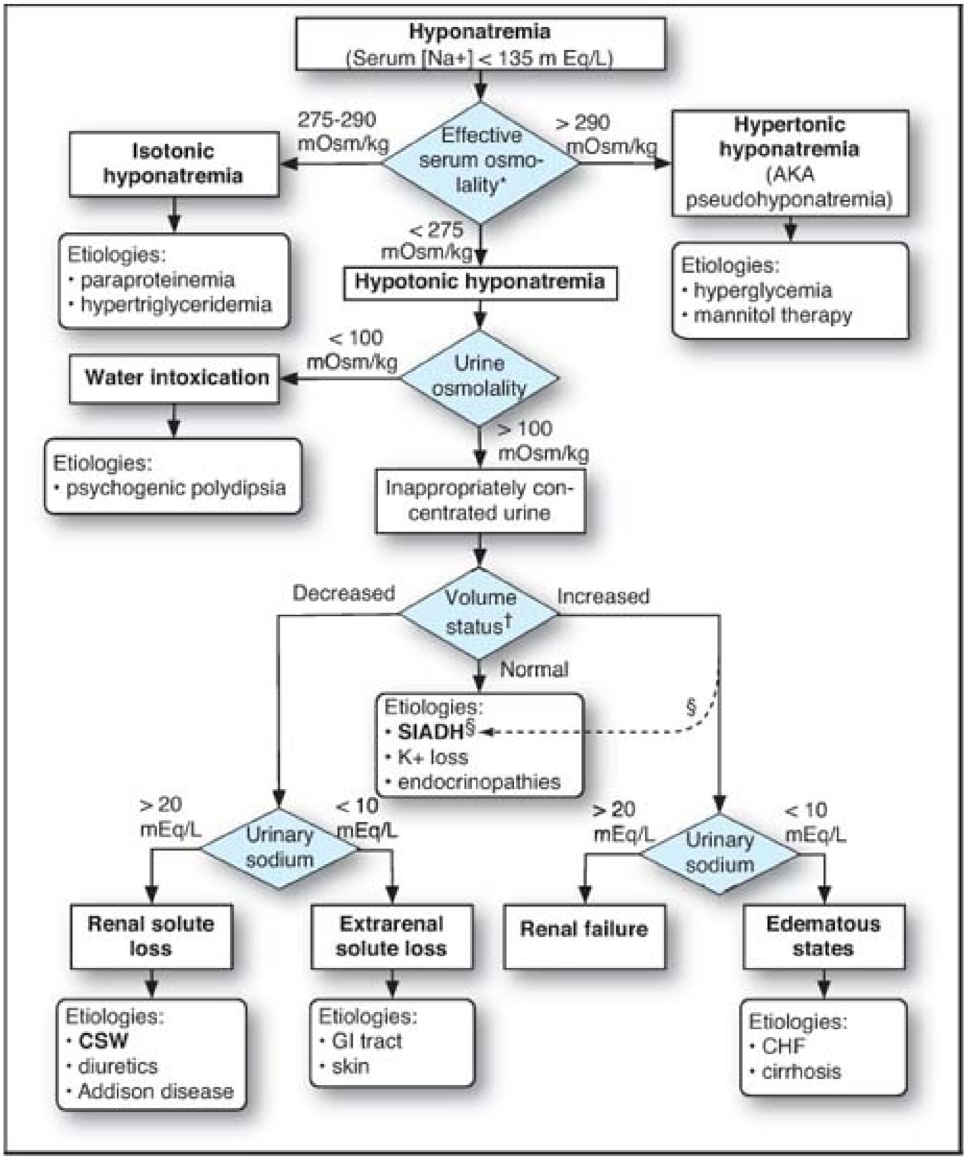

Figure 2-1 Evaluation of the etiology of hyponatremia
(adapted from Powers C, Friedman A H: Diagnosis and management of hyponatremia in neurosurgical patients. **Contemp Neurosurg** 29 (20): 1-5, 2007)

* effective serum osmolality = measured osmolality - [BUN]/2.8 (*see Eq 2-1*)

† volume status is usually assessed clinically, but this may be insensitive to volume depletion (*see text*)

§ SIADH may be associated with euvolemia or hypervolemia

$$\boxed{\text{effective serum osmolality} = \text{measured osmolality} - \frac{[\text{BUN}]\ (\text{mg/dl})}{2.8}} \qquad \textbf{Eq 2-1}$$

Work-up requires assessment of:

1. **serum sodium**: must be < 135 mEq/L to qualify as hyponatremia

2. ***effective*** **serum osmolality** (AKA tonicity): the definition is shown in *Eq 2-1*, and should be used when the blood urea nitrogen **(BUN)** level is elevated (for a normal [BUN] of 7-18 mg/dl, just subtract 5 from the measured osmolality). Values **< 275 mOsm/kg** indicate hypotonic hyponatremia
3. **urine osmolality**: values > 100 mOsm/kg are inappropriately high if serum tonicity is < 275 mOsm/kg
4. **volume status**: differentiates SIADH from CSW
   A. clinical assessment: better for hypervolemia (edema, upward trend in patient weights) but is insensitive in identifying extracellular fluid depletion as an etiology of hyponatremia[6] (look for dry mucous membranes, loss of skin turgor, orthostatic hypotension)
   B. **normal saline infusion test** used in uncertain cases. If base-line urine osmolality is < 500 mOsm/kg, it is usually safe to infuse 2 L of 0.9% saline over 24-48 hours. Correction of the hyponatremia suggests extracellular fluid volume depletion was the cause
   C. central venous pressure **(CVP)** may be used: CVP < 5-6 cm H_2O suggests hypovolemia in patients with normal cardiac function[3, 5]
5. check **urinary [Na^+]** if volume status is high or low
6. determine duration of hyponatremia:
   A. duration documented as < 48 hours is considered acute
   B. hyponatremia of > 48 hours duration or of unknown duration is chronic
   C. hyponatremia that occurs outside the hospital is usually chronic and asymptomatic except in marathoners and MDMA ("ecstasy") drug users

Table 2-2 Etiologies of SIAD*

Malignant tumors:
1. especially bronchogenic small-cell Ca 2. tumors of GI or GU tract 3. lymphomas 4. Ewing's sarcome
CNS disorders
1. infection: A. encephalitis B. meningitis: especially in peds C. TB meningitis D. AIDS E. brain abscess 2. head trauma: 4.6% prevalence

3. increased ICP: hydrocephalus, SDH… 4. SAH 5. brain tumors 6. cavernous sinus thrombosis 7. ★ post craniotomy, especially following surgery for pituitary tumors, craniopharyngiomas, hypothalamic tumors 8. MS 9. Guillain-Barré 10. Shy-Drager 11. delerium tremens (DTs)
Pulmonary disorders
1. infection: pneumonia (bacterial & viral), abscess, TB, aspergillosis 2. asthma 3. respiratory failure associated with positive pressure respiration
Drugs
1. drugs that release ADH or potentiate it A. chlorpropramide (Diabinese®): increasies renal sensitivity to ADH B. carbamazepine (Tegretol®), even more common with oxcarbazepine C. HCTZ (*see page 18*) D. SSRIs, TCAs E. clofibrate F. vincristine G. antipsychotics H. NSAIDs I. MDMA (“ecstasy”) 2. ADH analogues A. DDAVP B. oxytocin: ADH cross activity, may also be contaminated with ADH
Endocrine disturbances
1. adrenal insufficiency 2. hypothyroidism
Miscellaneous
1. anemia 2. stress, severe pain, nausea or hypotension (all can stimulate ADH release), postoperative state 3. acute intermittent porphyria **(AIP)**

* *excerpted and modified*[1, 7]

Symptoms

Due to slow compensatory mechanisms in the brain, a gradual decline in serum sodium is better tolerated than a rapid drop. Symptoms of mild ([Na] < 130 mEq/L) or gradual hyponatremia include: anorexia, headache, difficulty concentrating, irritability, dysgeusia and muscle weakness. Severe hyponatremia (< 125 mEq/L) or a rapid drop (> 0.5 mEq/hr) can cause neuromuscular excitability, cerebral edema, muscle twitching and cramps, nausea/vomiting, confusion, seizures, respiratory arrest and possibly permanent neurologic injury, coma or death.

SYNDROME OF INAPPROPRIATE ANTIDIURESIS (SIAD)

This term covers excess water retention in the face of hyponatremia, including cases due to inappropriate ADH secretion (SIADH, *see below*) as well as others without increased circulating levels of ADH (e.g. heightened response to ADH, certain drugs…). A partial list of etiologies is shown in *Table 2-2* (see references[1, 7] for details).

The diagnostic criteria of SIAD is shown in *Table 2-3*. It is critical to <u>measure serum osmolality</u> to rule-out pseudohyponatremia (*see page 7*) an artifact of indirect lab techniques.

Table 2-3 Diagnostic criteria for SIAD[1]

Essential features
• decreased effective serum osmolality* (< 275 mOsm/kg of water)
• simulatneous urine osmolality > 100 mOsm/kg of water
• clinical euvolemia A. no clinical signs of extracellular **(EC)** volume depletion (orthostatic hypotension, tachycardia, decreased skin turgor, dry mucous membranes…) B. no clinical signs of excess EC volume (edema, ascites…)
• urinary [Na] > 40 mEq/L with normal dietary Na intake
• normal thyroid and adrenal function
• no recent diuretic use
Supplemental features
• plasma [uric acid] < 4 mg/dl
• [BUN] < 10 mg/dl
• fractional Na excretion > 1%; fractional urea excretion > 55%
• NS infusion test: failure to correct hyponatremia with IV infusion of 2 L 0.9% saline over 24-48 hrs†
• correction of hyponatremia with fluid restriction
• abnormal result on water load test‡: A. < 80% excretion of 20 ml of water/kg body weight over 5 hours, or B. inadequate urinary dilution (< 100 mOsm/kg of water)
• elevated plasma [ADH]‡ with hyponatremia and euvolemia

* effective osmolality (AKA tonicity) = (measured osmolality) – [BUN]/2.8 with [BUN] measured in mg/dl

† this test is used n uncertain cases (corrects volume depletion), and is usually safe when baseline urine osmolality is < 500 mOsm/L

‡ water load test & [ADH] levels are rarely recommended (*see text* for details)

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION (SIADH)

Key concepts:

> • definition: release of ADH in the absence of physiologic (osmotic) stimuli
> • results in hyponatremia with hypervolemia (occasionally with euvolemia)

with inappropriately high urine osmolality (> 100 mOsm/L)
- may be seen with certain malignancies and many intracranial abnormalities
- critical to distinguish from cerebral salt wasting which produces hypovolemia
- treatment: (initial guidelines in brief, *see page 11* for details)
  - avoid rapid correction or overcorrection to reduce risk of osmotic demyelination (*see page 11*). Check serum $[Na^+]$ q 2-4 hours and do not exceed 1 mEq/L per hour, or 8 mEq/L in 24 hrs or 18 mEq/L in 48 hrs
  - severe ($[Na^+]$ < 125 mEq/L of < 48 hrs duration or with severe symptoms (coma, Sz): start 3% saline at 1-2 ml/kg body weight/hr + furosemide 20 mg IV qd
  - severe ($[Na^+]$ < 125 mEq/L of duration > 48 hours or unknown without severe symptoms: normal saline infusion @ 100 ml/hr + furosemide 20 mg IV qd
  - chronic or unknown duration and asymptomatic: fluid restriction (*see Table 2-4*) with dietary salt and protein, and, if necessary, adjuvant drugs (demeclocycline, conivaptan…)

SIADH, AKA Schwartz-Bartter syndrome, was first described with bronchogenic cancer which is one cause of SIAD. SIADH is the release of antidiuretic hormone **(ADH)** (AKA arginine vasopressin **(AVP) -** *see page 111*) in the absence of physiologic (osmotic) stimuli. Result: elevated urine osmolality, and expansion of the extracellular fluid volume leading to a dilutional hyponatremia which can produce fluid overload (hypervolemia), but SIADH may also occur with euvolemia. For unclear reasons, edema does not occur.

The hyponatremia of SIADH must be differentiated from that due to cerebral salt wasting **(CSW)** (*see below*) due to differences in treatment recommendations.

Etiologies: *see Table 2-2*.

Diagnosis of SIADH

In general, 3 diagnostic criteria are: hyponatremia, inappropriately concentrated urine, and no evidence of renal or adrenal dysfunction. In more detail:

1. low serum sodium (hyponatremia): usually < 134 mEq/L
2. low effective serum osmolality: < 275 mOsm/L
3. high urinary sodium[A] (salt wasting): at least > 18 mEq/L, often 50-150

4. high ratio of urine:serum osmolality: often 1.5-2.5:1, but may be 1:1
5. normal renal function (check BUN & creatinine): BUN commonly < 10
6. normal adrenal function (no hypotension, no hyperkalemia)
7. no hypothyroidism
8. no signs of dehydration or overhydration (in many patients with acute brain disease, there is significant hypovolemia often due to CSW (*see below*) and as this is a stimulus for ADH secretion, the ADH release may be "appropriate"[8]). In uncertain cases, the NS infusion test may be used (*see page 9*)

A. there has not been an adequate explanation of the high urinary sodium in SIADH

If further testing is required, the following are options, but are rarely recommended:

1. measure serum or urinary levels of ADH. Rarely indicated since urine osmolality > 100 mOsm/kg is usually sufficient to indicate excessive ADH[1]. ADH is normally undetectable in etiologies of hyponatremia other than SIADH
2. **water-load test**: considered to be the definitive test[9]. The patient is asked to consume a water load of 20 ml/kg up to 1500 ml. In the absence of adrenal or renal insufficiency, the failure to excrete 65% of the water load in 4 hrs or 80% in 5 hrs indicates SIAD. ✖ CONTRAINDICATIONS: this test is dangerous if the starting serum [Na^+] is ≤ 124 mEq/L or if the patient has symptoms of hyponatremia

Symptoms of SIADH

Symptoms are those of hyponatremia (*see page 9*) and possibly fluid overload. If mild, or if descent of [Na^+] is gradual, it may be tolerated. [Na^+] < 120-125 mEq/L is almost always symptomatic. These patients often have a paradoxical (inappropriate) thirst.

Treatment of hyponatremia with SIADH

Management is based on the severity and duration of hyponatremia, and the presence of symptoms. Two caveats:

1. ✖ be sure that hyponatremia is not due to CSW (*see below*) before

restricting fluids

2. avoid too rapid correction or correction to normal or supranormal (overcorrection) sodium to reduce the risk of osmotic demyelination syndrome (*see below*)

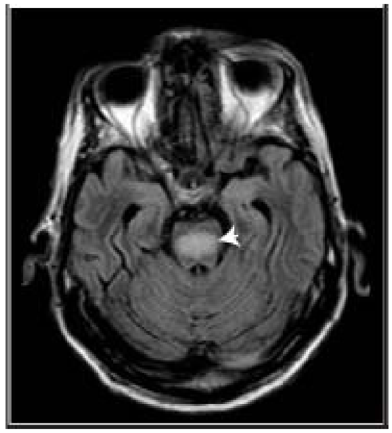

Figure 2-2 Central pontine myelinolysis (arrowhead). Axial FLAIR MRI

Osmotic demyelination syndrome: A complication associated with some cases of treatment for hyponatremia. While excessively slow correction of acute hyponatremia is associated with increased morbidity and mortality[10], some cases of inordinately rapid treatment have been associated with osmotic demyelination syndrome (which includes **central pontine myelinolysis (CPM)** a rare disorder of pontine white matter[11] (*see Figure 2-2*) and extrapontine myelinolysis (*see Figure 2-3*), as well as other areas of cerebral white matter). First described in alcoholics[12], producing insidious flaccid quadriplegia, mental status changes, and cranial nerve abnormalities with a pseudobulbar palsy appearance. In one review[13], no patient developed CPM when treated slowly as outlined below. And yet, the rate of correction correlates poorly with CPM; it may be that the magnitude is another critical variable[14]. Features common to patients who develop CPM are[13]:

- delay in the diagnosis of hyponatremia with resultant respiratory arrest or seizure with probable hypoxemic event
- rapid correction to normo- or hypernatremia (> 135 mEq/L) within 48 hours of initiating therapy
- increase of serum sodium by > 25 mEq/L within 48 hours of initiation of therapy
- over-correcting serum sodium in patients with hepatic encephalopathy

- NB: many patients developing CPM were victims of chronic debilitating disease, malnourishment, or alcoholism and never had hyponatremia. Many had an episode of hypoxia/anoxia[15]
- presence of hyponatremia > 24 hrs prior to treatment[14]

Treatment of underlying cause

The only definitive treatment

- if caused by anemia: usually responds to transfusion
- if caused by malignancy, may respond to antineoplastic therapy
- most drug related cases respond rapidly to discontinuation of the offending drug

Figure 2-3 Osmotic demyelination of pons (black arrowhead) & thalamus (white arrowhead). Coronal T2WI MRI

Treatment algorithms

Figure 2-4 depicts an algorithm for selecting the correct SIADH treatment protocol.

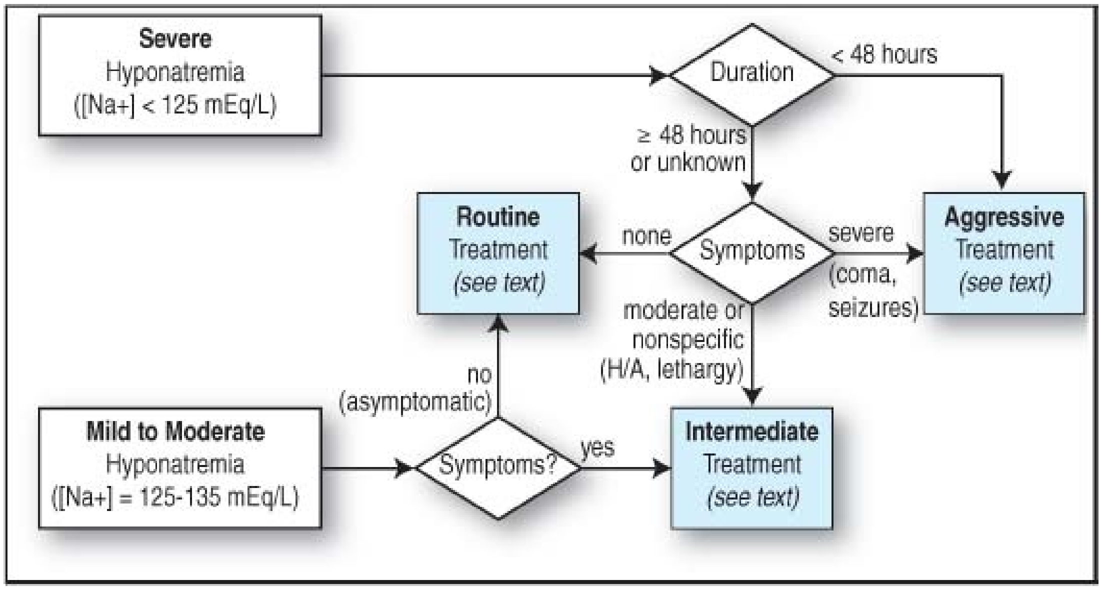

Figure 2-4 Treatment protocol selection for hyponatremia in SIADH

Aggressive treatment protocol

Indications (also refer to *Figure 2-4*):

1. severe hyponatremia (serum $[Na^+]$ < 125 mEq/L)
2. AND either
   A. duration known to be < 48 hours
   B. or severe symptoms (coma, seizures)

Treatment

1. transfer patient to ICU
2. medications
   A. 3% saline: start infusion 1-2 ml/kg body weight per hour[A]
   B. and furosemide[B] (Lasix®) 20 mg IV q d
3. check serum $[Na^+]$ every 2-3 hours and adjust infusion rate of 3% saline
   A. goal: raise serum sodium by 1-2 mEq/L/hr[16] (use lower end of range for hyponatremia > 48 hours duration or unknown duration)
   B. limits: do not exceed 8-10 mEq/L in 24 hrs and 18-25 mEq/L in 48 hrs[1] (use lower end of these ranges for hyponatremia > 48 hours duration or unknown duration)
4. measure K^+ lost in urine and replace accordingly
5. if symptoms of osmotic demyelination occur (early symptoms are lethargy and affective changes, usually after initial improvement): deficits may

improve by stopping treatment and modestly relowering the serum sodium e.g. with DDAVP[17, 18]

A. infusion rate may be doubled to 2-4 ml/kg/hr for limited periods in patients with coma or seizures[1]

B. furosemide accelerates the increase in [Na^+] and prevents volume overload with subsequent increase in atrial natriuretic factor and resultant urinary dumping of the extra Na^+ being administered

---

Intermediate treatment protocol

Indications (also refer to *Figure 2-4*):

1. symptomatic nonsevere hyponatremia (serum [Na^+] = 125-135 mEq/L), or
2. severe hyponatremia (serum [Na^+] < 125 mEq/L), AND
   A. duration > 48 hours or unknown AND
   B. only moderate symptoms or nonspecific symptoms (e.g. H/A, or lethargy)

Treatment

1. medications
   A. 0.9% saline (normal saline) infusion
   B. and furosemide (Lasix®) 20 mg IV q d
   C. consider conivaptan (*see below*) for refractory cases
2. check serum [Na^+] every 4 hours and adjust infusion rate of normal saline
3. goals: [Na^+] increase of 0.5-2 mEq/L/hr
4. limits: do not exceed 8-10 mEq/L in 24 hrs and 18-25 mEq/L in 48 hrs[1]

Routine treatment protocol and maintenance therapy

Indications (also refer to *Figure 2-4*):

1. asymptomatic nonsevere hyponatremia (serum [Na^+] = 125-135 mEq/L), or
2. severe hyponatremia (serum [Na^+] < 125 mEq/L) AND
   A. duration > 48 hours or unknown AND
   B. asymptomatic

Treatment

1. interventions

A. fluid restriction (*see Table 2-4* for adults, for peds: 1 $L/m^2/day$) while encouraging use of dietary salt and protein. Caution restricting fluids in hyponatremia following SAH (*see page 1043*)

B. for refractory cases, consider

1. **demeclocycline**: a tetracycline antibiotic that partially antagonizes the effects of ADH on the renal tubules[19-21]. Effects are variable, and nephrotoxicity may occur. ***Rx*** 300-600 mg PO BID
2. **conivaptan** (Vaprisol®): a nonpeptide antagonist of V_{1A} & V_2 vasopressin receptors. FDA approved for euvolemic and hypervolemic moderate-to-severe hyponatremia in hospitalized patients (NB: severe symptoms of seizures, coma, delerium… warrants aggressive treatment with hypertonic saline[1]). Use in the neuro-ICU has been described for treating elevated ICP when serum [Na] is not responding to traditional methods[22] (off-label use - use with caution). ***Rx*** loading dose 20 mg IV over 30 minutes, followed by infusions of 20 mg over 24 hours **x** 3 days. If serum $[Na^+]$ are not rising as desired, the infusion may be increased to the maximal dose of 40 mg over 24 hours. Use is approved for up to 4 days total. Caution re drug interactions
3. **lithium**: not very effective and many side effects. Not recommended

Table 2-4 Fluid restriction recommendations[1]

Solute ratio*	Recommended fluid intake
> 1	< 500 ml/d
1	500-700 ml/d
< 1	< 1 L/d

* *solute ratio defined as:*

$$\frac{\text{urinary [Na]} + \text{urinary [K]}}{\text{plasma [Na]}}$$

CEREBRAL SALT WASTING

Cerebral salt wasting (CSW): renal loss of sodium as a result of intracranial disease, producing hyponatremia and a decrease in extracellular fluid volume[9]. CAUTION: patients with aneurysmal SAH may have CSW with hyponatremia which mimics SIADH, however there is usually also hypovolemia

in CSW. In this setting, fluid restriction may exacerbate vasospasm induced ischemia[9, 23-25].

The mechanism whereby the kidneys fail to conserve sodium in CSW is not known, and may be either a result of an as yet unidentified natriuretic factor or direct neural control mechanisms (see *Hyponatremia following SAH*, page 1043).

Laboratory tests (serum and urinary electrolytes and osmolalities) may be identical with SIADH and CSW[26]. Further-more, hypovolemia in CSW may stimulate ADH release. To differentiate: CVP, PCWP, and plasma volume (a nuclear medicine study) are low in hypovolemia (i.e. CSW). *Table 2-5* compares some features of CSW and SIADH, the two most important differences being extracellular volume and salt balance. An elevated serum [K^+] with hyponatremia is incompatible with the diagnosis of SIADH.

Table 2-5 Comparison of CSW and SIADH[9]*

Parameter	CSW	SIADH
★ Plasma volume	↓ (< 35 ml/kg)	↑ or WNL
★ Salt balance	negative	variable
Signs & symptoms of dehydration	present	absent
Weight	↓	↑ or no Δ
PCWP	↓ (< 8 mm Hg)	↑ or WNL
CVP	↓ (< 6 mm Hg)	↑ or WNL
Orthostatic hypotension	+	±
Hematocrit	↑	↓ or no Δ
Serum osmolality	↑ or WNL[†]	↓
Ratio of serum BUN]:[creatinine]	↑	WNL
Serum [protein]	↑	WNL
Urinary [Na^+]	↑↑	↑
Serum [K^+]	↑ or no Δ	↓ or no Δ
Serum [uric acid]	WNL	↓

* abbreviations: ↓ = decreased, ↑ = increased, ↑↑ = significantly increased, WNL = within normal limits, no Δ = no change, [] = concentration, + = present, ± = may or may not be present

† in reality, serum osmolality is usually ↓ in CSW

Treatment of CSW

Goals: volume replacement and positive salt balance.

Hydrate patient with 0.9% NS at 100-125 ml/hr. Do not give furosemide. For severe cases, 3% saline at 25-50 cc/hr is occasionally required. Salt may also be simultaneously replaced orally. Blood products may be needed if anemia is present.

Rapid correction of hyponatremia may be associated with osmotic demyelination (*see page 11*) and care should be taken to avoid overcorrection, as with SIADH (*see page 11*).

Fludrocortisone acetate acts directly on the renal tubule to increase sodium absorption. Benefits of giving 0.2 mg IV or PO q d in CSW have been reported[27], but significant complications of pulmonary edema, hypokalemia and HTN may occur.

Urea: an alternative treatment using urea may be applicable to the hyponatremia of either SIADH *or* CSW, and therefore may be used before the cause has been ascertained: urea (Ureaphil®) 0.5 grams/kg (dissolve 40 gm in 100-150 ml NS) IV over 30-60 mins q 8 hrs[28]. Use NS + 20 mEq KCl/L at 2 ml/kg/hr as the main IV until the hyponatremia is corrected (unlike mannitol, urea does not increase ADH secretion). They supplemented with colloids (viz. 250 ml of 5% albumin IV q 8-12 hrs **x** 72 hrs).

HYPERNATREMIA

Definition: serum sodium > 150 mEq/L. In neurosurgical patients, this is most often seen in the setting of diabetes insipidus **(DI)** (*see below*).

Since normal total body water **(TBW)** is ≈ 60% of the patient's normal body weight, the patient's current TBW may be estimated by *Eq 2-2*.

$$TBW_{current} = \frac{[Na^+]_{normal} \times TBW_{normal}}{[Na^+]_{current}} = \frac{140\ mEq/L \times 0.6 \times \text{usual body wt (kg)}}{[Na^+]_{current}} \quad \text{Eq 2-2}$$

The free water deficit to be replaced is given by *Eq 2-3*. Correction must be made slowly to avoid exacerbating cerebral edema. One half the water deficit is replaced over 24 hours, and the remainder is given over 1-2 additional days. Judicious replacement of deficient ADH in cases of true DI must also be made (*see below*).

$$\text{free water deficit} = 0.6 \times \text{usual body wt (kg)} - TBW_{current}$$

$$= \frac{[Na^+]_{current} - 140\text{ mEq/L}}{[Na^+]_{current}} \times 0.6 \times \text{usual body wt (kg)}$$

Eq 2-3

DIABETES INSIPIDUS

Key concepts:

- due to low levels of ADH (or, rarely, renal insensitivity to ADH)
- high output of dilute urine (< 200 mOsmol/L or SG < 1.003) with normal or high serum osmolality and high serum sodium
- often accompanied by craving for water, especially ice-water
- danger of severe dehydration if not managed carefully

Diabetes insipidus **(DI)** is due to insufficient ADH, and results in the excessive renal loss of water and electrolytes. DI may be produced by two different etiologies:

- central or neurogenic DI: subnormal levels of ADH caused by hypothalamic-pituitary axis dysfunction. This is the type most often seen by neurosurgeons
- "**nephrogenic DI**": due to relative resistance of the kidney to normal or supra-normal levels of ADH. Seen with some drugs (*see below*)

Etiologies of DI[29]:

1. (neurogenic) diabetes insipidus
   - A. familial (autosomal dominant)
   - B. idiopathic
   - C. posttraumatic (brain injury, including surgery)
   - D. tumor: craniopharyngioma, metastasis, lymphoma…
   - E. granuloma: neurosarcoidosis, histiocytosis
   - F. infectious: meningitis, encephalitis
   - G. autoimmune
   - H. vascular: aneurysm, Sheehan's syndrome (rarely causes DI)
2. nephrogenic diabetes insipidus
   - A. familial (X-linked recessive)
   - B. hypokalemia
   - C. hypercalcemia

D. Sjögren's syndrome
E. drugs: lithium, demeclocycline, colchicine…
F. chronic renal disease: pyelonephritis, amyloidosis, sickle cell disease, polycystic kidney disease, sarcoidosis

Central DI

85% of ADH secretory capacity must be lost before clinical DI ensues. Characteristic features: high urine output (polyuria) with low urine osmolality, and (in the conscious patient) craving for water (polydipsia), especially ice-water.

Differential diagnosis of DI:

1. (neurogenic) diabetes insipidus (true DI)
2. nephrogenic diabetes insipidus
3. psychogenic
   A. idiopathic: from resetting of the osmostat
   B. psychogenic polydipsia (excess free water intake)
4. osmotic diuresis: e.g. following mannitol, or with renal glucose spilling
5. diuretic use: furosemide, hydrochlorothiazide…

Central DI may be seen in the following situations:

1. following transsphenoidal surgery or removal of craniopharyngioma: (usually transient, therefore avoid long-acting agents until it can be determined if long-term replacement is required). Injury to the posterior pituitary or stalk usually causes one of three patterns of DI[30]:
   A. transient DI: supra-normal urine output **(UO)** and polydipsia which typically normalizes ≈ 12-36 hrs post-op
   B. "prolonged" DI: UO stays supra-normal for prolonged period (may be months) or even permanently: only about one third of these patients will not return to near-normal at one year post-op
   C. "**triphasic response**": least common
      - phase 1: injury to pituitary reduces ADH levels for 4-5 days → DI (polyuria/polydipsia)
      - phase 2: cell death liberates ADH for the next 4-5 days → transient normalization or even SIADH-like water retention (✖ NB: there is a danger of inadvertently continuing vasopressin therapy beyond the initial DI phase into this phase causing significant hemodilution)

- phase 3: reduced or absent ADH secretion → either transient DI (as in "A" above) or a "prolonged" DI (as in "B" above)

2. central herniation: shearing of pituitary stalk may occur (*see page 285*)
3. brain death: hypothalamic production of ADH ceases
4. with certain tumors:
   A. pituitary adenomas: DI is rare even with very large macroadenomas. DI may occur with pituitary apoplexy (*see page 635*)
   B. craniopharyngioma: DI usually only occurs postoperatively since damage to pituitary or lower stalk does not prevent production and release of ADH by hypothalamic nuclei
   C. suprasellar germ cell tumors
   D. rarely with a colloid cyst
   E. hypothalamic tumors: eosinophilic granuloma
5. mass lesions pressing on hypothalamus: e.g. a-comm aneurysm
6. following head injury: primarily with basal (clival) skull fractures (*see page 889*)
7. with encephalitis or meningitis
8. drug induced:
   A. ethanol and phenytoin can inhibit ADH release
   B. exogenous steroids may seem to "bring out" DI because they may correct adrenal insufficiency (see *Diagnosis* below) and they inhibit ADH release
9. granulomatous diseases
   A. Wegener's granulomatosis: a vasculitis (*see page 78*)
   B. neurosarcoidosis involving the hypothalamus (*see page 71*)
10. inflammatory: autoimmune hypophysitis[31] (*see page 1217*) or lymphocytic infundibuloneurohypophysitis[32] (distinct conditions)

Diagnosis

The following are usually adequate to make the diagnosis of DI, especially in the appropriate clinical setting:

1. dilute urine:
   A. **urine osmolality < 200** mOsm/L (usually 50-150)[A] or **specific gravity (SG) < 1.003** (may be 1.001 to 1.005)
   B. or the inability to concentrate urine to > 300 mOsm/L in the presence of clinical dehydration

C. NB: large doses of mannitol as may be used in head trauma can mask this by producing a more concentrated urine
2. urine output **(UO)** > 250 cc/hr (peds: > 3 cc/kg/hr)
3. normal or above-normal serum sodium
4. normal adrenal function: DI cannot occur in primary adrenal insufficiency because a minimum of mineralocorticoid activity is needed for the kidney to make free water, ∴ steroids may reveal latent DI by correcting adrenal insufficiency

---

A. normally, urine osmolality averages between 500-800 mOsm/L (extreme range: 50-1400)

In uncertain cases, plot urine and simultaneous serum osmolality on the graph in *Figure 2-5*:

1. low serum osmolality: the patient has polydipsia
2. if the point falls in the "normal" range, a supervised water deprivation test is needed to determine if the patient can concentrate their urine with dehydration (caution: *see below*)
3. high serum osmolality: diagnosis of DI is established, and further testing is not needed (except to differentiate central from nephrogenic DI, if desired)
   • to differentiate central from nephrogenic DI, give aqueous Pitressin® 5 U SQ: in central DI the urine osmolality should double within 1-2 hours
4. plotting more than one data point may help as some patients tend to "vacillate" around the border zones

Water deprivation test

If still unclear, the diagnosis of DI is confirmed by a water deprivation test (✖ CAUTION: perform only under close supervision as rapid and potentially fatal dehydration may ensue in DI). This test is rarely necessary if serum osmolality > 298 mOsm/L[A]. Stop IVs and make the patient NPO; check urine osmolality q hr.

1. continue the test until one of the following occurs:
   A. normal response occurs: urine output decreases, and urine osmolality rises to 600-850 mOsm/L
   B. 6-8 hours lapse
   C. urine osmolality plateaus (i.e. changes < 30 mOsm in 3 consecutive

hours)

D. patient loses 3% of body weight

2. if patient fails to demonstrate the normal response, then:

A. give exogenous ADH (5 U aqueous Pitressin® SQ), which normally increases urine osmolality to > 300 mOsm/L

B. check urine osmolality 30 and 60 minutes later

C. compare highest urine osmolality after Pitressin® to the osmolality just before Pitressin® according to *Table 2-6*

A. in compensated DI serum osmolality is more likely to be lower and to overlap with normals[33]

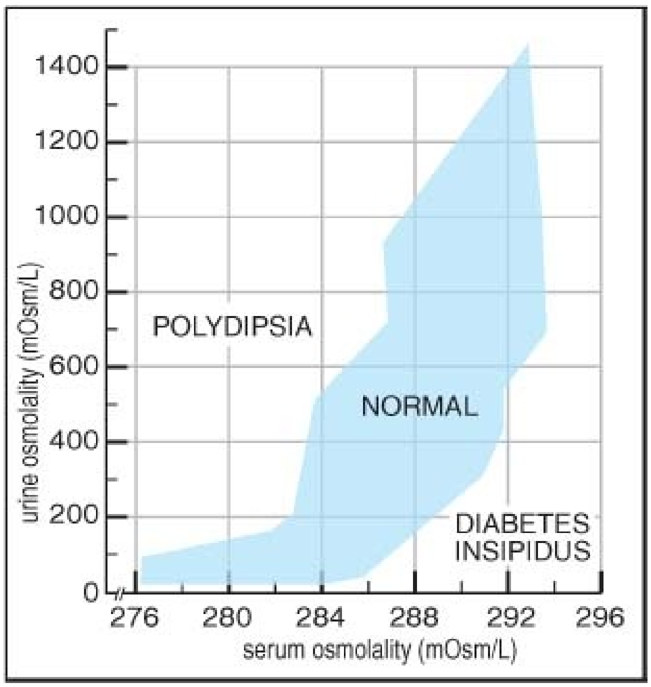

Figure 2-5 Interpretation of simultaneous serum vs. urine osmolality
(Provided by Arnold M. Moses, M.D., used with permission)

Table 2-6 Highest urinary osmolality after Pitressin in water deprivation test

Δ in urinary Osm	Interpretation
< 5% increase	normal
6-67% increase	partial ADH deficiency
> 67% increase	severe ADH deficiency

TREATMENT OF DI

See *Table 2-7* and *Table 2-8* for dosing forms and duration of action of vasopressin analogues.

Pitressin® is aqueous solution of 8-arginine vasopressin and should be used with caution in patients with vascular disease (especially coronary arteries). ✖ Caution in pre-scribing: sometime pitocin is confused with pitressin because of similarities of the name.

DDAVP (1-deamino-8-D-arginine vasopressin) AKA **desmopressin**. More potent and longer acting than vasopressin.

Table 2-7 Available preparations of vasopressin analogues

Generic name	Trade name	Route	Concentration	Availability	Manufacturer
desmopressin	DDAVP®	SQ, IM, IV	4 mcg/ml	1 & 10 ml	Aventis
desmopressin	DDAVP® Nasal Spray	nasal spray	100 mcg/ml, each spray delivers 10 mcg	50 doses per bottle	Aventis
desmopressin	DDAVP® Tablets	PO		0.1 & 0.2 mg	Aventis
arginine vaso-pressin	aqueous Pitressin®	SQ, IM	20 U/ml (50 mcg/ml)	0.5 and 1 ml	Parke-Davis
posterior pituitary powder in oil	Pitressin tannate in oil	IM (poor ab-sorption)	5 U/ml	1 ml	Parke-Davis

In <u>conscious</u> ambulatory patient

If DI is mild, and natural thirst mechanism is intact, instruct patient to drink <u>only</u> when thirsty and they usually "keep up" with losses and will not become overhydrated. If severe, patient may not be able to continue adequate intake of fluid (and constant trips to bathroom), in this case administer either:

1. desmopressin (DDAVP®)
   A. PO: 0.1 mg PO BID, adjust up or down PRN urine output (typical dosage range: 0.1-0.;8 mg/d in divided doses)
   B. nasal spray: 2.5 mcg (0.025 ml) by nasal insufflation BID, titrate up to 20 mcg BID as needed (the nasal *spray* may be used for doses that are multiples of 10 mcg)

OR

2. ADH enhancing medications (works primarily in chronic partial ADH deficiency. Will not work in total absence of ADH)
   A. clofibrate (Atromid S®) 500 mg PO QID
   B. chlorpropramide: increases renal sensitivity to ADH
   C. hydrochlorothiazide: thiazide diuretics may act by depleting Na^+

which increases reabsorption in proximal tubules and shifting fluid away from distal tubules which is where ADH works. ***Rx***: e.g. Dyazide® 1 PO q d (may increase up to 2 per day PRN)

Table 2-8 Mean time of hypertonic urine* (relative to plasma)†

Generic name	Route	Dose	Mean duration of action‡
desmopressin	SQ, IM, IV	0.5 mcg	8 hrs
desmopressin§	SQ, IM, IV	1.0 mcg	12 hrs
desmopressin	SQ, IM, IV	2.0 mcg	16 hrs
desmopressin	SQ, IM, IV	4.0 mcg	20 hrs
desmopressin	intranasal	10 mcg (0.1 ml)	12 hrs
desmopressin	intranasal	15 mcg (0.15 ml)	16 hrs
desmopressin	intranasal	20 mcg (0.2 ml)	20 hrs
arginine vasopressin	SQ, IM	5 U (12.5 mcg)	4 hrs (range: 4-8)
posterior pituitary powder in oil	IM	5 U	48-72 hrs

* provided by Arnold M. Moses, M.D., used with permission

† onset of antidiuretic action of these preparations is 30-45 minutes following administration (except pituitary powder in oil which takes 2-4 hrs to start working)

‡ times may vary from patient to patient, but are usually consistent in any individual

§ Note: 1 mcg BID of desmopressin is as effective as 4 mcg q d, but would obviously be less expensive

In <u>conscious</u> ambulatory patient with impaired thirst mechanisms

If thirst mechanisms are <u>not</u> intact in conscious ambulatory patient, they run the risk of dehydration or fluid overload. For these patients:

1. have patient follow UO and daily weights, balance fluid intake and output using antidiuretic medication as needed to keep UO reasonable
2. check serial labs (approximately q weekly) including serum sodium, BUN

In non-ambulatory, comatose/stuporous, or brain-dead patient

(also see *Management after brain death for organ donation*, page 294)

1. follow I's & O's q 1 hr, with urine specific gravity **(SG)** q 4 hrs and whenever urine output **(UO)** > 250 ml/hr

2. labs: serum electrolytes with osmolality q 6 hrs
3. IV fluid management:
   BASE IV: D5 1/2 NS + 20 mEq KCl/L at appropriate rate (75-100 ml/hr)
   PLUS: replace UO above base IV rate ml for ml with 1/2 NS

   NB: for post-op patients, if the patient received significant intraoperative fluids, then they may have an appropriate post-op diuresis, in this case use 1/2 NS to replace only ≈ 2/3 of UO that exceeds the basal IV rate
4. if unable to keep up with fluid loss with IV (or NG) replacement (usually with UO > 300 ml/hr), then EITHER
   - 5 U arginine vasopressin (aqueous Pitressin®) IVP/IM/SQ q 4-6 hrs (avoid tannate oil suspension due to erratic absorption and variable duration)
   - or vasopressin IV drip: start at 0.2 U/min & titrate (max: 0.9 U/min)
   - or desmopressin injection SQ/IV titrated to UO, usual adult dose: 0.5-1 ml (2-4 mcg) daily in 2 divided doses

2.1.2. Serum osmolality

Clinical significance of various serum osmolarity values is shown in *Table 2-9*.

Table 2-9 Clinical correlates of serum osmolality

Value (mOsm/L)	Comment
282-295	normal
< 240 or > 321	panic values
> 320	risk of renal failure
> 384	produces stupor
> 400	risk of generalized seizures
> 420	usually fatal

Serum osmolality may be estimated using using *Eq 2-4* (with [Na^+] in mEq/L or mmol/L, and glucose and BUN in mg/dL).

$$\text{Osmolality (mOsm/L)} = 2 \times \{[Na^+] + [K^+]\} + \frac{[BUN]}{2.8} + \frac{[glucose]}{18} \qquad \textbf{Eq 2-4}$$

NB: terms in square brackets [] represent the serum concentrations (in mEq/L for electrolytes).

2.2. Blood pressure management

2.2.1. Hypertension

PARENTERAL AGENTS

Table 2-10 shows some parenteral agents for acute control of hypertension grouped based on their effect on ICP[34, 35].

Table 2-10 Effect of antihypertensives on ICP

Agents that may raise ICP (mostly vasodilators)	Agents that do not raise ICP
nitroglycerin (NTG)	trimethaphan (Arfonad®)
nitroprusside (NTP) (Nipride®)	methyldopa (Aldomet®)
	labetalol (Normodyne®…)
	nicardipine (Cardene®)

★ nicardipine (Cardene®) DRUG INFO

Calcium channel blocker **(CCB)** that may be given IV. Unlike NTP, does not require arterial line, does not raise ICP, and no cyanide toxicity. Does not reduce heart rate, but may be used in conjunction with e.g. labetalol or esmolol if that is desired. **SIDE EFFECTS:** H/A 15%, nausea 5%, hypotension 5%, reflex tachycardia 3.5%.

Rx start at 5 mg/hr IV (off label: 10 mg/hr may be used in situations where urgent reduction is needed). Increase by 2.5 mg/hr every 5-15 minutes up to a maximum of 15 mg/hr. Decrease to 3 mg/hr once control is achieved. ✖ Ampules contain 25 mg and must be diluted before administration.

✖ nitroprusside (NTP) (Nipride®) DRUG INFO

Use is diminishing because of side effects and effect on ICP. Raises ICP in patients with intracranial mass lesions[36] due to direct vasodilatation, arterial > venous (small coronaries > large). May preferentially dilate peripheral vessels before cerebral vessels, thus producing a "cerebral steal" phenomenon. Acts in seconds, duration 3-5 min.

SIDE EFFECTS: thiocyanate and cyanide toxicity (may cause neurologic deterioration[37] or hypotension) (follow thiocyanate levels if used > 24 hrs, at a rate ≥ 10 mcg/kg/min, or in renal failure; D/C if thiocyanate levels > 10 mg%), tachycardia, tachyphylaxis, hypotension which can extend an MI, "coronary steal". Avoid in pregnancy.

Rx IV drip 0.25-8 mcg/kg/min (ave. = 3). To reduce risk of cyanide toxicity, start at very low rate of 0.3 mcg/kg/min, and do not give maximum rate of 10 mcg/kg/min for more than 10 minutes. To prepare: put 50 mg in 500 ml D5W (can only be mixed in D5W; solution can be double concentrated to reduce fluid or glucose load) = 100 mcg/ml; cover bottle with foil (light sensitive).

nitroglycerin (NTG) DRUG INFO

Raises ICP (less than with nitroprusside due to preferential venous action[36]). Vasodilator, venous > arterial (large coronaries > small). Result: decreases LV filling pressure (pre-load). Does not cause "coronary steal" (cf nitroprusside).

Rx 10-20 mcg/min IV drip (increase by 5-10 mcg/min q 5-10 min). For angina pectoris: 0.4 mg SL q 5 min **x** 3 doses, check BP before each dose.

labetalol (Normodyne®, Trandate®) DRUG INFO

Blocks α_1 selective, ß non-selective (potency < propranolol). ICP reduces or no change[38]. Pulse rate: decreases or no change. Cardiac output does not change. Does not exacerbate coronary ischemia. May be used in controlled CHF, but not in overt CHF. Contraindicated in asthma. Renal failure: same dose. **SIDE EFFECTS:** fatigue, dizziness, orthostatic hypotension.

Intravenous (IV)

Onset 5 mins, peak 10 mins, duration 3-6 hrs.

Rx IV: patient supine; check BP q 5 min; give each dose slow IVP (over 2 min) q 10 minutes until desired BP achieved; dose sequence: 20, 40, 80, 80, then 80 mg (300 mg total). Once controlled, use ≈ same total dose IVP q 8 hrs.

Rx IV drip: add 40 ml (200 mg) to 160 ml of IVF (result: 1 mg/ml); run at 2 ml/min (2 mg/min) until desired BP (usual effective dose = 50-200 mg) or until 300 mg given; then titrate rate (bradycardia limits dose, increase slowly since effect takes 10-20 minutes).

Oral (PO)

Undergoes first pass liver degradation, therefore requires higher doses PO. PO onset: 2 hrs, peak: 4 hrs.

Rx PO: to convert IV → PO, start with 200 mg PO BID. To start with PO, give 100 mg BID, and increase 100 mg/dose q 2 day; max. = 2400 mg/day.

enalaprilat (Vasotec®) DRUG INFO

An angiotensin-converting enzyme **(ACE)** inhibitor. The active metabolite of the orally administered drug enalapril (*see below*). Acts within ≈ 15 mins of administration.

SIDE EFFECTS: hyperkalemia occurs in ≈ 1%. Do not use during pregnancy.

Rx IV: start with 1.25 mg slow IV over 5 mins, may increase up to 5 mg q 6 hrs PRN.

esmolol (Brevibloc®) DRUG INFO

Cardioselective short-acting beta blocker[39]. Being investigated for hypertensive emergencies. Metabolized by RBC esterase. Elimination half-life: 9 mins. Therapeutic response (> 20% decrease in heart rate, HR < 100, or conversion to sinus rhythm) in 72%. **SIDE EFFECTS:** dose related hypotension (in 20-50%), generally resolves within 30 mins of D/C. Bronchospasm less likely than other beta blockers. Avoid in CHF.

Rx 500 mcg/kg loading dose over 1 min, follow with 4 min infusion starting with 50 mcg/kg/min. Repeat loading dose and increment infusion rate by 50 mcg/kg/min q 5 mins. Rarely > 100 mcg/kg/min required. Doses > 200

mcg/kg/min add little.

fenoldopam (Corlopam®) DRUG INFO

Vasodilator. Onset of action < 5 minutes, duration 30 mins.

Rx IV infusion (no bolus doses): start with 0.1-0.3 mcg/kg/min, titrate by 0.1 mcg/kg/min q 15 min up to a maximum of 1.6 mcg/kg/min.

propranolol (Inderal®) DRUG INFO

Main use IV is to counteract tachycardia with vasodilators (usually doesn't lower BP acutely when used alone).

Rx IV: load with 1-10 mg slow IVP, follow with 3 mg/hr. PO: 80-640 mg q d in divided doses.

ORAL AGENTS

For less urgent control of HTN (exception: sublingual nifedipine (*see below*)).

clonidine (Catapres®) DRUG INFO

Acts on cardiovascular control receptors in medulla oblongata, inhibits sympathetic outflow. Less confusion than Aldomet, but still sedating. Tachycardia rare. Onset: < 30 min.

SIDE EFFECTS: fluid retention (which may reduce effectiveness, counter with diuretic), dry mouth, sedation (minimize by slow dose increments), constipation, decreased CO & HR (by increased vagal tone), rebound HTN if withdrawn rapidly (caution in unreliable patients; treatment for rebound HTN: clonidine and labetalol, *see page 20*). Rebound is less likely and less severe with clonidine patches (Catapres TTS®), applied once per week.

Rx Rapid control: 0.2 mg PO, then 0.1 mg PO q 1 hr, stop at 0.8 mg total or if orthostatic. Maintenance dose: 0.1 mg PO BID or TID, increase slowly to max. 2.4 mg/day (usual 0.2-0.8 mg/day).

propranolol (Inderal®) DRUG INFO

Beta blocker. Use in HTN: blunts reflex tachycardia from vasodilators.

SIDE EFFECTS: CHF, symptomatic bradycardia, bronchospasm (avoid in asthmatics), rapid withdrawal → reflex tachycardia → exacerbates myocardial ischemia in CAD.

Rx 40 mg PO BID (usually with diuretic), titrate up to 640 mg/day in 2-3 divided doses. Or, Inderal-LA, 80 mg PO q d. **SUPPLIED**: 10, 20 40, 60 & 80 mg scored tabs. Inderal-LA (long acting) 60, 80, 120 & 160 mg capsules.

nifedipine (Procardia®, Adalat®) DRUG INFO

Short-acting calcium channel blocker **(CCB)**. Decreases systemic vascular resistance. Increases cardiac index, CBF (by 10-20%), GFR, and Na excretion. Response some-what variable. Onset: 1-15 mins. Duration: 3-5 hrs.

SIDE EFFECTS: flushing H/A, palpitation, edema; reflex tachycardia, caution with beta blocker as negative inotropy may be additive. May cause severe hypotension in volume depleted patients (thus use with caution with mannitol or furosemide). May increase serum phenytoin (Dilantin®) levels. Use of short-acting CCBs may be associated with cardiac risk, thus long-acting agents should be used unless specific benefit outweighs the risk.

Rx 10-20 mg PO, faster onset with sublingual or buccal administration (puncture capsule), or if chewed (patient expels capsule after chewing). Note: the beneficial effects of the drug results from swallowing the capsule contents, the medication is not absorbed through the mucosa. If no response after 20-30 min, give additional 10 mg.

labetalol (Normodyne®, Trandate®) DRUG INFO

See page 20. Chronic administration may have higher incidence of orthostatic hypotension, fever, sexual dysfunction, and hepatic toxicity than other beta blockers.

metoprolol (Lopressor®) DRUG INFO

Beta blocker that is relatively cardioselective at doses < 200 mg. ***Rx*** 50-200 mg in 1 or 2 doses.

enalapril (Vasotec®) **DRUG INFO**

Angiotensin converting enzyme **(ACE)** inhibitor. Do not use during pregnancy. May be less effective in black patients. See *enalaprilat* above for IV use.

Rx initial dose 2.5-5 mg in one dose; maintenance 5-40 mg in 1 or 2 doses.

2.2.2. Hypotension (shock)

Classification:

1. hypovolemic: first sign usually tachycardia. > 20-40% of blood volume loss must occur before perfusion of vital organs is impaired. Includes:
   A. hemorrhage (external or internal)
   B. bowel obstruction (with third spacing)
2. septic: most often due to gram negative sepsis
3. cardiogenic: includes MI, cardiomyopathy, dysrhythmias (including A-fib)
4. neurogenic: e.g. paralysis due to spinal cord injury. Blood pools in venous capacitance vessels
5. miscellaneous
   A. anaphylaxis
   B. insulin reaction

CARDIOVASCULAR AGENTS FOR SHOCK

Plasma expanders. Includes:

1. crystalloids: normal saline has less tendency to promote cerebral edema than others (see *IV fluids*, page 878 under control of elevated ICP)
2. colloids: e.g. hetastarch (Hespan®). ✖ CAUTION: repeated administration over a period of days may prolong PT/PTT and clotting times and may increase the risk of rebleeding in aneurysmal SAH[40] (*see page 1042*)

3. blood products: expensive. Risk of transmissible diseases or transfusion reaction

dopamine DRUG INFO

See *Table 2-11* for a summary of the effects of dopamine **(DA)** at various dosages. DA is primarily a vasoconstrictor ($ß_1$ effects usually overridden by α–activity). 25% of dopamine given is rapidly converted to norepinephrine **(NE)**. At doses > 10 mcg/kg/min one is essentially giving NE. May cause significant hyperglycemia at high doses.

Rx Start with 2-5 mcg/kg/min and titrate.

Table 2-11 Dopamine dosage

Dose (mcg/kg/min)	Effect	Result
0.5-2.0 (sometimes up to 5)	dopaminergic	renal, mesenteric, coronary, & cerebral vasodilatation, (+) inotrope
2-10	$ß_1$	positive inotrope
> 10	α, ß & dopaminergic	releases nor-epi (vasoconstrictor)

dobutamine (Dobutrex®) DRUG INFO

Vasodilates by $ß_1$ (primary) and by increased CO from (+) inotropy ($ß_2$); result: little or no fall in BP, less tachycardia than DA. No alpha release nor vasoconstriction. May be used synergistically with nitroprusside. Tachyphylaxis after ≈ 72 hrs. Pulse increases > 10% may exacerbate myocardial ischemia, more common at doses > 20 mcg/kg/min. Optimal use requires hemodynamic monitoring. Possible platelet function inhibition.

Rx usual range 2.5-10 mcg/kg/min; rarely doses up to 40 used (to prepare: put 50 mg in 250 ml D5W to yield 200 mcg/ml).

amrinone (Inocor®) DRUG INFO

Nonadrenergic cardiotonic. Phosphodiesterase inhibitor, effects similar to

dobutamine (including exacerbation of myocardial ischemia). 2% incidence of thrombocytopenia.

Rx 0.75 mg/kg initially over 2-3 min, then drip 5-10 mcg/kg/min.

phenylephrine (Neo-Synephrine®) DRUG INFO

Pure alpha sympathomimetic. Useful in hypotension associated with tachycardia (atrial tachyarrhythmias). Elevates BP by increasing SVR via vasoconstriction, causes reflex increase in parasympathetic tone (with resultant slowing of pulse). Lack of ß action means non-inotropic, no cardiac acceleration, and no relaxation of bronchial smooth muscle. Cardiac output and renal blood flow may decrease. Avoid in spinal cord injuries (*see page 935*).

Rx pressor range: 100-180 mcg/min; maintenance: 40-60 mcg/min. To prepare: put 40 mg (4 amps) in 500 ml D5W to yield 80 mcg/ml; a rate of 8 ml/hr = 10 mcg/min.

norepinephrine DRUG INFO

Primarily vasoconstrictor (? counterproductive in cerebral vasospasm, ? decreases CBF). ß-agonist at low doses. Increases pulmonary vascular resistance.

epinephrine (adrenalin globally) DRUG INFO

Rx 0.5-1.0 mg of 1:10,000 solution IVP; may repeat q 5 minutes (may bolus per ET tube). Drip: start at 1.0 mcg/min, titrate up to 8 mcg/min (to prepare: put 1 mg in 100 ml NS or D5W).

isoproterenol (Isuprel®) DRUG INFO

Positive chronotropic and inotropic, → increased cardiac O_2 consumption, arrhythmias, vasodilatation (by $ß_1$ action) skeletal muscle > cerebral vessels.

levophed **DRUG INFO**

Direct ß stimulation (positive inotropic and chronotropic).

Rx start drip at 8-12 mcg/min; maintenance 2-4 mcg/min (0.5-1.0 ml/min) (to prepare: put 2 mg in 500 ml NS or D5W to yield 4 mcg/cc).

2.3. Sedatives & paralytics

Richmond agitation-sedation scale (RASS)

A validated scale[41, 42] that uses positive numbers for agitation and negative numbers for sedation as shown in *Table 2-12*. Useful for quantitating the desired level of sedation when titrating sedatives for agitated patients.

Procedure for performing RASS assessment:

1. on observation, patient is alert, restless or agitated: score 0 to +4
2. if patient is not alert, state patient's name and verbally instruct to open eyes and look at speaker: score –1 to –3
3. if no response to verbal stimulus, physically stimulate by shaking shoulder and/or sternal rub: score –4 or –5

Table 2-12 Richmond agitation-sedation scale

	Score	Term	Description	
AGITATION	+4	combative	overly combative, violent, immediate danger to staff	
AGITATION	+3	very agitated	pulls or removes tubes or catheters; aggressive	
AGITATION	+2	agitated	frequent non-purposeful movements, fights ventilator	
AGITATION	+1	restless	anxious, but movements not aggressive vigorous	
	0	alert & calm		
SEDATION	–1	drowsy	not fully alert, but has sustained awakening (eye-opening/contact) to *voice* (≥ 10 seconds)	verbal stimulation
SEDATION	–2	light sedation	briefly awakens with eye contact to *voice* (< 10 seconds)	verbal stimulation
SEDATION	–3	moderate sedation	movement or eye opening to *voice* (no eye contact)	verbal stimulation
SEDATION	–4	deep sedation	no response to voice, but movement or eye-opening to *physical* stimulation	physical stimulation
SEDATION	–5	unarousable	no response to *voice* or *physical* stimulation	physical stimulation

2.3.1. Conscious sedation

Use of these agents requires ability to provide immediate emergency ventilatory support (including intubation). Agents include:

- midazolam (Versed®): *see page 51*
- pentobarbital (Nembutal®): a barbiturate. ***Rx*** for 70 kg adult: 100 mg slow IVP

methohexital (Brevital®) DRUG INFO

More potent and shorter acting than thiopental (useful e.g. for percutaneous rhizotomy where patient needs to be sedated and awakened repeatedly). Lasts 5-7 min. Similar cautions with the added problem that methohexital may induce seizures. May no longer be available in the U.S.

Rx Adult: 1 gm% solution (add 50 ml diluent to 500 mg to yield 10 mg/ml), 2 ml test dose, then 5-12 ml IVP at rate of 1 ml/5 secs, then 2 to 4 ml q 4-7 min PRN.

haloperidol (Haldol®) DRUG INFO

SIDE EFFECTS: rare neuroleptic malignant syndrome. ✖ Contraindicated in Parkinson's disease. Anticholinergic effects may exacerbate urinary retention.

Rx For "rapid sequence tranquilization" (to sedate acutely agitated patient): 5-10 mg haloperidol IM q 15 minutes until patient controlled.

2.3.2. Sedation

Generally requires intubation and mechanical ventilatory support in the ICU. Doses are generally lower than those used by anesthesiologists for general anesthesia.

thiopental (Pentothal®) DRUG INFO

A short acting barbiturate. 1st dose causes unconsciousness in 20-30 secs (circulation time), depth increases up to 40 secs, duration = 5 mins (terminated by redistribution), consciousness returns over 20-30 mins.

SIDE EFFECTS: dose related respiratory depression, irritation if extravasated, intraarterial injection → necrosis, agitation if injected slowly, an antianalgesic, myocardial depressant, hypotension in hypovolemic patients.

Rx Adult: initial concentration should not exceed 2.5%, give 50 mg test dose moderately rapid IVP, then if tolerated give 100-200 mg IVP over 20-30 secs (500 mg may be required in large patient).

★ remifentanil (Ultiva®) DRUG INFO

Ultrashort acting micro-opioid receptor agonist. Potency similar to fentanyl. Rapidly crosses BBB. Onset: < 1 min. Offset: 3-10 mins. Lowers ICP. Metabolism: non-hepatic hydrolysis by nonspecific blood and tissue esterases, ∴ no accumulation. Synergy with thiopental, propofol, isoflurane, midazolam requires reducing doses of these agents by up to 75%. **SIDE EFFECTS:** bradycardia, hypotension (these side effects may be blunted by pretreatment with anticholinergics), N/V, muscle rigidity, pruritus (especially facial) dose dependent respiratory depression at doses > 0.05 mcg/kg/min.

Rx Adult: avoid bolus doses. Start with drip of 0.05 mcg/kg/min. Titrate in

0.025 mcg/kg/min increments to a maximum of 0.1-0.2 mcg/kg/min. Add a sedative if adequate sedation not achieved at maximum dose. Wean infusion in 25% decrements over 10 minutes after extubation. **SUPPLIED**: vials of 1, 2 or 5 mg powder to be reconstituted to 1 mg/ml solution.

fentanyl (Sublimaze®) DRUG INFO

Narcotic, potency ≈ 100 **x** morphine. High lipid solubility → rapid onset. Offset (small doses): 20-30 mins. Unlike morphine and meperidine, does not cause histamine release. Lowers ICP. **SIDE EFFECTS:** dose dependent respiratory depression, large doses given rapidly may cause chest wall rigidity. Repeated dosing may cause accumulation. Diminished sensitivity to CO_2 stimulation, may persist longer than the depression of respiratory rate (up to 4 hours).

Rx Adult: 25-100 mcg (0.5-2 ml) IVP, repeat PRN. **SUPPLIED**: 50 mcg/ml; requires refrigeration.

⭑ propofol (Diprivan®) DRUG INFO

A sedative hypnotic. Also useful in high doses during aneurysm surgery as a neuroprotectant (*see page 1064*). Protection seems to be less than with barbiturates. Offset time increases after ≈ 12 hours of use.

Rx for sedation: start at 5-10 mcg/kg/min. Increase by 5-10 mcg/kg/min q 5-10 minutes PRN desired sedation (up to a max of 50 mcg/kg/min).

SIDE EFFECTS: include **Propofol Infusion Syndrome**: hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure, rhabdomyolysis, renal failure and sometimes death[43]. First identified in children, but may occur at any age. NB: metabolic acidosis of unknown etiology in a patient on propofol is propofol infusion syndrome until proven otherwise. Use with caution at doses > 50 mcg/kg/min or at any dose for > 48 hrs. Also note that the lipid carrier provides 1.1 kCal/ml and hypertriglyceridemia may occur.

SUPPLIED: 500 mg suspended in a 50 ml bottle of fat emulsion. The bottle and tubing must be changed every 12 hours since it contains no bacteriostatic agent.

★ Precedex® (dexmedetomidine) **DRUG INFO**

An alpha-2 adrenoceptor agonist. Acts in locus ceruleus and dorsal root ganglia. Has both sedative and analgesic properties and dramatically reduce the risk of respiratory depression and the amount of narcotic analgesics required. Reduces shivering.

Rx: usual loading dose is 1 mcg/kg IV over 10 minutes (loading dose not needed if patient already sedated with other agents), followed by continuous IV infusion of 0.2-1.0 mcg/kg/hr titrated to desired effect, not to exceed 24 hours (for short sedation or use as a "transition" drug). **SIDE EFFECTS:** clinically significant bradycardia and sinus arrest have occurred in young, healthy volunteers with increased vagal tone (anticholinergics such as atropine 0.2 mg IV or glycopyrrolate 0.2 mg IV may help). Use with caution in patients with advanced heart block, baseline bradycardia, using other drugs that lower heart-rate, and hypovolemia. **SUPPLIED**: 2 ml vials of 100 mcg/ml to be diluted in 48 ml NS for a final concentration of 4 mcg/ml for IV use.

2.3.3. Paralytics (neuromuscular blocking agents)

CAUTION: requires ventilation (intubation or Ambu-bag/mask). Reminder: paralyzed patients may still be conscious and therefore able to feel pain, the simultaneous use of sedation is thus required for conscious patients.

Early routine use in head-injured patients lowers ICP (e.g. from suctioning[44]) and mortality, but does not improve overall outcome[45].

Neuromuscular blocking agents **(NMBAs)** are classified clinically by time to onset and duration of paralysis as shown in *Table 3-13*. Additional information for some agents follows the table along with some considerations for neurosurgical patients.

Table 3-13 Onset and duration of muscle relaxants

Clinical class	Agent	Trade name (®)	Onset (min)	Duration (min)	Spontaneous recovery (min)	Comment
Ultra-short	succinylcholine	Anectine	1	5-10	20	shortest onset and duration; plasma cholinesterase dependent; many side effects
Short	rocuronium	Zemuron	1-1.5	20-35	40-60	close to succinylcholine in onset in large doses; some vagolytic action in children
Intermediate	atracurium	Tracrium	3-5	20-35	40-60	no renal or hepatic metabolism; histamine release in larger doses
	vecuronium	Norcuron	3-5	20-35	40-60	minimal cardiovascular side effects (bradycardia reported); no histamine release
	cisatracurium	Nimbex	1.5-2	40-60	60-80	no histamine release at recommended doses
Long	d-tubocurarine		4-6	45-60	60-180	histamine release; ↑ ICP; ganglion block
	metocurine	Metubine	4-6	45-60	60-180	fewer side effects than d-tubocurarine*
	pancuronium	Pavulon	4-6	45-60	60-180	cardiovascular side effects; vagolytic
	doxacurium	Nuromax	4-6	45-60	60-180	minimal cardiovascular side effects*

* not commonly used in ICU due to lack of clinical experience

ULTRA-SHORT ACTING PARALYTICS

succinylcholine (Anectine®) **DRUG INFO**

The only depolarizing ganglionic blocker (the rest are competitive blockers). Rapidly inactivated by plasma pseudocholinesterases. A single dose produces fasciculations then paralysis. Onset: 1 min. Duration of action: 5-10 min.

Indications

Due to significant side effects (*see below*), use is now limited primarily to the following indications. Adults: generally recommended only for emergency intubations where the airway is not controlled. In children: only when intubation is needed with a full stomach, or if laryngospasm occurs during attempted intubation using other agents.

Side effects

✖ CAUTIONS: usually increases serum K^+ by 0.5 mEq/L (on rare occasion causes severe hyperkalemia ($[K^+]$ up to 12 mEq/L) in patients with neuronal or muscular pathology, causing cardiac complications which cannot be blocked),

therefore contraindicated in acute phase of injury following major burns, multiple trauma or extensive denervation of skeletal muscle or upper motor neuron injury. Do not use for routine intubations in adolescents and children (may cause cardiac arrest even in apparently healthy youngsters, many of whom have undiagnosed myopathies). Linked to malignant hyperthermia (*see page 5*).

May cause dysrhythmias, especially sinus bradycardia (treat with atropine). May get autonomic stimulation from ACh-like action → HTN, and brady- or tachycardia (especially in peds with repeated doses). The fasciculations may increase ICP, intragastric pressure, and intraocular pressure (contraindicated in penetrating eye injury, especially to anterior chamber; OK in glaucoma).

Precurarization with a "priming dose" of a nondepolarizing blocker (usually ≈ 10% of the intubating dose, e.g. pancuronium 0.5-1 mg IV 3-5 minutes prior to succinylcho-line) in patients with elevated ICP or increased intraocular pressure (to ameliorate further pressure increases during fasciculation phase) and in patients who have eaten recently (controversial[46]). Phase II block (similar to nondepolarizing blocker) may develop with excessive doses or in patients with abnormal pseudocholinesterase.

Dosing

***Rx* Adult**: 0.6-1.1 mg/kg (2-3 ml/70 kg) IVP (err on high side to allow time for procedure & to avoid multi-dosing complications), may repeat this dose **x** 1.

***Rx* Peds** (CAUTION: Not recommended for routine use, *see above*) Children: 1.1 mg/kg. Infants (< 1 mos): 2 mg/kg.

SUPPLIED: 20 mg/ml concentration.

SHORT ACTING PARALYTICS

rocuronium (Zemuron®) DRUG INFO

In large doses, has speed of onset that approaches succinylcholine. However, in these doses, paralysis usually lasts ≈ 1-2 hrs. Expensive.

***Rx* Adult**: initial dose 0.6-1 mg/kg. May be used as infusion of 10-12 mcg/kg/min.

INTERMEDIATE ACTING PARALYTICS

⋆ vecuronium (Norcuron®) DRUG INFO

Nondepolarizing (competitive) NMBA. Adequate paralysis for intubation within 2.5-3 minutes of administration. About one third more potent than pancuronium, shorter duration of action (lasts ≈ 30 minutes after initial dose). Unlike pancuronium, very little vagal (i.e. cardiovascular) effects. No CNS active metabolites. Does not affect ICP or CPP. Hepatically metabolized. Due to active metabolites, paralysis has been reported to take 6 hrs to 7 days to recede following discontinuation of the drug after ≥ 2 days use in patients with renal failure[47]. Must be mixed to use.

Dosing

Supplied: 10 mg freeze-dried cakes requiring reconstitution. Use within 24 hrs.

Rx Adult and children > 10 years age: 0.1 mg/kg (for most adults use 8-10 mg as initial dose). May repeat q 1 hr PRN. Infusion: 1-2 mcg/kg/min.

Rx Pediatric: children (1-10 yrs) require slightly higher dose and more frequent dosing than adult. Infants (7 weeks - 1 yr): slightly more sensitive on a mg/kg basis than adults, takes ≈ 1.5 **x** longer to recover. Use in neonates and continuous infusion in children is insufficiently studied.

⋆ cisatracurium (Nimbex®) DRUG INFO

Nondepolarizing (competitive) blocker. This isomer of atracurium does not release histamine unlike its parent compound (*see below*). Provides about 1 hour of paralysis. Also undergoes Hofmann degradation, with laudanosine as one of its metabolites.

Rx Adult and children > 12 years age: 0.15 or 0.2 mg/kg as part of propofol/nitrous oxide/oxygen induction-intubation technique produces muscle paralysis adequate for intubation within 2 or 1.5 minutes, respectively. Infusion: 1-3 mcg/kg/min.

Rx Pediatric: children (2-12 yrs): 0.1 mg/kg given over 5-10 seconds during inhalational or opioid anesthesia.

atracurium (Tracrium®) DRUG INFO

Nondepolarizing (competitive) blocker. After IV bolus: onset 2-2.5 mins, peak 3-5 mins, duration 15-20 mins (initial dose may last up to 30 minutes). Undergoes nonenzymatic Hofmann degradation and ester hydrolysis at normal physiologic pH and temperature, inactivating the drug in ≈ 30 minutes. Therefore useful in patients with liver or renal failure. Reversible with neostigmine (*see below*). Causes histamine release which can produce hypotension (consider cisatracurium instead, *see above*). A metabolite, laudanosine, is neuroexcitatory, and accumulation could theoretically cause seizures (no documented cases)[46].

Dosing

SUPPLIED: 5 & 10 ml ampules of 10 mg/ml concentration.

Rx Adult & children > 2 yrs age: 0.4-0.5 mg/kg IVP. Reduce subsequent doses to 0.02 mg/kg.

Rx Neonates (1 month - 2 yrs): 0.3-0.4 mg/kg.

LONG ACTING PARALYTICS

pancuronium (Pavulon®) DRUG INFO

The "prototype" nondepolarizing (competitive) paralytic. Peak: 3-5 mins, duration up to 60 mins. Reversible with anticholinesterases such as neostigmine (*see below*). Renal elimination.

SIDE EFFECTS: usefulness is limited because the drug is vagolytic and an indirect sympathomimetic which increases cardiac output, pulse rate and ICP. Consider vecuronium as an alternative (*see above*).

Dosing

Rx Adult & children: 0.04-0.10 mg/kg IVP (start with 3 mg). Reduce subsequent doses to 0.02 mg/kg.

Rx Neonates: especially sensitive, test dose 0.02 mg/kg.

REVERSAL OF COMPETITIVE MUSCLE BLOCKADE

It takes ≈ 20 minutes for full reversal of pancuronium (Pavulon®) (depending on the amount of time since the last dose). Reversal is usually not attempted until patient has at least 1 twitch to a train of 4 stimulus, otherwise

reversal may be incomplete if patient is profoundly blocked and blockade may reoccur as the reversal wears off

1. neostigmine (Prostigmin®): 2.5 mg (minimum) to 5 mg (maximum) IV (start low, no efficacy from > 5 mg and can produce severe weakness especially if the maximum dose is exceeded in the absence of neuromuscular blockade)

PLUS (to prevent bradycardia…), EITHER

• 0.5 mg atropine for each mg of neostigmine

OR

• 0.2 mg glycopyrrolate (Robinul®) for each mg of neostigmine

2.4. Neurogenic pulmonary edema

A rare condition associated with a variety of intracranial pathologies, including: subarachnoid hemorrhage, generalized seizures, and head injury.

Pathophysiology

Two possibly synergistic mechanisms. Sudden increased ICP or hypothalamic injury may produce a salvo of sympathetic discharge causing redistribution of blood to the pulmonary circulation, resulting in elevation of pulmonary capillary wedge pressures **(PCWP)** and increased permeability. Secondly, the associated surge of catecholamines directly disrupts the capillary endothelium which increases alveolar permeability.

Treatment

Supportive, using measures such as positive pressure ventilation with low levels of PEEP (*see page 880*) and treatment to normalize ICP. A PA-catheter is usually helpful.

There may be some efficacy in using a dobutamine infusion[48] supplemented with furosemide as needed. The theoretical advantage of dobutamine over previously attempted alpha- and beta-blockers is that dobutamine does not reduce cerebral perfusion. Nitroprusside may help dilate the pulmonary vasculature.

NOTES

3. General care

3.1. Endocrinology

3.1.1. Steroids

3.1.1.1. Replacement therapy

Under normal, basal conditions, the adrenal cortex secretes 15-25 mg/day of **cortisol** (hydrocortisone is the name for the identical pharmaceutical compound for administration), and 1.5-4 mg/day of **corticosterone**. Cortisol has a half-life of ≈ 90 minutes.

In primary adrenocortical insufficiency (Addison's disease), both glucocorticoids and mineralocorticoids must be replaced. In secondary adrenal insufficiency caused by deficient corticotropin **(ACTH)** release by the pituitary, mineralocorticoid secretion is usually normal and only glucocorticoids need to be replaced.

Table 3-1 shows equivalent daily corticosteroid doses for replacement therapy.

Table 3-1 Equivalent corticosteroid doses*

Steroid: generic (proprietary)	Equiv dose (mg)	Route	Dosing	Mineralo-corticoid potency	Oral dosing forms
cortisone (Cortone®)	25	PO, IM	2/3 in AM, 1/3 in PM	2+	tabs: 5, 10 & 25 mg
hydrocortisone AKA cortisol (Cortef®)	20	PO	2/3 in AM, 1/3 in PM	2+	tabs: 5, 10 & 20 mg
(Solu-Cortef®)		IV, IM†			
prednisone (Deltasone®)	5	PO only	divided BID-TID	1+	tabs: 1, 2.5, 5, 10, 20, 50 mg‡
methylprednisolone (Solumedrol®)	4	PO, IV, IM		0	tabs§: 2, 4, 8, 16, 24, 32 mg
dexamethasone (Decadron®)	0.75	PO, IV	divided BID-QID	0	scored tabs: 0.25, 0.5, 0.75, 1.5, 4, 6 mg

* doses given are daily doses. Steroids listed are used primarily as glucocorticoids: equivalent glucocorticoid PO or IV dose is given; IM may differ

† IM route recommended only for emergencies where IV access cannot be rapidly obtained

‡ Sterapred Uni-Pak® contains 21 tabs of 5 mgs prednisone and tapers dosage from 30 to 5 mgs over 6 days; "DS" contains 10 mg tabs and tapers from 60 mg to 10 mg over 6 days; "DS 12-Day" contains 48 10 mg tabs and tapers from 60 mg to 20 mg over 12 days

§ Medrol Dosepak® contains 21 tabs of 4 mgs methylprednisolone and tapers dosage from 24 mg/d to 4 mg/d over 6 days

Physiologic replacement (in the absence of stress) can be accomplished with either:

1. hydrocortisone: 20 mg PO q AM and 10 mg PO q PM
2. or prednisone: 5 mg PO q AM and 2.5 mg PO q PM

Cortisol and cortisone are useful for chronic primary adrenocortical insufficiency or for Addisonian crisis. Because of mineralocorticoid activity, use for chronic therapy of other conditions (e.g. hypopituitarism) may result in salt and fluid retention, hypertension and hypokalemia.

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS SUPPRESSION

Chronic steroid administration suppresses the hypothalamic-pituitary-adrenal **(HPA)** axis, and eventually causes adrenal atrophy. If steroids are abruptly stopped or if acute illness develops, symptoms of adrenocortical insufficiency **(AI)** may ensue (*see Table 3-2*), which if severe may progress to Addisonian crisis (*see page 34*). Recovery of adrenal cortex lags behind the pituitary, so basal ACTH levels increase before cortisol levels.

HPA suppression depends on the specific glucocorticoid used, the route,

frequency, time, and duration of treatment. Suppression is unlikely with < 40 mg prednisone (or equivalent) given in the morning for less than ≈ 7 days, or with every-other-day therapy of < 40 mg for ≈ 5 weeks[1]. Some adrenal atrophy may occur after 3-4 days of high dose steroids, and some axis suppression will almost certainly occur after 2 weeks of 40-60 mg hydrocortisone (or equivalent) daily. After a month or more of steroids, the HPA axis may be depressed for as long as one year.

Measuring morning plasma hydrocortisone can evaluate the degree of recovery of basal adrenocortical function, but does not assess adequacy stress response.

Table 3-2 Symptoms of adrenal insufficiency (AI)

• fatigue • weakness • arthralgia • anorexia • nausea • hypotension	• orthostatic dizziness • hypoglycemia • dyspnea • Addisonian crisis (if severe; with risk of death, *see page 34*)

STEROID WITHDRAWAL[1]

In addition to the above dangers of hypocortisolism in the presence of HPA suppression, too rapid a taper may cause a flare-up of the underlying condition for which steroids were prescribed.

When the risk of HPA suppression is low (as is the case with short courses of steroids for less than ≈ 5-7 days[2] generally prescribed for most neurosurgical indications) abrupt discontinuation usually carries a low risk of AI. For up to≈ 2 weeks of use, steroids are usually safely withdrawn by tapering over 1-2 weeks. For longer treatment, or when withdrawal problems develop, use the following conservative taper:

1. make small decrements (equivalent to 2.5-5 mg prednisone) every 3-7 d. Patient may experience mild withdrawal symptoms of[3]:
   A. fatigue
   B. anorexia
   C. nausea
   D. orthostatic dizziness
2. “backtrack” (i.e. increase the dose and resume a more gradual taper) if any of the following occur:
   A. exacerbation of the underlying condition for which steroids were used
   B. evidence of steroid withdrawal symptoms (*see Table 3-2*)

C. intercurrent infection or need for surgery (see *Stress doses* below)

3. once "physiologic" doses of glucocorticoid have been reached (about 20 mg hydrocortisone/day or equivalent (*see Table 3-1*)):
   A. the patient is switched to 20 mg hydrocortisone PO q AM (do not use long acting preparations)
   B. after ≈ 2-4 weeks, a morning cortisol level is checked (prior to the AM hydrocortisone dose), and the hydrocortisone is tapered by 2.5 mg weekly until 10 mg/d is reached (lower limits of physiologic)
   C. then, every 2-4 weeks, the AM cortisol level is drawn (prior to AM dose) until the 8 AM cortisol is > 10 mcg/100 ml, indicating return of baseline adrenal function
   D. when this return of baseline adrenal function occurs:
      1. daily steroids are stopped, but stress doses must still be given when needed (*see below)*
      2. monthly cosyntropin stimulation tests (*see page 647*) are performed until normal. The need for stress doses of steroids ceases when a positive test is obtained. The risk for adrenal insufficiency persists ≈ <u>2 years</u> after cessation of chronic steroids (especially the first year)

STRESS DOSES

During physiologic "stress" the normal adrenal gland produces ≈ 250-300 mg hydrocortisone/day. With chronic glucocorticoid therapy (either at present, or within last 1-2 yrs), suppression of the normal "stress-response" necessitates supplemental doses.

In patients with a suppressed HPA axis:

- for mild illness (e.g. UTI, common cold), single dental extraction: double the daily dose (if off steroids, give 40 mg hydrocortisone BID)
- for moderate stress (e.g. flu), minor surgery under local anesthesia (endoscopy, multiple dental extractions…): give 50 mg hydrocortisone BID
- for major illness (pneumonia, systemic infections, high fever), severe trauma, or emergency surgery under general anesthesia: give 100 mg hydrocortisone IV q 6-8 hrs for 3-4 days until the stress is resolved
- for elective surgery, *see Table 3-3* for guidelines

Table 3-3 Steroid stress doses for elective surgery

On day of surgery, 50 mg cortisone acetate IM, followed by 200 mg hydrocortisone IV infused over 24 hrs

Post-op day	Hydrocortisone (mg)		
	8 AM	4 PM	10 PM
1	50	50	50
2	50	25	25
3	40	20	20
4	30	20	10
5	25	20	5
6	25	15	–
7	20	10	–

POSSIBLE DELETERIOUS SIDE EFFECTS OF STEROIDS

Although these side effects are more common with prolonged administration[4], some can occur even with short treatment courses. Some evidence suggests that low-dose glucocorticoids (≤ 10 mg/d of prednisolone or prednisone equivalent) for rheumatoid arthritis does not increase osteoporotic fractures, blood pressure, cardiovascular disease, or peptic ulcers[5], but weight gain and skin changes are common. Possible side effects include[3, 6]:

- cardiovascular and renal
  - hypertension
  - sodium and water retention
  - hypokalemic alkalosis
- CNS
  - progressive multifocal leukoencephalopathy **(PML)** (*see page 364*)
  - mental agitation or "steroid psychosis"
  - spinal cord compression from spinal epidural lipomatosis: rare (*see page 1186*)
  - pseudotumor cerebri (see *Idiopathic intracranial hypertension (IIH)*, page 713)
- endocrine
  - caution: because of growth suppressant effect in children, daily glucocorticoid dosing over prolonged periods should be reserved for the most urgent indications
  - secondary amenorrhea
  - suppression of hypothalamic-pituitary-adrenal axis: reduces endogenous steroid production → risk of adrenal insufficiency with steroid withdrawal

(*see above*)
- ♦ Cushingoid features with prolonged usage (iatrogenic Cushing's syndrome): obesity, hypertension, hirsutism…

• GI: risk increased only with steroid therapy > 3 weeks duration and regimens of prednisone > 400-1000 mg/d or dexamethasone > 40 mg/d[7]
- ♦ gastritis and steroid ulcers: incidence lowered with the use of antacids and/or H_2 antagonists (e.g. cimetidine, ranitidine…)
- ♦ pancreatitis
- ♦ intestinal or sigmoid diverticular perforation[8]: incidence ≈ 0.7%. Since steroids may mask signs of peritonitis, this should be considered in patients on steroids with abdominal discomfort, especially in the elderly and those with a history of diverticular disease. Abdominal x-ray usually shows free intraperitoneal air

• inhibition of fibroblasts
- ♦ impaired wound healing or wound breakdown
- ♦ subcutaneous tissue atrophy

• metabolic
- ♦ glucose intolerance (diabetes) and disturbance of nitrogen metabolism
- ♦ hyperosmolar nonketotic coma
- ♦ hyperlipidemia
- ♦ tend to increase BUN as a result of protein catabolism

• ophthalmologic
- ♦ posterior subcapsular cataracts
- ♦ glaucoma

• musculoskeletal
- ♦ avascular necrosis **(AVN)** of the hip or other bones: usually with prolonged administration → cushingoid habitus and increased marrow fat within the bone[9]
- ♦ osteoporosis: may predispose to vertebral compression fractures which occur in 30-50% of patients on prolonged glucocorticoids (*see page 992*). Steroid induced bone loss may be reversed with cyclical administration of etidronate[10] in 4 cycles of 400 mg/d **x** 14 days followed by 76 days of oral calcium supplements of 500 mg/d (not proven to reduced rate of VB fractures, *see page 992*)
- ♦ muscle weakness (steroid myopathy): often worse in proximal muscles

• infectious
- ♦ immunosuppression: with possible superinfection, especially fungal, parasitic

  - possible reactivation of TB, chickenpox
- hematologic
  - hypercoagulopathy from inhibition of tissue plasminogen activator
  - steroids cause demargination of white blood cells, which may artifactually elevate the WBC count even in the absence of infection
- miscellaneous
  - hiccups: may respond to chlorpromazine (Thorazine®) 25-50 mg PO TID-QID **x** 2-3 days (if symptoms persist, give 25-50 mg IM)
  - steroids readily cross the placenta, and fetal adrenal hypoplasia may occur with the administration of large doses during pregnancy

---

3.1.1.2. Hypocortisolism

8 A.M. serum cortisol is the best way to test for hypocortisolism.

ADDISONIAN CRISIS

An adrenal insufficiency emergency.

Symptoms: mental status changes (confusion, lethargy, or agitation), muscle weakness.

Signs: postural hypotension or shock, hyperthermia (as high as 105° F, 45.6 C)

Labs: hyponatremia, hyperkalemia, hypoglycemia.

TREATMENT OF ADDISONIAN CRISIS

If possible, draw serum for cortisol determination (do <u>not</u> wait for these results to institute therapy). Give fluids sufficient for dehydration and shock.

For “glucocorticoid emergency”

- hydrocortisone sodium succinate (Solu-Cortef®): 100 mg IV STAT and then 50 mg IV q 6 hrs

AND

- cortisone acetate 75-100 mg IM STAT, and then 50-75 mg IM q 6 hrs

For “mineralocorticoid emergency”

Usually not necessary in secondary adrenal insufficiency (e.g. panhypopituitarism)

• desoxycorticosterone acetate (Doca®): 5 mg IM BID
OR
• fludrocortisone (Florinef®): 0.05- 0.2 mg PO q d

NOT recommended for emergency treatment

✖ methylprednisolone

3.2. Hematology

3.2.1. Blood component therapy

PLATELETS

Normal platelet count **(PC)** is 150K-400K[A]. Thrombocytopenia is defined as PC < 150K. Bleeding (spontaneously or with invasive procedures) is rarely a problem with PC > 50K. Spontaneous hemorrhage is very likely with PC < 5K. Spontaneous intracranial hemorrhage is uncommon with PC > 30K, and is more common in adults than children. Based on patients with ITP, the risk of fatal hemorrhage in patients with PC < 30K is 0.0162-0.0389 cases per patient-year[11] (risk of death from infection is higher). Intracranial bleeding is usually subarachnoid or intraparenchymal, with petechial hemorrhages common.

A. abbreviation used here: 150K = 150,000/mm^3 = 150 **x** 109/l

Platelet therapy

1 unit of platelets contains 5.5 **x** 1010 (minimum) to 10 **x** 1010 platelets. The volume of 6 units is 250-300 ml. Platelets may be stored up to 5 days.

Recommended transfusion criteria[12]:

1. thrombocytopenia due to ↓ production (with or without increased destruction) (the most common causes are aplastic anemia and leukemia)
   A. PC < 10K even if no bleeding (prophylactic transfusion to prevent bleeding)

B. PC < 20K and bleeding

C. PC < 30K and patient at risk for bleeding: complaints of H/A, presence of confluent (c.f. scattered) petechiae, continuous bleeding from a wound, increasing retinal hemorrhage

D. PC < 50K *AND*

1. major surgery planned within 12 hours
2. PC rapidly falling
3. patient < 48 hours post-op
4. patient requires lumbar puncture
5. acute blood loss of > 1 blood volume in < 24 hours

2. platelet transfusions have limited usefulness when thrombocytopenia is due to platelet destruction (e.g. by antibodies as in ITTP) or consumption (if production is adequate or increased, platelet transfusion usually will not be useful)
3. documented platelet dysfunction in a patient scheduled for surgery or in a patient with advanced hepatic and/or renal insufficiency (consider pharmacologic enhancement of platelet function, e.g. desmopressin[13])

Other indications for platelet transfusion:

1. patients who have been on Plavix® or aspirin who need urgent surgery that cannot be postponed for ≈ 5 days to allow new platelets to be synthesized

Dosage

Approximately 25% of platelets are lost just with transfusion.

Peds: 1 U/m^2 raises PC by ≈ 10K, usually give 4 U/m^2.

Adult: 1 U raises platelet count by ≈ 5-10K. Typical dose for thrombocytopenic bleeding adult: 6-10 U (usual order: “8-pack”). Alternatively, 1 U of pheresed platelets may be given (obtained from a single donor by apheresis, equivalent to 8-10 U of pooled donor platelets).

Check PC 1-2 hrs after transfusion. The increase in PC will be less in DIC, sepsis, splenomegaly, with platelet antibodies, or if the patient is on chemotherapy. In the absence of increased consumption, platelets will be needed q 3-5 days.

PLASMA PROTEINS

FFP (FRESH FROZEN PLASMA)

1 bag = 200-250 ml (usually referred to as a "unit", not to be confused with 1 unit of *factor activity* which is defined as 1 ml). FFP is plasma separated from RBCs and platelets, and contains all coagulation factors and natural inhibitors. FFP has an out-date period of 12 months. The risk of AIDS and hepatitis for each unit of FFP is equal to that of a whole unit of blood.

Recommended transfusion criteria (modified[12]):

1. history or clinical course suggestive of coagulopathy due to congenital or acquired coagulation factor deficiency with active bleeding or pre-op, with PT > 18 sec or APTT > 1.5 **x** upper limit of normal (usually > 55 sec), fibrinogen functioning normally and level > 1 g/l, and coagulation factor assay < 25% activity
2. proven coagulation factor deficiency with active bleeding or scheduled for surgery or other invasive procedure
   A. congenital deficiency of factor II, V, VII, X, XI or XII
   B. deficiency of factor VIII or IX if safe replacement factors unavailable
   C. von Willebrand's disease unresponsive to DDAVP
   D. multiple coagulation factor deficiency as in hepatic dysfunction, vitamin K depletion or DIC
3. reversal of warfarin (Coumadin®) effect (PT > 18 sec, or INR > 1.6) in patient actively bleeding or requiring emergency surgery or procedure with insufficient time for vitamin K to correct (which usually requires > 6-12 hrs) (*see page 40*)
4. deficiency of antithrombin III, heparin cofactor II, or protein C or S
5. massive blood transfusion: replacement of > 1 blood volume (≈ 5 L in 70 kg adult) within several hours with evidence of coagulation deficiency as in (1) and with continued bleeding
6. treatment of thrombotic thrombocytopenic purpura, hemolytic uremic syndrome
7. ✖ because of associated hazards and suitable alternatives, the use of FFP as a volume expander is relatively contraindicated

Dosage: Usual starting dose is 2 bags of FFP (400-600 ml). If PT is 18-22 secs or APTT is 55-70 secs, 1 bag may suffice. Doses as high as 10-15 ml/kg may be needed for some patients. Monitor PT/PTT (or specific factor assay) and clinical bleeding. Since factor VII has a shorter half-life (≈ 6 hrs) than the other factors, PT may become prolonged before APTT.

Remember: if patient is also receiving platelets, that for every 5-6 units of platelets the patient is also receiving coagulation factors equivalent to ≈ 1 bag of

FFP.

ALBUMIN AND PLASMA PROTEIN FRACTION (PPF, AKA PLASMANATE®)

Usually from outdated blood, treated to inactivate hepatitis B virus. Ratio of albumin:globulin percentage in "albumin" is 96%:4%, in PPF it is 83%:17%. Available in 5% (oncotically and osmotically equivalent to plasma) and 25% (contraindicated in dehydrated patients). 25% albumin may be diluted to 5% by mixing 1 volume of 25% albumin to 4 volumes of D5W or 0.9% NS (✖ caution: mixing with sterile water will result in a hypotonic solution that can cause hemolysis and possible renal failure).

Expensive for use simply as a volume expander (≈ $60-80 per unit). Indicated only when total protein < 5.2 gm% (otherwise, use crystalloid which is equally effective). Rapid infusion (> 10 cc/min) has been reported to cause hypotension (due to Naacetate and Hegeman factor fragments). Use in ARDS is controversial. In neurosurgical patients, may be considered as an adjunct for volume expansion (along with crystalloids) for hyperdynamic therapy (*see page 1052*) when the hematocrit is < 40% following SAH where there is concern about increasing the risk of rebleeding e.g. with the use of hetastarch (*see page 1042*).

CRYOPRECIPITATE

Recommended transfusion criteria:

1. hemophilia A
2. von Willebrand disease
3. documented fibrinogen/factor VIII deficiency
4. documented disseminated intravascular coagulation (DIC): along with other modes of therapy

3.2.2. Coagulation

3.2.2.1. Anticoagulation

ANTICOAGULANT CONSIDERATIONS IN NEUROSURGERY

Most of these issues have not been studied in a rigorous, prospective fashion. Yet, these questions frequently arise. The following is to be considered a framework of guidelines, and is not to be construed as a standard of care. Table

3-4 acts as an index to the topics discussed below. Grayed cells are for future determination.

Contraindications to heparin

Contraindications to heparin therapy are constantly being reevaluated. Massive PE producing hemodynamic compromise should be treated with anticoagulation in most cases despite intracranial risks. Contraindications to full anticoagulation with heparin include:

- recent severe head injury
- recent craniotomy: *see below*
- patients with coagulopathies
- hemorrhagic infarction
- bleeding ulcer or other inaccessible bleeding site
- uncontrollable hypertension
- severe hepatic or renal disease
- < 4-6 hours before an invasive procedure (*see below*)
- brain tumor: *see below*

Table 3-4 Anticoagulation issues in neurosurgery

Issue	Page
General neurosurgical contraindications to full anticoagulation with heparin	36
Starting/continuing anticoagulation in the presence of the following neurosurgical conditions	
• incidental aneurysm	37
• subarachnoid hemorrhage	37
• brain tumor	37
• following craniotomy	37
• ischemic stroke • after tAP • for prevention of	1017 1011
• intracerebral hemorrhage	1127
Managing patients who are already anticoagulated who need a neurosurgical procedure	
• warfarin (Coumadin®)	37
• heparin	38
• LMW-heparin	38
• antiplatelet drugs (aspirin, Plavix, NSAIDs)	38

Patients with unruptured (incidental) cerebral aneurysms

Anticoagulation may not increase the risk of hemorrhage (i.e. rupture), however, should rupture occur, anticoagulation would most likely increase volume of hemorrhage and thus increase morbidity and mortality.

The decision to start/continue anticoagulant depends on the indication for the drugs, the size of the aneurysm (a small aneurysm < 4 mm is not as worrisome). Patients needing Plavix® for drug-eluting cardiac stents should probably be left on their drugs.

Patients on anticoagulation/antiplatelet drugs who develop SAH

Coumadin and antiplatelet drugs are usually reversed.

In patients with brain tumor

Some authors are reluctant to administer full-dose heparin to a patient with a brain tumor[14], although a number of studies found no higher risk in these patients when treated with heparin or oral anticoagulation[15-17] (PT should be followed very closely, one study recommended maintaining PT ≈ 1.25 **x** control[17]).

Post-operatively following craniotomy

Requires individualization based on the reason for the craniotomy. Surgery for parenchymal lesions where the surgery disrupts small vessels (e.g. brain tumor) is probably higher risk for hemorrhage than e.g. aneurysm surgery (expert opinion). Options:

Full anticoagulation: most neurosurgeons would probably not *fully* anticoagulate patients < 3-5 days following craniotomy[18], and some recommend at least 2 weeks. How-ever, one study found no increased incidence of bleeding when anticoagulation was resumed 3 days post craniotomy[19].

Low-dose anticoagulation: either with mini-dose heparin (5000 U SQ 2 hrs prior to craniotomy and continuing q 12 hrs post-op **x** 7 d[A]) or enoxaparin

(Lovenox)[B] (30 mg SQ BID or as a single dose of 40 MG SQ q d).

A. RPDB study[20]: assessed safety (not efficacy), 55 patients undergoing craniotomy for tumor received mini-dose heparin as indicated had no increased bleeding tendency by any of the parameters measured

B. RPNB study[21]: incidence of post-op hemorrhage increased to 11% with enoxaparin

---

MANAGEMENT OF ANTICOAGULANTS PRIOR TO NEUROSURGICAL PROCEDURES

Warfarin

Management guidelines: Patients on warfarin who must be anticoagulated as long as possible (e.g. mechanical heart valves) may stop warfarin at least **3 days** prior to the procedure, and begin self-administered LMW heparin injections (e.g. Lovenox, *see page 39*) which are discontinued as outlined below (see *Low-molecular weight heparins (LMWH)*).

Patients with less critical anticoagulation needs (e.g. chronic a-fib) can usually stop the warfarin at least 4-5 days before the procedure, and a PT/INR is then checked on admission to the hospital. Patients must be advised that during the time that they are not anticoagulated, they are at risk of possible complications from the condition for which they are receiving the agents (annual risk for mechanical valve: ≈ 6%; for a-fib: depends on several factors including age & history of prior stroke, an average for patients > 65 years age is ≈ 5-6% (for details, *see page 1022*)).

For non-emergent neurosurgical procedures: For procedures where post-op mass effect from bleeding would pose serious risk (which includes most neurosurgical operations), it is recommended that the **PT should be ≈ ≤ 13.5 sec** (i.e. ≤ upper limits of normal) or the **INR should be ≈ ≤ 1.4** (e.g. for reference, this INR is considered safe for performing a percutaneous needle liver biopsy). To reverse anticoagulants, *see page 40*.

For emergent neurosurgical procedures:, Give FFP (start with 2 units) and vitamin K (10-20 mg IV at ≤ 1 mg/min) as soon as possible (*see page 40* for reversal of anticoagulation). The timing of surgery is then based on the urgency of the situation and the nature of the procedure (e.g. the decision might be to evacuate a spinal epidural hematoma in an acutely paralyzed patient before anticoagulation is fully reversed).

Heparin

For emergencies: if it would be deleterious to wait 4-6 hours after discontinuing heparin and then repeating the PTT to verify that anticoagulation has been corrected, then heparin can be reversed with protamine (*see page 41*).

For non-emergencies:

IV heparin: stop the drip ≈ 4-6 hours prior to the planned procedure. Option: recheck PTT just prior to starting the procedure.

"Mini-dose" SQ heparin: not mandatory to stop for craniotomy[A], but if desired to discontinue, then give last dose ≥ 12 hours prior to surgery.

Low-molecular weight heparins (LMWH)

For emergencies: can be reversed with protamine (*see page 41*).

Non-emergencies: 24-48° after the last dose is usually safe for surgery. Longer time is needed in renal failure. A factor Xa level can be used to check anticoagulation status, but this usually must be sent out, making it unsuitable for acute management.

Antiplatelet drugs and neurosurgical procedures

Plavix® (clopidogrel) (*see page 1147*) and **aspirin** cause permanent inhibition of platelet function that persists ≈ 5 days after discontinuation of the drug and can increase the risk of bleeding. For elective cases, 5-7 days off these drugs is recommended (surveys of German neurosurgeons[22, 23]: an average of 7 days was used for low-dose ASA, with a few who do spine surgery even while the patient is on ASA).

Cardiac stents: dual antiplatelet therapy (e.g. ASA + Plavix®) are mandatory for 4 weeks (90 days is preferable[24]) after placement of a bare metal cardiac stent, and for at least 1 year with drug-eluting stents **(DES)**[25]. Even short gaps in drug therapy (e.g. to perform neurosurgical procedures) is associated with significant risk of acute stent occlusion (and therefore elective surgery during this time is discouraged[26]). DES are so effective in suppressing endothelialization that lifetime dual antiplatelet therapy may be required. Bridging DES patients with antithrombin, anticoagulants, or glycoprotein IIb/IIIa agents has not been proven effective[26].

Reversal of antiplatelet drugs: While heparin and warfarin can be reliably and measurably reversed, the situation is less clear with antiplatelet agents[27]. Agents

used preop to reverse these drugs include: Desmopressin (DDAVP®)[22, 23] (*see* *page 41*) and FFP[22].

Reversal of Plavix for emergency surgery: platelets may be given (*see* *page 35*), however, Plavix effects persists for up to a couple of days after the last dose, and can actually inhibit platelets given *after* the drug is discontinued (the half-life of aspirin is lower and should not be an issue after 1 day). In cases with continued oozing in the first day or so after discontinuing Plavix, the following regimen is an option:

1. recombinant activated coagulation factor VII **(rFVIIa)**: even though the defect is in the platelets, rFVIIa works, via a mechanism not mediated by protein clotting factors. Very expensive (≈ $10,000 per dose), but this must be balanced against the cost of repeat craniotomy, increased ICU stay and additional morbidity
   - A. initial dose[28]: 90-120 mcg/kg
   - B. same dose 2 hrs later
   - C. 3rd dose 6 hrs after initial dose
2. platelets every 8 hours for 24 hours, <u>either</u>
   - A. 6 U of regular platelets
   - B. if patient is on fluid or volume restriction: 1 unit of pheresed platelets

Anticoagulants

For platelet function inhibitors, *see* *page 1146*.

warfarin (Coumadin®) **DRUG INFO**

An oral vitamin K antagonist. To anticoagulate average weight patient, give 10 mg PO q d **x** 2-4 days, then ≈ 5 mg q d. Follow coagulation studies, titrate to PT = 1.2-1.5 **x** control (or INR ≈ 2-3) for most conditions (e.g. DVT, single TIA). Higher PT ratios of 1.5-2 **x** control (INR ≈ 3-4) may be needed for recurrent systemic embolism, mechanical heart valves… (the recommended ranges for the **International Normalized Ratio (INR)** are shown in *Table 3-5*).

NB: Warfarin should not be started until a therapeutic PTT has been achieved on heparin to reduce the risk of “Coumadin necrosis.” During the first ≈ 3 days of warfarin therapy, patients are actually <u>hypercoagulable</u> (secondary to reduction of vitamin-K dependent anticoagulation factors protein C and protein S), therefore, continue heparin during the first few days.

Supplied: scored tabs of 1, 2, 2.5, 5, 7.5 and 10 mg. IV form: 5mg/vial.

Table 3-5 Recommended INRs[29]

Indication	INR
• mechanical prosthetic heart valve • prevention of recurrent MI	2.5-3.5
antiphospholipid antibody syndrome[30] (*see page 1025*)	≥ 3
all other indications (DVT prophylaxis and treatment, PE, atrial fibrillation, recurrent systemic embolism, tissue heart valves)	2-3

heparin DRUG INFO

Rx: administered as IV drip or sub-Q bolus. To anticoagulate average weight patient, give 5000 U bolus IV, follow with 1000 U/hr IV drip. Titrate to therapeutic anticoagulation of APTT = 2-2.5 **x** control (for DVT, some recommend 1.5-2 **x** control[31]).

Rx low-dose ("mini-dose") heparin: 5000 IU SQ q 8 or 12 hrs. Routine monitoring of APTT is usually not done, although occasionally patients may become fully anticoagulated on this regimen.

Side effects: (see *Anticoagulant considerations in neurosurgery* above): hemorrhage, thrombosis[32] (heparin activates anti-thrombin III and can cause platelet aggregation) which can result in MIs, CVAs, DVTs, PEs, etc. Heparin induced thrombocytopenia (HIT): transient mild thrombocytopenia is fairly common in the first few days after initiating heparin therapy, however severe thrombocytopenia occurs in 1-2% of patients receiving heparin > 4 days (usually has a delayed onset of 6-12 days, and is due to consumption in heparin-induced thrombosis or to antibodies formed against a heparin-platelet protein complex). The incidence of HIT in SAH is 5-6% and was similar with enoxaparin[33]. Consider use of lepirudin (*see below*) in thrombocytopenic patients. Chronic therapy may cause osteoporosis.

dabigatran (Pradaxa®) DRUG INFO

An oral anticoagulant in the class of direct thrombin inhibitors.

Administered as the prodrug dabigatran etexilate. Must be stopped 24 hrs prior to surgery.

LOW MOLECULAR WEIGHT HEPARINS[34, 35]

Low molecular weight heparins **(LMWH)** (average molecular weight = 3000-8000 daltons) are derived from unfractionated heparin (average MW = 12,000-15,000 daltons). LMWHs differ from unfractionated heparin because they have a higher ratio of anti-factor Xa to anti-factor IIa (antithrombin) activity which theoretically should produce anti-thrombic effects with fewer hemorrhagic complications. Realization of this benefit has been very minor in clinical trials. LMWH have greater bioavailability after sub-Q injection leading to more predictable plasma levels which eliminates the need to monitor biologic activity (such as APTT). LMWH have a longer half-life and therefore require fewer doses per day. LMWH have a lower incidence of thrombocytopenia. More effective in DVT prophylaxis than warfarin in orthopedic surgery[36].

Spinal epidural hematomas: There have been a number of case reports of spinal epidural hematomas occurring in patients on LMWH (primarily enoxaparin) who also underwent spinal/epidural anesthesia or lumbar puncture, primarily in elderly women undergoing orthopedic surgery. Some have had significant neurologic sequelae, including permanent paralysis[37]. The risk is further increased by the use of NSAIDs, platelet inhibitors, or other anticoagulants, and with traumatic or repeated epidural or spinal puncture.

Reversal of anticoagulation: Protamine sulfate may be used (*see page 41*).

Available low molecular weight heparins

Drugs include:

- enoxaparin (Lovenox®): *see below*
- dalteparin (Fragmin®): ***Rx*** 2500 anti-Xa U SQ q d
- ardeparin (Normiflo®): half-life = 3.3 hrs. ***Rx*** 50 anti-Xa U/kg SQ q 12 hrs
- danaparoid (Orgaran®): a heparinoid. Even higher anti-Xa:anti-IIa ratio than LMWHs. Does not require laboratory monitoring. ***Rx*** 750 anti-Xa U SQ BID
- tinzaparin (Logiparin®, Innohep®): not available in U.S. ***Rx*** 175 anti-Xa U per kg SQ once daily
- fondaparinux (Arixta®): *see below*

• lepirudin (Refludan®): *see below*
• bivalirudin: *see below*

enoxaparin (Lovenox®) DRUG INFO

Rx dosage established following hip replacement is 30 mg SQ BID **x** 7-14 days (alternative: 40 mg SQ q d). **Pharmacokinetics:** After SQ injection, peak serum concentration occurs in 3-5 hrs. Half-life: 4.5 hrs.

lepirudin (Refludan®) DRUG INFO

A direct thrombin inhibitor which blocks the thrombogenic activity of thrombin, and, unlike heparin, also acts on clot-bound thrombin. It is FDA approved for anticoagulation in patients with heparin-induced thrombocytopenia[38].

Rx: loading dose of 0.4 mg/kg (up to 44 mg) IV, followed by continuous infusion of 0.15 mg/kg/hr for 2-10 days. The dose is titrated to a target aPTT ratio of 1.5-2.5. **Supplied**: 1 ml vials containing 50 mg.

bivalirudin DRUG INFO

Directly inhibits thrombin and increases rapidity of plasminogen activator-mediated recanalization. No effective reversal.

Rx: IV loading dose of 0.5 mg/kg IV, followed by continuous infusion of 1.75 mg/kg/hr. Intraarterial: inject 15 mg in 10 ml of heparinized saline via a microcatheter.

Factor Xa inhibitors

fondaparinux (Arixtra®) DRUG INFO

A synthetic analog of the pentasaccharide binding sequence of heparin. Increases factor Xa inhibition without affecting factor IIa (thrombin)[39]. Unfractionated & LMW can cause immune-mediated heparin-induced thrombocytopenia **(HIT)**. Fondaparinux has not caused HIT. May be more

effective than enoxaparin (Lovenox®) for preventing postop DVTs. **SIDE EFFECTS:** Bleeding is the most common side effect (may be increased by concurrent NSAID use). ✖ Contraindicated with severe renal impairment.

Rx: 2.5 mg SQ injection q d. **SUPPLIED**: 2.5 mg single-dose syringes. **PHARMACOKINETICS:** Peak activity occurs in 2-3 hrs. Elimination: in urine. Half-life: 17-21 hrs.

3.2.2.2. Coagulopathies

CORRECTION OF COAGULOPATHIES OR REVERSAL OF ANTICOAGULANTS

For recommended normal values for coagulation studies in neurosurgery, *see page 37*.

Platelets

See page 34 for indications and administration guidelines.

Fresh frozen plasma

To reverse warfarin anticoagulation, use the following as a starting point and recheck PT/PTT afterwards:

- when patient is “therapeutically anticoagulated” start with 2-3 units FFP (approximately 15 ml/kg is usually needed)
- for severely prolonged PT/PTT, start with 6 units FFP

Prothrombin complex concentrate

Warfarin induced anticoagulation may be reversed up to 4 or 5 times more quickly with prothrombin complex concentrate **(PCC)** (contains coagulation factors II, IX, and X) than with FFP[40]. Patient may become hyperthrombotic with this.

vitamin K (Aquamephyton®) **DRUG INFO**

To reverse elevated PT from warfarin, give aqueous colloidal solution of vitamin K_1 (phytonadione, Aquamephyton®). Doses > 10 mg may produce warfarin resistance for up to 1 week. FFP may be administered concurrently for more rapid correction (*see above*). For recommended levels of PT, *see*

page 37.

***Rx* adult**: start with 10-15 mg IM; the effect takes 6-12 hrs (in absence of liver disease). Repeat dose if needed. The average total dose needed to reverse therapeutic anticoagulation is 25-35 mg.

IV administration has been associated with severe reactions (possibly anaphylactic), including hypotension and even fatalities (even with proper precautions to dilute and administer slowly), therefore IV route is reserved only for situations where other routes are not feasible and the serious risk is justified. ***Rx* IV** (when IM route not feasible): 10-20 mg IV at a rate of injection not to exceed 1 mg/min (e.g. put 10 mg in 50 ml of D5W and give over 30 minutes).

protamine sulfate DRUG INFO

For **heparin**: 1 mg protamine reverses ≈ 100 U heparin (give slowly, not to exceed 50 mg in any 10 min period). Therapy should be guided by coagulation studies.

Low molecular weight heparins (LMWH): slow IV injection of a 1% solution of protamine can also be used to reverse LMWHs as follows:

Enoxaparin (Lovenox®): ≈ 60% of Lovenox can be reversed with 1mg of protamine for every mg of Lovenox given (maximum dose = 50 mg) within the last 8 hrs, and 0.5 mg of protamine for every mg of Lovenox given from 8-12 hrs prior. Protamine is probably not needed for Lovenox given > 12 hrs earlier.

Dalteparin (Fragmin®) or **ardeparin** (Normiflo®): 1 mg of protamine for every 100 anti-Xa IU of the LMWH (maximum dose = 50 mg) with a second infusion of 0.5 mg protamine for every 100 anti-Xa IU of LMWH if the APTT remains elevated 2-4 hours after the first dose is completed.

Danaparoid and Hirudin: no known reversing agent.

desmopressin (DDAVP®) DRUG INFO

Causes an increase in factor III coagulant activity and von Willebrand factor which helps coagulation and platelet activity in hemophilia A and in von Willebrand's disease Type I (where the factors are normal in makeup but low in concentration, ✖ but may cause thrombocytopenia in von Willebrand's disease Type IIB where factors may be ab-normal or missing).

Rx 0.3 mcg/kg (use 50 ml of diluent for doses $\leq$ 3 mcg, use 10 ml for doses > 3 mcg) given over 15-30 minutes 30 minutes prior to a surgical procedure.

Elevated pre-op PTT

In a patient with no history of coagulopathy, a significantly elevated pre-op PTT is commonly due to either a factor deficiency or to lupus anticoagulant. Work-up:

1. mixing study
2. lupus coagulant

If the mixing study corrects the elevated PTT, then there is probably a factor deficiency. Consult a hematologist.

Lupus anticoagulant: If the test for lupus anticoagulant is positive, then the major risk to the patient with surgery is not bleeding, rather it is thromboembolism. Management recommendations:

1. as soon as feasible post-op, start patient on heparin (*see page 39*) or LMW heparin (*see page 39*), e.g. Lovenox
2. at the same time start warfarin, and maintain therapeutic anticoagulation for 3-4 weeks (the risk of DVT/PE is actually highest in the first few weeks post-op)
3. mobilize as soon as possible post-op
4. consider vena-cava interruption filter in patients for whom anticoagulation is contraindicated

THROMBOEMBOLISM IN NEUROSURGERY

Deep-vein thrombosis (DVT) is of concern primarily because of the potential for material (clot, platelet clumps…) to dislodge and form emboli (including pulmonary emboli, **(PE)**) which may cause pulmonary infarction, sudden death (from cardiac arrest), or cerebral infarction (from a paradoxical embolus, which may occur in the presence of a patent foramen ovale, see *Cardiogenic brain embolism*, page 1022). The reported mortality from DVT in the LEs ranges from 9-50%[41]. DVT limited to the calf has a low threat (< 1%) of embolization, however, these clots later extend into the proximal deep veins in 30-50% of cases[41], from where embolization may occur (in 40-50%), or they may produce postphlebitic syndrome.

Neurosurgical patients are particularly prone to developing DVTs (estimated risk: 19-50%) due at least in part to the relatively high frequency of the following:

1. long operating times of some procedures
2. prolonged bed rest pre- and/or post-op
3. paralyzed limbs (e.g. in spinal cord injuries or stroke patients)
4. alterations in coagulation status
   A. in patients with brain tumors (*see below*) or head injury[42]
      1. related to the condition itself
      2. due to release of brain thromboplastins during brain surgery
   B. increased blood viscosity with concomitant "sludging"
      1. from dehydration therapy sometimes used to reduce cerebral edema
      2. from volume loss following SAH (cerebral salt wasting)
   C. use of high-dose glucocorticoids

Specific "neurological" risk factors for DVT and PE include[41]:

1. spinal cord injury (*see* *page 937*)
2. brain tumor: autopsy prevalence of DVT = 28%, of PE = 8.4%. Incidence using 125Ifibrinogen[43]: meningioma 72%, malignant glioma 60%, metastasis 20%. Risk may be reduced by pre-op use of aspirin[44]
3. subarachnoid hemorrhage
4. head trauma: especially severe TBI (*see* *page 907*)
5. stroke: incidence of PE = 1-19.8%, with mortality of 25-100%
6. neurosurgical operation: risk is higher following craniotomy for supratentorial tumors (7% of 492 patients) than p-fossa tumors (0 out of 141)[45]

Prophylaxis against DVT

Options include:

1. general measures
   A. passive range of motion
   B. ambulate appropriate patients as early as possible
2. mechanical techniques (minimal risk of complications):
   A. pneumatic compression boots[46] **(PCBs)** or sequential compression devices **(SCDs)**: reduces the incidence of DVTs and probably PEs. Do not use if DVTs already present. Continue use until patient able to

walk 3-4 hrs per day

B. TED Stockings®[A]: **(TEDS)** applies graduated pressure, higher distally. As effective as PCB. No evidence that the benefit is additive[41]. Care should be taken to avoid a tourniquet effect at the proximal end

C. electrical stimulation of calf muscles

D. rotating beds

3. anticoagulation[B]

A. full anticoagulation is associated with perioperative complications[47]

B. "low-dose" anticoagulation[48] (low-dose heparin): 5000 IU SQ q 8 or 12 hrs, starting 2 hrs pre-op or on admission to hospital. Potential for hazardous hemorrhage within brain or spinal canal has limited its use

C. low molecular weight heparins and heparinoids (*see page 39*): not a homogeneous group. Efficacy in neurosurgical prophylaxis has not been determined

D. aspirin: role in DVT prophylaxis is limited because ASA inhibits platelet aggregation, and platelets play only a minor role in DVT

4. combination of PCBs and "mini-dose" heparin starting on the morning of post-op day 1 (with no evidence of significant complications)[49]

A. TEDS® is a registered trademark. "TED" stands for thromboembolic disease

B. for contraindications and considerations of anticoagulation in neurosurgery, *see page 36*

Recommendations

Recommended prophylaxis varies with the risk of developing DVT, as illustrated in *Table 3-6*[41]. Also *see page 937* for details of prophylaxis in cervical spinal cord injuries.

Diagnosis of DVT

The clinical diagnosis of DVT is very unreliable. A patient with the "classic signs" of a hot, swollen, and tender calf, or a positive Homans' sign (calf pain on dorsiflexion of the ankle) will have a DVT only 20-50% of the time[41]. 50-60% of patients with DVT will not have these findings.

Table 3-6 Risk & prophylaxis of DVT in neurosurgical patients*

Risk group	Estimated risk of calf DVT	Typical neurosurgical patients	Treatment recommendation
low risk	< 10%	age < 40 yrs, minimal general risk factors, surgery with < 30 minutes general anesthesia	no prophylaxis, or PCB/TEDS
moderate risk	10-40%	age ≥ 40 yrs, malignancy, prolonged bed rest, extensive surgery, varicose veins, obesity, surgery > 30 minutes duration (except simple lumbar discectomy), SAH, head injury	PCB/TEDs; or for patients without ICH or SAH, minidose heparin
high risk	40-80%	history of DVT or PE, paralysis† (para- or quadriplegia or hemiparesis), brain tumor (especially meningioma or malignant glioma)	PCB/TEDS + (in patients without ICH or SAH) minidose heparin

* abbreviations: DVT = deep venous thrombosis, PCB = pneumatic compression device, TEDS = TED (thromboembolic disease) Stockings®, ICH = intracerebral hemorrhage, SAH = subarachnoid hemorrhage

† *see page 937* for specifics regarding DVT prophylaxis in cervical SCI

Laboratory tests

- contrast venography: the "gold standard", however it is invasive and carries risk of iodine reaction, occasionally produces phlebitis, not readily repeated
- Doppler ultrasound with B-mode imaging: 95% sensitive and 99% specific for proximal DVT. Less effective for calf DVT[50]. May be used in immobilized or casted LE (unlike IPG). Widely accepted as the non-invasive test of choice for DVT[51]
- impedance plethysmography **(IPG)**: looks for reduced electrical impedance produced by blood flow from the calf following relaxation of a pneumatic tourniquet. Good in detecting proximal DVT, not sensitive for calf DVT. A positive study indicates DVT that should be treated, a negative study can occur with non-occlusive DVT or with good collaterals, and should be repeated over a 2 week period
- 125I-fibrinogen: radiolabeled fibrinogen is incorporated into the developing thrombus. Better for calf DVT than proximal DVT. Expensive, and many false positives. Risk of HIV transmission has resulted in withdrawal of use
- **D-dimer** (a specific fibrin degradation product): high levels are associated with DVT and PE[52]

Treatment of DVT

1. bed rest, with elevation of involved leg(s)
2. unless anticoagulation is contraindicated (*see page 36*), start heparin (as outlined in *Anticoagulation* on page 36, aim for APTT = 1.5-2 **x** control) or fixed dose of LMW heparinoids (e.g. tinzaparin (Logiparin®[53], or in the U.S. enoxaparin (Lovenox®) *see page 40*): simultaneously initiate warfarin therapy. Heparin can be stopped after ≈ 5 days[54]
3. in patients where anticoagulation is contraindicated, consider inferior vena cava interruption or placement of a filter (e.g. Greenfield filter)
4. in non-paralyzed patients, cautiously begin to ambulate after ≈ 7-10 days
5. wear anti-embolic stocking on affected LE indefinitely (limb is always at risk of recurrent DVT)

3.2.3. Extramedullary hematopoiesis

In chronic anemias (especially thalassemia major, AKA Cooley's anemia), low hematocrit results in chronic over-stimulation of bone marrow to produce RBCs. This results in systemic bony abnormalities, cardiomyopathy (due to hemochromatosis caused by increased breakdown of defective RBCs).

Pertinent to the CNS, there are three sites where extramedullary hematopoiesis **(EMH)** can cause findings:

- skull: produces "hair-on-end" appearance on skull x-ray
- vertebral bodies: may result in epidural cord compression[55] (*see below*)
- choroid plexus

Epidural cord compression from EMH

The exuberant tissue is very radiosensitive, however, the patient may be somewhat dependent on the hematopoietic capacity of the tissue.

Treatment

Surgical excision followed by radiation therapy has been the recommended treatment. Repeated blood transfusions may help reduce EMH and may be useful post-op instead of RTX except for refractory cases[55].

Surgery on these patients is difficult because of:

1. low platelet count
2. poor condition of bone

3. cardiomyopathy: increased anesthetic risk
4. anemia, coupled with the fact that most of these patients are "iron-toxic" from multiple previous transfusions
5. total removal of the mass is not always possible

3.3. Pharmacology

3.3.1. Analgesics

For a discussion of types of pain and pain procedures, *see page 548*.

GENERAL PRINCIPLES

The key to good pain control is the early use of adequate levels of effective analgesics. For cancer pain, scheduled dosing is superior to PRN dosing, and "rescue" medication should be available[56]. Nonopioid analgesics should be continued as more potent medications and invasive techniques are utilized.

ANALGESICS FOR SOME SPECIFIC TYPES OF PAIN

Visceral or deafferentation pain

May sometimes be effectively treated with tricyclic antidepressants (*see page 50*) or with anticonvulsant class drugs (gabapentin or pregabalin - *see page 50*).

Tryptophan may be effective (*see page 50*).

Carbamazepine (Tegretol®) may be useful for paroxysmal, lancinating pain.

Pain from metastatic bone disease

Steroids, aspirin, or NSAIDs are especially helpful, probably by reducing prostaglandin mediated sensitization of A-delta and C fibers, and therefore may be preferred to acetaminophen.

3.3.1.1. Nonopioid analgesics

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

The anti-inflammatory properties of NSAIDs is primarily due to inhibition of the enzyme cyclooxygenase **(COX)** which participates in the synthesis of prostaglandins and thromboxanes[57].

Characteristics of nonselective nonsteroidal anti-inflammatory drugs:

- all are given orally except ketorolac tromethamine (Toradol®) (*see below*)
- no dependence develops
- additive effect improves the pain relief with opioid analgesics
- NSAIDs (and APAP) demonstrate a **ceiling effect**: a maximum dose above which no further analgesia is obtained. For aspirin and APAP, this is usually between 650-1300 mg, and is often higher for other NSAIDs which may also have a longer duration of action
- risk of GI upset is common, more serious risks of hepatotoxicity[58], or GI ulceration, hemorrhage, or perforation are less common
- taking medication with meals or antacids has not been proven effective in reducing GI side effects. **Misoprostol** (Cytotec®), a prostaglandin, may be effective in mitigating NSAID-induced gastric erosion or peptic ulcer. Contraindicated in pregnancy. ***Rx*** 200 mcg PO QID with food as long as patient is on NSAIDs. If not tolerated, use 100 mcg. ✖ CAUTION: an abortifacient. Should not be given to pregnant women or women of childbearing potential
- most reversibly inhibit platelet function and prolong bleeding time (nonacetlyated salicylates have less antiplatelet action, e.g. salsalate, trisalicylate, nabumetome). Aspirin, unlike all other NSAIDS, irreversibly binds to cyclooxygenase and thus inhibits platelet function for the 8-10 day life of the platelet
- all cause sodium and water retention and carry the risk of NSAID-induced nephrotoxicity[59] (renal insufficiency, interstitial nephritis, nephrotic syndrome, hyperkalemia)

Table 3-7 Nonsteroidal anti-inflammatory drugs (NSAIDs)

Generic name	Proprietary (®)	Typical adult oral dose*	Tabs/caps availability (mg)†	Daily maximum (mg)
aspirin‡	(many)	500-1000 mg PO q 4-6 hrs (ceiling dose ≈ 1 gm)	325, 500	4000
bromfenac[60]	Duract	25 mg PO q 6-8 hrs on empty stomach up to 10 d	25	150
diclofenac	Voltaren, Cataflam	start at 25 mg QID; additional dose q hs PRN; increase up to 50 mg TID or QID, or 75 mg BID	25, 50, 75	200
diflunisol	Dolobid	1000 mg initial; then 500 mg BID	250, 500	1500
etodolac	Lodine	for acute pain: 200-400 mg q 6-8 hrs	200, 300 caps, 400 tabs	1200
fenoprofen	Nalfon	200 mg q 4-6 hrs; for rheumatoid arthritis 300-600 mg TID-QID	200, 300, 600	3200
flurbiprofen	Ansaid	50 mg TID-QID or 100 mg TID	50, 100	300
ketoprofen	Orudis	start at 75 mg TID or 50 mg QID, ↑to 150-300 mg daily DIV TID-QID	25, 50, 75	300
	Oruvail	extended release capsule 150 mg q d	ER† 150	
ketorolac	Toradol	*see below*	*see below*	
ibuprofen§	Motrin	400-800 mg QID (ceiling dose: 800 mg)	300, 400, 600, 800	3200
indomethacin	Indocin	25 mg TID, ↑ by 25 mg total per day PRN	25, 50, SR 75	150-200
meclofenamate	Meclomen	50 mg q 4-6 hrs; ↑ to 100 mg QID if needed	50, 100	400
mefenamic	Ponstel	500 mg initial; then 250 mg q 6 hrs	250	
nabumetomeΔ	Relafen	1000-2000 mg/d given in 1 or 2 doses	500, 750	2000
naproxen	Naprosyn	500 mg, then 250 mg q 6-8 hrs	250, 375, 500	<1250
naproxen sodium	Anaprox	550 mg, followed by 275 mg q 6-8 hrs	275, DS = 550	1375
oxaprozin	Daypro	1200 mg q d (1st day may take 1800)	600	1800
phenylbutazone	Butazolidin	high incidence of agranulocytosis. Not first DOC, and not a simple analgesic		
piroxicam	Feldene	10-20 mg q d (steady state takes 7-12 d)	10, 20	
sulindac	Clinoril	200 mg BID; ↓ to 150 BID when pain controlled	150, 200	400
salsalate	Disalcid	3000 mg divided BID-TID (e.g. 500 mg 2-tabs TID)	500, 750	
tolmetin	Tolectin	400 mg TID (bioavailability is reduced by food)	200, DS = 400, 600	1800
trisalicylate	Trilisate	2000-3000 mg/d usually divided BID (but may be divided TID)	500, 750, 1000, liquid 500mg/5ml	

* when dosage ranges are given, use the smallest effective dose

† abbreviations: DS = double strength; SR = slow release; ER = extended release; DOC = drug of choice

‡ aspirin: has unique effectiveness in pain from bone metastases

§ ibuprofen: is available as a suspension (PediaProfen®) 100 mg/ml; dose for children 6 mos to 12 yrs age is 5-10 mg/kg with a maximum of 40 mg/kg/day (not FDA approved for children because of possible Reye's syndrome)

Δ unlike most NSAIDs, nabumetome does not interfere with platelet function

ketorolac tromethamine (Toradol®) DRUG INFO

The only parenteral NSAID approved for use in pain control in the U.S. Analgesic effect is more potent than anti-inflammatory effect. Half-life ≈ 6 hrs. May be useful to control pain in the following situations:

1. where the avoidance of sedation or respiratory depression is critical

2. when constipation cannot be tolerated
3. for patients who are nauseated by narcotics
4. where narcotic dependency is a serious concern
5. when epidural morphine has been used and further analgesia is needed without risk of respiratory depression (agonist type narcotics are contraindicated)
6. cautions:
   A. not indicated for use > 72 hrs (complications have been reported primarily with prolonged use of the oral form)
   B. use with caution in postoperative patients since (as with most NSAIDs) bleeding time is prolonged by platelet function inhibition (risk of GI or opsite hemorrhage is small, but is increased in patients > 75 yrs old, when used > 5 days, and when used in higher doses[61])
   C. even though IM dosing circumvents the GI system, gastric mucosal irritation and erosions may occur as with all NSAIDs (avoid use with PUD)
   D. as with all NSAIDs, use with caution in patients at risk for renal side effects

***Rx* Parenteral:** For single dose administration: 30 mg IV or 60 mg IM in healthy adult. For multiple dosing: 30 mg IV or IM q 6 hrs PRN. Maximum dosage: 120 mg/day. Parenteral use should not exceed 5 days (3 days may be a better guideline).

For patient weight < 50 kg, age > 65 yrs, or reduced renal function (creatinine clearance < 50 ml/min), all of the above dosages are halved (max daily dose: 60 mg). Creatinine clearance can be estimated using the Cockcroft-Gault equation[62] (*Eq 3-1*), with normal values ≥ 60 ml/min.

$$\text{Creatinine clearance (ml/min)} = \frac{[140 - \text{age (years)}] \times \text{ideal wt (kg)}}{72 \times \text{serum creatinine (mg/dl)}} \times (0.85 \text{ for females}) \qquad \textbf{Eq 3-1}$$

***Rx* PO:** Indicated only as a continuation of IV or IM therapy, not for routine use as an NSAID. Switching from IM to PO: start with 10 mg PO q 4-6 hrs (combined PO and IM dose should be ≤ 120 mg on the day of transition). **SUPPLIED**: 10 mg tablets.

ACETAMINOPHEN

Table 3-8 Acetaminophen dosing

Medication	Dosage
acetaminophen **(APAP)** (Tylenol®)	adult dose: 650 or 1000 mg PO/PR q 4-6 hrs, not to exceed 4000 mg/day* lpediatric dose: infants: 10-15 mg/kg PO/PR q 4-6 hrs children: 1 grain/yr age (= 65 mg/yr up to 650 mg) PO/PR q 4-6 hrs not to exceed 15 mg/kg q 4 hrs

* hepatic toxicity from APAP: usually with doses ≥ 10 gm/day, rare at doses < 4000 mg. However, may occur at lower doses (even at high therapeutic doses) in alcoholics, fasting patients, and those taking cytochrome P-450 enzyme-inducing drugs

3.3.1.2. Opioid analgesics

Narcotics are most commonly used for moderate to severe acute pain or cancer pain (some experts characterize cancer pain as recurrent acute pain and not chronic pain).

Characteristics of narcotics:

- <u>no</u> **ceiling effect** (*see page 45*): i.e. increasing dosage increases the effectiveness (although with weak opioids for moderate pain, side effects may limit dosages to relatively low levels[56])
- with chronic use, tolerance develops (physical and psychological)
- overdose possible, with the potential for respiratory depression with all, and seizures with some (*see page 275*)

MILD TO MODERATE PAIN

Some useful medications are shown in *Table 3-9*.

Table 3-9 Weak opioids for mild to moderate pain

Medication	Dosage
codeine	usual adult dose: 30-60 mg IM/PO q 3 hrs PRN; use with caution in nursing mothers (30 mg PO is equivalent to 300 mg aspirin) pediatric dose: 0.5-1 mg/kg/dose q 4-6 hrs PO or IV PRN
propoxyphene (Darvon®…)	usually used as propoxyphene napsylate with acetaminophen (Darvocet-N)* Darvocet-N 100 ***Rx***: 1-2 PO q 4-6 hrs PRN
pentazocine (Talwin®, Talwin® Nx, Talacen®)	pentazocine is a mixed agonist-antagonist
	→ 12.5 mg pentazocine, 325 mg ASA. ***Rx***: 2 PO TID-QID PRN
	→ 50 mg pentazocine, 0.5 mg naloxone. ***Rx***: 1-2 PO q 3-4 hrs PRN up to 12 tabs/day

	→ 25 mg pentazocine, 650 mg APAP. ***Rx***: 1 PO q 4-6 hrs PRN up to 6 tabs/day
tramadol (Ultram®)	(*see below*)

* *CAUTION: propoxyphene can cause dangerous elevations of carbamazepine levels*

Codeine and its congeners, propoxyphene and pentazocine, are usually no more effective that ASA or APAP and are usually combined with these drugs.

tramadol (Ultram®) DRUG INFO

An oral opioid agonist that binds to μ-opioid receptors, and is also a centrally acting analgesic that inhibits reuptake of norepinephrine and serotonin. For acute pain, 100 mg is comparable to codeine 60 mg with ASA or APAP[63, 64]. There has been no report of respiratory depression when oral dosing recommendations are followed. Seizures and opioid-like dependence have been reported[64].

Rx 50 to 100 mg PO q 4-6 hrs PRN pain up to a maximum of 400 mg/day (or 300 mg/d for older patients). For moderately severe acute pain, an initial dose of 100 mg followed by 50 mg doses may suffice. **SUPPLIED**: 50 mg tabs.

MODERATE TO SEVERE PAIN

Table 3-10 Opioids for moderate to severe pain

Medication	Dosage
hydrocodone	(Vicodin®, Lorcet®, Lortab®...): 5 mg hydrocodone + 500 mg acetaminophen; (Vicodin ES®, Lortab 7.5/500®): 7.5 mg hydrocodone + 500 mg APAP; ***Rx*** 1 PO q 6 hrs PRN (may increase up to 2 tabs PO q 3-4 hrs not to exceed 8 pills/24 hrs).
	(Lorcet® Plus, Lorcet® 10/650): 7.5 or 10 mg hydrocodone (respectively) + 650 mg APAP; ***Rx*** 1 tab PO q 6 hrs PRN (not to exceed 6 tabs in 24 hrs).
	(Lortab® 10/500: 10 mg. hydrocodone + 500 mg APAP); ***Rx***: 1-2 PO q 4 hrs PRN up to 6 tabs/day.
	(Norco®): 10 mg hydrocodone + 325 mg APAP scored tabs; ***Rx***: 1 PO q 4 hrs PRN up to 6 tabs/day.
hydromorphone	Dilaudid®: (*see Table 3-11*)
morphine	used in low doses (*see Table 3-11*)
levorphanol	Levo-Dromoran®: 2 mg IM ≈ 10 mg morphine; long half-life (*see Table 3-11*)

oxycodone	**Supplied**: usually available in combination as: aspirin 325 mg with oxycodone 5 mg (Percodan®) or acetaminophen (APAP) (Tylox® = APAP 500 mg + oxycodone 5 mg) (Percocet® = oxycodone/APAP in 2.5/325, 5/325, 7.5/500, 10/650) dose: 1 PO q 3-4 hrs PRN (may increase up to 2 PO q 3 hrs*) **Supplied**: also available alone as **OxyIR**® 5 mg, OxyFast® oral solution of 20 mg/ml, or in controlled-release tablets as **OxyContin**® 10, 20, 40, 80† & 160† mg (which last 12 hours, achieving steady state in 24-36 hours). ***Rx*** Adult: OxyContin® tablets are taken whole and are not to be divided, chewed or crushed. It is intended for management of moderate to severe pain when continuous around-the-clock analgesic is needed for an extended period of time and is not intended for use as a PRN analgesic. For opiate naive patients, start with 10 mg PO q 12 hrs. For patients on narcotic medications, a conversion table is provided below for some medications. Titrate dose every 1-2 days, increasing dose by 25-50% q 12 hrs.

Conversion table for starting OxyContin®

Preparation currently being used	Dose	Suggested starting dose of OxyContin®
oxycodone combination pills (Tylox, Percodan…) or Lortab, Vicodin or Tylenol #3	1-5 pills/day	10-20 mg PO q 12 hrs
	6-9 pills/day	20-30 mg PO q 12 hrs
	10-12 pills/day	30-40 mg PO q 12 hrs
IV PCA morphine	determine total MSO4 dose used per 24 hrs	multiply total MSO4 dose in 24 hrs X 1.3 for total OxyContin dose in 24 hrs

* not to exceed 4000 mg of acetaminophen/24 hrs (see footnote to *Table 3-8* on *page 46*)

† for use only in opioid-tolerant patients

Severe pain

Table 3-11 Equianalgesic doses for SEVERE pain, AGONIST opioids*

Drug name: generic (proprietary®)	Route	Dose (mg)	Peak (hrs)	Duration (hrs)	Comments
morphine	IM	10	0.5-1	4-6	respiratory depression
	PO	20-60†	1.5-2	4-7	long acting PO forms: MS Contin®, Avinza® (*see below*)
codeine (not recommended at these doses)	IM	130		3-5	these high doses cause unacceptable side effects
	PO	200			
meperidine‡ (Demerol®)	IM	75	0.5-1	4-5	avoid prolonged use‡, irritating to tissues
	PO	300-400	1-2	4-6	
methadone§ (Dolophine®)	IM	10	0.5-1	4-6	long half-life§
	PO	20	1.5-2	4-7	
levorphanol§ (Levo-Dromoran®)	IM	1.5-2.5		4-6	long half-life§
	PO	2-4			
oxycodone	IM	15			
(e.g. Tylox®Δ)	PO	30	1	3-4	combination (Tylox®) or liquid
(OxyContin®)	PO	30-40		12	*see Table 3-10*
oxymorphone (Numorphan®)	IM	1		3-5	available as suppository
	PR	10			
hydromorphone (Dilaudid®)	IM	1.5	0.5-1	3-4	
	PO	7.5	1.5-2	3-4	supplied: 1, 2, 3, & 4 mg tabs
fentanyl (Sublimaze®)	IV	0.1		1-2	not recommended for acute pain control, esp. in narcotic naive pts.
transdermal fentanyl patch (Duragesic®)¶	transdermal	**	12-24	72	patches of 25, 50, 75, 100 or 125 mcg/hr (use lowest effective)

* parenteral route is referenced to 10 mg IM morphine

† IM:PO potency ratio for morphine is 1:6 for single doses, but changes to 1:2-3 with chronic dosing

‡ high doses or long-term use is not recommended because meperidine is metabolized to nor-meperidine, a stimulant with a 15-20 hour half-life, that may accumulate and cause agitation or other CNS hyperactivity (including delerium and seizures), may also manifest when given agonist/antagonist drugs. Meperidine may also cause severe encephalopathy and death when given with MAOIs

§ due to long half-life, repeated dosing can lead to accumulation and CNS depression (must reduce dose after ≈ 3 days, even though the analgesic half-life does not change), especially in the elderly or debilitated patient. Use should be limited to physicians with experience using these drugs

Δ may not be practical for use in severe pain since 1 Tylox® contains only 5 mg oxycodone (the acetaminophen limits the dosage), may use OxyContin® for higher doses of oxycodone

¶ ✖ should not be used as routine post-op analgesic (risk of respiratory depression). Apply 1 patch to upper torso, replace q 72 hrs PRN.

** conversion from total daily parenteral morphine as follows:

8-27 mg MSO4/day	Duragesic 25 mcg/hr
28-37 mg MSO4/day	Duragesic 50 mcg/hr
38-52 mg MSO4/day	Duragesic 75 mcg/hr
53-67 mg MSO4/day	Duragesic 100 mcg/hr
68-82 mg MSO4/day	Duragesic 125 mcg/hr

Avinza® (extended release morphine) DRUG INFO

Once daily oral morphine formulation using a spherical oral drug absorption system **(SODAS)** (numerous ammonio-methacrylate copolymer

beads, ≈ 1 mm dia.).

Rx: Dosage is titrated based on patient's opioid tolerance and degree of pain. Taken as 1 capsule p.o. q d. Not to be taken "PRN". Not for post-op pain. ✖ CAUTION: To prevent potentially fatal doses of morphine, capsules are to be swallowed whole, and are not to be chewed, crushed or dissolved. However, the contents of the capsule (the beads) may be sprinkled on applesauce for those unable to swallow the capsules, but the beads are not to be chewed or crushed. **Side effects:** Due to the potentially nephrotoxic effect of fumaric acid used in SODAS, the maximum dose of Avinza is 1600 mg/d. Doses ≥ 60 mg are for opioid tolerant patients only. **Supplied**: 30, 60, 90 & 120 mg capsules.

Palladone® (extended release hydromorphone) DRUG INFO

Once daily extended release hydromorphone HCl (immediate release forms include Dilaudid®), a semisynthetic congener of morphine and active metabolite of hydrocodone. Risk for abuse or accidental overdosage by violating capsule or concurrent use of alcohol. Recommended only for opioid tolerant patients who have failed other therapies[65].

Rx A schedule II drug. For opioid tolerant patients only, start with 12-32 mg PO q 24 hours. Titrate upward by 25-50% increments every 2-3 days PRN. ✖ Capsules are not to be opened, broken, chewed, dissolved or crushed or taken with alcohol. Do not use if severe hepatic insufficiency. **Supplied**: 12, 16, 24 & 32 mg capsules.

Table 3-12 Equianalgesic doses for SEVERE pain, AGONIST/ANTAGONIST opioids (referenced to 10 mg IM morphine)

Drug name: generic (proprietary®)	Route	Dose (mg)	Peak (hrs)	Duration (hrs)	Comments

	IV	140 mcg/kg	0.5	2-5	
pentazocine (Talwin®‡)	IM†	20-40	0.5-1	4-6	
	PO†	180 (start @ 50)	1.5-2	4-7	
dezocine (Dalgan®)	IM	10		3-6	

* all can precipitate withdrawal symptoms in patients physically dependent on agonists

† most agonist/antagonist drugs occupy sigma receptors (Stadol > Nubain), which may cause hallucinations

‡ Talwin injectable (for IM use) contains only pentazocine. Talwin® Compound tablets contain ASA, ∴ for high PO doses, use Talwin Nx which contains no ASA (see *Table 3-9*, page 47)

3.3.1.3. Adjuvant pain medications

The following may have efficacy in enhancing the effectiveness of opioid analgesics (and thereby may reduce the required dose).

Tricyclic antidepressants: *see page 548*.

Tryptophan: an amino acid and a precursor of serotonin, may work by increasing serotonin levels. Requires high doses and has hypnotic effects, therefore 1.5-2 gm given usually q hs. Must give daily MVI as chronic tryptophan therapy depletes vitamin B_6.

Antihistamines: histamines play a role in nociception. Antihistamines, which are also anxiolytic, antiemetic, and mildly hypnotic, are effective as analgesics or as adjuvants. Hydroxyzine (Atarax®, Vistaril®): ***Rx*** start with 50 mg PO q AM and 100 mg PO q hs. May increase up to ≈ 200 mg daily.

Anticonvulsant-class drugs: carbamazepine, clonazepam, phenytoin, gabapentin or pregabalin tend to be more effective in *neuropathic* pain, e.g. from diabetic neuropathy, trigeminal neuralgia, post-herpetic neuralgia, glossopharyngeal neuralgia, and neuralgias due to nerve injury or infiltration with cancer[64]. See index for entries.

Phenothiazines: some cause mild reduction in nociception. Most are tranquilizing and antiemetic. Best known for this use is fluphenazine

(Prolixin®), usually given with a tricyclic antidepressant for neuropathic pain, see *Diabetic neuropathy*, *Treatment* on page 797. Phenothiazines may reduce the seizure threshold.

Corticosteroids: in addition to the reduction of toxic effects of radiation or chemo-therapy, they may potentiate narcotic analgesics. There are also a number of nonspecific beneficial effects: increased appetite, sense of well being, antiemetic. Side effects may limit usefulness (see *Possible deleterious side effects of steroids*, page 33).

Caffeine: although it possesses no intrinsic analgesic properties, doses of 65-200 mg enhance the analgesic effect of APAP, ASA or ibuprofen in for pain including: H/A, oral surgery pain and post-partum pain.

3.3.2. Antispasmodics/muscle relaxants for LBP

chlorpromazine (Thorazine®) **DRUG INFO**

Oral centrally-acting muscle relaxants have a sedating effect on the central nervous system, and there is little evidence of any other beneficial effect. Efficacy of use in patients with acute low back problems is dubious[66] (*see page 438*). Only doses are listed below. Be familiar with approved indications and precautions. For agents used for clinically significant spasticity, *see page 537*.

cyclobenzaprine (Flexeril®) **DRUG INFO**

Rx Adult: 10 mg PO TID-QID, usually not to exceed 2-3 weeks.

methocarbamol (Robaxin®) **DRUG INFO**

Robaxisal® is a combination of methocarbamol 400 mg + ASA 325 mg.

Rx Adult oral dose: initial dose with 500 mg tabs: 3 tabs PO QID **x** 48-72 hrs, and then 2 tabs PO QID. With 750 mg tabs: 2 tabs PO QID **x** 48-72 hrs, and then 1 tab PO q 4 hrs or 2 tabs PO TID. With Robaxisal®: for severe spasm/pain start at 3 tabs QID if patient can tolerate the ASA, then drop down

to maintenance dose of 2 tabs QID.

Rx Adult IV methocarbamol: 750 mg IVPB q 6-8 hrs for severe spasms.

Supplied: Injectable 1 g in 10 ml. Oral: 500 mg tablet. Robaxin®–750 has 750 mg methocarbamol.

✖ chlorzoxazone (Parafon Forte® DSC) DRUG INFO

Due to risk of serious and possibly fatal hepatotoxicity and questionable effectiveness as a muscle relaxant, there is little indication to use this drug[67].

diazepam (Valium®) DRUG INFO

Rx Adult dose for muscle spasms: 2-10 mg PO TID-QID. Also *see page 537* for more information and for use in spasticity.

carisoprodol (Soma®) DRUG INFO

Caution: not a true muscle relaxant (more of a sedative). May produce euphoria with resulting potential for abuse.

Rx Adult: 350 mg PO TID and q hs.

Supplied: 250 & 350 mg tablets.

quinine sulfate DRUG INFO

For "night cramps". Over 70% of people > 65 yrs old experience nocturnal cramps at some time (usually in the legs, sometimes in the hands). No well-controlled trials to document effectiveness. Meta-analysis suggested that the frequency of cramps can be reduced by ≈ 25% over 2 weeks of treatment, and by more over 4 weeks, but there was no change in severity or duration[68]. Avoid in pregnancy (abortifacient). Caution: even low dose can cause TTP in sensitive patients, repeated doses can cause cinchoism (watch for tinnitus, H/A, N/V, hearing loss) 69. Rule-out uremic neuropathy before treating (*see page 800*).

Rx Adult: 200 or 300 mg PO q hs PRN (better efficacy seen with regular dosing).

3.3.3. Benzodiazepines

Also see *Sedatives & paralytics*, page 23. All are effective for treating anxiety and insomnia, and vary only in pharmacokinetics or site of metabolism. Those with shorter duration of action are less likely to sedate, but are more prone to cause rebound depression or withdrawal syndrome (may include tachycardia, HTN, tremulousness, diaphoresis, dysphoria, confusion, muscle twitching, and seizures) upon discontinuation. Those with long duration of action are more likely to result in cumulative sedation, and impairment of psychomotor and intellectual function[70]. Lower doses are used for elderly patients. May be reversed with flumazenil (*see below*).

Side effects: ventilatory depression and hypotension exacerbated by opioids, worse in patients with COPD. All contraindicated in first trimester of pregnancy (cause congenital malformations)[71].

alprazolam (Xanax®) DRUG INFO

May have antidepressant effects similar to tricyclics, with more rapid onset.

Rx Adult: start at 0.25-0.5 mg PO TID, titrate to max of 4 mg/day divided; comes in 0.25, 0.5 & 1 mg tabs.

midazolam (Versed®) DRUG INFO

3 to 4 times as potent as diazepam (Valium®). Dissolves in aqueous solution, thus less burning and phlebitis than diazepam. At physiologic pH, is lipid soluble and readily crosses BBB. Greater amnestic effect than diazepam. Excellent anticonvulsant properties. Given IM, onset occurs at 15 min, peak at 30 min, duration 1-2 hrs[72].

Rx:

1. for **conscious sedation** (slow IVP): 1-2 mg over 2 min (do not exceed 2.5 mg with initial dose), wait 2-3 mins, and repeat up to total of 0.1-0.15 mg/kg. Reduce by at least 25% if opioids are also being used or in patients > 60 yrs. To maintain sedation, repeat doses of 25% of initial. Caution:

midazolam has been associated with respiratory arrest (even in young patients). Monitor patient continuously, use extra caution in elderly

2. for IM **pre-op**: 0.07-0.08 mg/kg (5 mg/70 kg) about 1 hr pre-op.
3. for induction for general anesthesia:
   A. initial dose (slow IVP) of:
      1. for unpremedicated average adult age ≤ 55 yrs: 0.25 mg/kg
      2. > 55 yrs, ASA class I or II: 0.2 mg/kg
      3. ASA III or IV: 0.15 mg/kg
   B. to maintain: repeat 25% of initial dose.

Midazolam drip:

Dilute 50 mg midazolam in 100 cc IV fluid (only glass bottle recommended, as plastic adsorbs midazolam); start at 1-2 mg/hr and titrate to desired level of sedation.

Table 3-13 Comparisons of oral benzodiazepines
(Taken from **The Medical Letter**, Vol. 30, pp. 28, 1988, with permission)

Generic name	Proprietary	Rapidity of onset	Duration	Typical daily dose
alprazolam	Xanax®	intermediate	intermediate	0.25-0.5 mg TID
chlordiazepoxide	Librium®	intermediate	long	5-10 mg TID-QID
clorazepate	Tranxene®	rapid	long	15-60 mg/d divided
diazepam	Valium®	rapid	long	2-10 mg BID-QID
lorazepam	Ativan®	intermediate	intermediate	1 mg BID-TID
flurazepam	Dalmane®	rapid to intermediate	long	30 mg
temazepam	Restoril®	intermediate to slow	intermediate	15-30 mg

BENZODIAZEPINE REVERSAL

flumazenil (Romazicon®) DRUG INFO

Competitively inhibits benzodiazepines **(BDZ)** at receptor sites. Since duration of action is shorter than most BDZs, resedation may occur, especially with large doses of BDZs given over a long procedure. BDZ antagonism begins < 2 mins after IV dose, peaks in 6-10 mins, and lasts ≈ 60 mins. Sedation is only partially reversed in some patients. Reversal of BDZ induced respiratory depression is partial or nil[73].

Contraindicated in patients chronically treated with BDZs (for seizures or for other indications) where antagonism may provoke a withdrawal syndrome and/or seizures. May provoke a panic attack. Not approved for use in pregnancy.

Rx To reverse BDZs used for conscious sedation or general anesthesia: 0.2 mg (2 ml) IV over 15 seconds; repeat at 1 minute intervals if level of reversal is inadequate up to a maximum of 1 mg (total of 5 doses). If resedation occurs, may repeat dosing at 20 minute intervals, keeping within a maximum of 3 mg per hour. For suspected overdosage, give 0.2 mg over 30 secs, wait 30 secs, then give 0.3 mg over 30 secs at 1 minute intervals up to 3 mg or until patient arouses.

3.3.4. Acid inhibitors

Stress ulcers in neurosurgery[7]

The risk of stress ulcers **(SU)** is high in critically ill patients with CNS pathology. 17% of SUs produce clinically significant hemorrhage. CNS risk factors include intracranial pathology: brain injury (especially Glasgow Coma scale score < 9), brain tumors, intracerebral hemorrhage, SIADH, CNS infection, ischemic CVA, as well as spinal cord injury. The odds are increased with the coexistence of extra-CNS risk factors including: long-term use of steroids (usually > 3 weeks), burns > 25% of body surface area, hypotension, respiratory failure, coagulopathies, renal or hepatic failure and sepsis.

CNS pathology, especially that involving the diencephalon or brain stem, can lead to reduction of vagal output which leads to hypersecretion of gastric acid and pepsin. There is a peak in acid and pepsin production 3-5 days after CNS injury.

Prophylaxis for stress ulcers

There is strong evidence that reduction of gastric acid (whether by antacids or agents that inhibit acid secretion) reduces the incidence of GI bleeding from stress ulcers in critically ill patients. Elevating gastric pH > 4.5 also inactivates pepsin.

Other therapies that don't involve alterations of pH that may be effective include sucralfate and enteral nutrition (controversial)[7]. Titrated antacids or sucralfate appear to be superior to H_2 antagonists in reducing the incidence of SUs.

Routine prophylaxis when steroids are used is not warranted unless one of the following risk factors are present: prior PUD, concurrent use of NSAIDs,

hepatic or renal failure, malnourishment, or prolonged steroid therapy > 3 weeks.

NOTES

4. Neurology

4.1. Dementia

Definition: loss of intellectual abilities previously attained (memory, judgement, abstract thought, and other higher cortical functions) severe enough to interfere with social and/or occupational functioning[1]. Memory deficit is the cardinal feature, however, the DSM-IV definition requires impairment in at least one other domain (language, perception, visuospatial function, calculation, judgement, abstraction, problem-solving skills). Affects 3-11% of community-dwelling adults > 65 yrs of age, with a greater presence among institutionalized residents[2].

Risk factors: advanced age, family history of dementia, and apolipoprotein E-4 allele.

Delerium: AKA acute confusional state. Distinct from dementia, however, patients with dementia are at increased risk of developing delerium[3, 4]. A primary disorder of attention that subsequently affects all other aspects of cognition[5]. Often represents life-threatening illness, e.g. hypoxia, sepsis, uremic encephalopathy (also *see page 73*), electrolyte abnormality, drug intoxication, MI. 50% of patients die within 2 yrs of this diagnosis.

Unlike dementia, delerium has acute onset, motor signs (tremor, myoclonus, asterixis), slurred speech, altered consciousness (hyperalert/agitated or lethargic, or fluctuations), hallucinations may be florid. EEG → pronounced diffuse slowing.

Brain biopsy for dementia

Clinical criteria are usually sufficient for the diagnosis of most dementias. Biopsy should be reserved for cases of a chronic progressive cerebral disorder with an unusual clinical course where all other possible diagnostic methods have been exhausted and have failed to provide adequate diagnostic certainty[6]. Biopsy may disclose CJD, low grade astrocytoma, and AD among others. The high incidence of CJD among patients selected for biopsy under these criteria

necessitates appropriate precautions (see *Creutzfeldt-Jakob disease*, page 361). In a report of 50 brain biopsies performed to assess progressive neurodegenerative disease of unclear etiology[7], the diagnostic yield was only 20% (6% were only suggestive of a diagnosis, 66% were abnormal but nonspecific, 8% were normal). The yield was highest in those with focal MRI abnormalities. Among the 10 patients with diagnostic biopsies, the biopsy result led to a meaningful therapeutic intervention in only 4.

Recommendations

Based on the above, the following recommendations are made for patients with an otherwise unexplained neurodegenerative disease:

1. those with a focal abnormality on MRI: stereotactic biopsy
2. those without focal abnormality (possibly including SPECT or PET scan): brain biopsy should only be performed within an investigative protocol

Recommendations for specimen

Ideally the biopsy specimen should[8]:

1. be large enough (usually 1 cm^3)
2. be taken from an affected area
3. include grey and white matter
4. be handled carefully to minimize artifact (electrocautery should not be used on the specimen side of the incision)

4.2. Headache

Headache **(H/A)** may be broadly categorized as follows:

1. chronic recurring headaches
   A. vascular type (migraine): *see below*
   B. muscle contraction (tension) headaches
2. headache due to pathology
   A. systemic pathology
   B. intracranial pathology: a wide variety of etiologies including:
      1. subarachnoid hemorrhage: <u>sudden</u> onset, severe, usually with vomiting, apoplexy, focal deficits possible (*see* *page 1035* for

differential diagnosis of paroxysmal H/A)
2. increased intracranial pressure from any cause (tumor, communicating hydrocephalus, inflammation, pseudotumor cerebri…)
3. irritation or inflammation of meninges: meningitis
4. tumor: with or without elevated ICP (*see page 587*)

C. local pathology of the eye, nasopharynx, or extracranial tissues (including giant cell arteritis, *see page 74*)
D. following head trauma (postconcussive syndrome): *see page 910*
E. following craniotomy ("syndrome of the trephined"): *see page 149*

A severe new H/A, or a change in the pattern of a longstanding or recurrent H/A (including developing associated N/V, or an abnormal neurologic exam) warrants further investigation with CT or MRI[9].

Unilateral H/A that never changes side over a period ≥ 1 year warrants an MRI (this would be atypical in migraine and may be a presentation of an occipital AVM - *see page 1099*).

4.2.1. Migraine

Migraine attacks usually occur in individuals predisposed to the condition, and may be activated by factors such as bright light, stress, diet changes, trauma, administration of radiologic contrast media (especially angiography) and vasodilators.

CLASSIFICATION

See also index under *Headache*, e.g. for: crash migraine (thunderclap headache) *page 1035*, post-myelogram headache *page 58*…

COMMON MIGRAINE

Episodic H/A with N/V and photophobia, without aura or neurologic deficit.

CLASSIC MIGRAINE

Common migraine + aura. May have H/A with occasional focal neurologic deficit(s) that resolve completely in ≤ 24 hrs.

Over half of the transient neurologic disturbances are visual, and usually consist of positive phenomena (spark photopsia, stars, complex geometric

patterns, fortification spectra) which may leave negative phenomena (scotoma, hemianopsia, monocular or binocular visual loss…) in their wake. The second most common symptoms are somatosensory involving the hand and lower face. Less frequently, deficits may consist of aphasia, hemiparesis, or unilateral clumsiness. A slow march-like progression of deficit is characteristic. The risk of stroke is probably increased in patients with migraine[10].

COMPLICATED MIGRAINE

Occasional attacks of classic migraine with minimal or no associated H/A, and complete resolution of neurologic deficit in ≤ 30 days.

MIGRAINE EQUIVALENT

Neurologic symptoms (N/V, visual aura, etc.) without H/A (acephalgic migraine). Seen mostly in children. Usually develops into typical migraine with age. Aura may be shortened by opening and swallowing contents of a 10 mg nifedipine capsule[11].

HEMIPLEGIC MIGRAINE

H/A typically precedes hemiplegia which may persist even after H/A resolves.

CLUSTER HEADACHE

AKA histaminic migraine. Actually a neurovascular event, distinct from true migraine. Recurrent unilateral attacks of severe pain. Usually oculofrontal or oculotemporal with occasional radiation into the jaw, usually recurring on the same side of the head. Ipsilateral autonomic symptoms (conjunctival injection, nasal congestion, rhinorrhea, lacrimation, facial flushing) are common. Partial Horner's syndrome (ptosis and miosis) sometimes occurs. Male:female ratio is ≈ 5:1. 25% of patients have a personal or family history of migraine.

Headaches characteristically have no prodrome, last 30-90 minutes, and recur one or more times daily usually for 4-12 weeks, often at a similar time of day, following which there is typically a remission for an average of 12 months[12].

Treatment for cluster H/A (prophylaxis is only minimally effective):

Treatment is difficult because there is no prodrome and the H/A often stop after 1-2 hrs. Treatment of acute attacks includes:

- 100% O_2 by face mask with patient sitting for ≤ 15 min or until attack

aborted

- ergotamine
- SQ sumatriptan: usually aborts attack within 15 minutes
- steroids
- refractory cases may be considered for:
    - percutaneous radiofrequency sphenopalatine ganglion blockade[13]
    - occipital nerve stimulation[14]
    - hypothalamic deep brain stimulation

BASILAR ARTERY MIGRAINE

Essentially restricted to adolescence. Recurrent episodes lasting minutes to hours of transient neurologic deficits in distribution of vertebrobasilar system. Deficits include: vertigo (most common), gait ataxia, visual disturbance (scotomata, bilateral blindness), dysarthria, followed by severe H/A and occasionally nausea and vomiting[15]. Family history of migraine is present in 86%.

4.2.2. Post LP (myelogram) H/A

AKA "postspinal headache" or "spinal headache". May also follow procedures other than LP/myelogram, such as dural opening (*see page 450*). Can also occur with spontaneous intracranial hypotension (*see page 305*).

Clinical features

Important distinctive characteristic: H/A occurs when patient is erect, and is completely or partially (but significantly) relieved when recumbent. May be associated with nausea, vomiting, dizziness, or visual disturbances.

Time course: Most post-LP headaches **(PLPHA)** have a delayed onset 24-48 hrs after the LP, and although they may occur weeks post-LP, most also develop within 3 days. The duration of PLPHA varies, with a mean of 4 days[16], and reports of duration of months[17] and even > 1 year[18].

Pathophysiology

Thought to be due to continued CSF leakage through the hole in the dura[19], which reduces the CSF "cushion" of the brain. In the upright position, the pull of

gravity on the brain produces traction on the blood vessels and any structures tethering the brain to the painsensitive dura. CSF may sometimes be demonstrable in the epidural space.

Epidemiology following LP

Reported incidence range is 2-40% (typically ≈ 20%), higher after diagnostic LP than for epidural anesthesia[16].

For variables in LP that impact upon the risk of PLPHA, *see page 204*

TREATMENT FOR H/A FOLLOWING LP

Initial "conservative" measures include:

1. flat in bed for at least 24 hrs
2. hydration (PO or IV)
3. analgesics for H/A
4. tight abdominal binder
5. desoxycortisone acetate 5 mg IM q 8 hrs[16]
6. caffeine sodium benzoate 500 mg in 2 cc IV q 8 hrs up to 3 d max (70% of patients had relief with 1 or 2 injections)[20]
7. high-dose steroids: report of success in a case of intracranial hypotension associated with spontaneous slit ventricles tapering down from a starting dose of dexamethasone 20 mg/day[21]
8. blood patch if refractory (*see below*)

EPIDURAL BLOOD PATCH

For refractory post-lumbar puncture or post-myelogram H/A. Works in one application in over 90% of cases, may be repeated if ineffective[17]. Theoretical risks: infection, cauda equina compression, failure to relieve H/A.

Technique

Accessing epidural space (one of several techniques): proceed as routine LP. When ligaments are traversed, and needle tip is nearing spinal canal, stylet is removed. Then, either place drop of sterile saline in hub (hanging drop technique) and advance while watching for it to be drawn into needle as epidural space is entered, or gently try injecting air with small syringe (preferably glass) while advancing, when the epidural space is entered, resistance to injection disappears, but CSF cannot be aspirated.

A venipuncture site is prepared aseptically. 10 ml of the patient's blood is with-drawn. After verifying CSF cannot be aspirated through the spinal needle, the blood is injected into the epidural space. After 30 minutes supine, patient may ambulate ad lib.

4.3. Parkinsonism

Parkinsonism may be primary or secondary to other conditions. All result from a relative loss of dopamine mediated inhibition of the effects of acetylcholine in the basal ganglia.

IDIOPATHIC PARALYSIS AGITANS (IPA)

Classical Parkinson's disease AKA shaking palsy.

Clinical

Affects ≈ 1% of Americans > age 50 yrs[22]. Male:female ratio is 3:2. Not clearly environmentally or genetically induced, but may be influenced by these factors.

The classic triad is shown in *Table 4-1*. Other signs may include: postural instability, micrographia, mask-like facies. Gait consists of small, shuffling steps (marche á petits pas) or festinating gait.

Table 4-1 Classic triad of Parkinson's disease

- tremor (resting, 4-7/second)
- rigidity (cogwheel)
- bradykinesia

Clinically distinguishing IPA from secondary parkinsonism (*see below*): May be difficult early. IPA generally exhibits gradual onset of bradykinesia with tremor that is often asymmetrical, and initially responds well to levodopa. Other disorders are suggested with rapid progression of symptoms, when the initial response to levodopa is equivocal, or when there is early midline symptoms (ataxia or impairment of gait and balance, sphincter disturbance…) or the presence of other features such as early dementia, sensory findings, profound orthostatic hypotension, or abnormalities of extraocular movements[23, 24].

Pathophysiology

Degeneration primarily of pigmented (neuromelaninladen) dopaminergic neurons of the pars compacta of the substantia nigra, resulting in reduced levels of dopamine in the neostriatum (caudate nucleus, putamen, globus pallidus). This decreases the activity of inhibitory neurons with predominantly D2 class of dopamine receptors which project directly to the internal segment of the globus pallidus **(GPi)**, and also increases (by loss of inhibition) activity of neurons with predominantly D1 receptors which project indirectly to the globus pallidus externa **(GPe)** and subthalamic nucleus[25]. The net result is increased activity in GPi which has inhibitory projections to the thalamus which then suppresses activity in the supplemental motor cortex among other locations.

Histologically: **Lewy bodies** (eosinophilic intraneuronal hyaline inclusions) are the hallmark of IPA.

SECONDARY PARKINSONISM

The differential diagnosis includes the following etiologies of secondary parkinsonism or Parkinson-like conditions (some referred to as "Parkinson plus"):

1. **olivopontocerebellar degeneration (OPC)**
2. striato-nigral degeneration **(SND)**: more aggressive than parkinsonism
3. postencephalitic parkinsonism: followed an epidemic of encephalitis lethargica (von Economo disease) in the 1920's, victims are no longer living. Distinguishing features: oculogyric crisis, tremor involves not only extremities but also trunk and head, asymmetrical, no Lewy bodies
4. progressive supranuclear palsy **(PSNP)**: impaired vertical gaze (*see below*)
5. multiple system atrophy (Shy-Drager syndrome): *see below*
6. drug induced: includes:
   A. prescription drugs (elderly females seem more susceptible)
      1. antipsychotics (AKA neuroleptics): haloperidol (Haldol®) which works by blocking postsynaptic dopamine receptors
      2. phenothiazine antiemetics: prochlorperazine (Compazine®)
      3. metoclopramide (Reglan®)
      4. reserpine

   B. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine): a commercially available chemical intermediate which is also a by-product of the synthesis of MPPP (a meperidine analog) that was synthesized and self-injected by a graduate student[26], and later

produced by illicit drug manufacturers to be sold as “synthetic heroin” and unwittingly injected by some IV drug abusers in northern California in 198327. MPTP was subsequently discovered to be a potent neurotoxin for dopaminergic neurons. As a rule, the response to levodopa is dramatic, but short-lived

C. there is an as yet unproven assertion that methylenedioxymethamphetamine **(MDMA)** AKA “ecstasy” (on the street), may hasten the onset of Parkinsonism

7. toxic: poisoning with
   A. carbon monoxide: symmetric low densities in the globus pallidus on CT
   B. manganese: may be seen in miners, welders, and pyrotechnics workers. Manganese is excreted by the liver, ∴ people with hepatic insufficiency are more susceptible. Imaging: symmetrical high signal abnormalities on T1WI primarily in the globus pallidus with essentially no findings on T2WI or GRASS (almost pathognomonic)
8. ischemic (lacunes in basal ganglia): produces so-called **arteriosclerotic parkinsonism** AKA vascular parkinsonism: “lower-half” parkinsonism (gait disturbance predominates[28]). Also causes pseudobulbar deficits, emotional lability. Tremor is rare
9. posttraumatic: parkinsonian symptoms may occur in chronic traumatic encephalopathy (dementia pugilistica, *see page 911*). There are usually other features not normally present in IPA (e.g. cerebellar findings)
10. normal pressure hydrocephalus **(NPH)**: urinary incontinence… (*see page 329*)
11. neoplasm in the region of the substantia nigra
12. Riley-Day (familial dysautonomia)
13. parkinson-dementia complex of Guam: classic IPA + amyotrophic lateral sclerosis **(ALS)**. Pathologically has features of parkinsonism and Alzheimer’s disease but no Lewy bodies nor senile plaques
14. Huntington’s disease **(HD)**: whereas adults typically show chorea, when HD manifests in a young person it may resemble IPA
15. (spontaneous) intracranial hypotension may present with findings mimicking IPA (*see page 305*)

Multiple system atrophy ***(MSA)***

AKA Shy-Drager syndrome. Parkinsonism (indistinguishable from IPA),

PLUS idiopathic orthostatic hypotension, *PLUS* other signs of autonomic nervous system **(ANS)** dysfunction (ANS findings may precede parkinsonism and may include urinary sphincter disturbance and hypersensitivity to noradrenaline or tyramine infusions). Degeneration of preganglionic lateral horn neurons of thoracic spinal cord. Unlike IPA, most do not respond to dopa therapy. NB: classic IPA may eventually produce orthostatic hypotension from inactivity or as a result of progressive autonomic failure.

Progressive supranuclear palsy (PSNP)

AKA Steele-Richardson-Olszewski syndrome[29].

Triad:

1. progressive supranuclear ophthalmoplegia (chiefly vertical gaze): paresis of voluntary vertical eye movement, but still moves to vertical doll's eyes maneuver
2. pseudobulbar palsy (mask-like facies with marked dysarthria and dysphagia, hyperactive jaw jerk, emotional incontinence usually mild)
3. axial dystonia (especially of neck and upper trunk)

Associated findings: subcortical dementia (inconstant), motor findings of pyramidal, extrapyramidal and cerebellar systems. Average age of onset: 60 yrs. Males comprise 60%. Response to anti-parkinson drugs is usually very short lived. Average survival after diagnosis: 5.7 yrs.

Differentiating from Parkinson's disease (IPA):

Patients with PSNP have a pseudo-parkinsonism. They have mask facies, but do not walk bent forward (they walk erect), and they do not have a tremor. They tend to fall backwards.

Course

1. early:
   A. many falls: due to dysequilibrium + downgaze palsy (can't see floor)
   B. eye findings may be normal initially, subsequently may develop difficulty looking down (especially to command, less to following), calorics have normal tonic component but absent nystagmus (cortical component)
   C. slurred speech
   D. personality changes

    E. difficulty eating: due to pseudobulbar palsy + inability to look down at food on plate
2. late:
    A. eyes fixed centrally (no response to oculocephalics or oculovestibulars): ocular immotility is due to frontal lobe lesions
    B. neck stiffens in extension (retrocollis)

SURGICAL TREATMENT FOR PARKINSON'S DISEASE

Before the introduction of L-dopa in the late 1960's, stereotactic thalamotomy was widely used for Parkinson's disease. The location ultimately targeted for lesioning was the ventrolateral nucleus. The procedure worked better for relieving the tremor than for the bradykinesia, however it was the latter symptom that was most disabling. This procedure cannot be done bilaterally without significant risk to speech function. The procedure fell out of favor when more effective drugs became available[30].

See *Surgical treatment of Parkinson's disease* on page 532 for further information.

4.4. Multiple sclerosis

Key concepts:

- an idiopathic demyelinating disease of thc CNS producing exacerbating and remitting symptoms disseminated in space and time
- classic clinical findings: optic neuritis, paresthesias, INO and bladder symptoms
- diagnostic criteria (McDonald criteria) use clinical and/or lab results (MRI, CSF…) to stratify patients as: MS, probable MS, or not MS
- MRI: multiple usually enhancing lesions involving optic nerves & white matter of brain (especially periventricular white matter), cerebellum and spinal cord

An idiopathic demyelinating disease (affecting only white matter) of the cerebrum, optic nerves, and spinal cord (especially corticospinal tracts and the posterior columns). Does not affect *peripheral* myelin. Produces multiple plaques of various age in diffuse locations in the CNS, especially in the

periventricular white matter. Lesions initially evoke an inflammatory response with monocytes and lymphocytic perivascular cuffing, but with age settle down to glial scars.

EPIDEMIOLOGY

Usual age of onset: 10-59 years, with the greatest peak between ages 20-40 years. Female to male ratio: 2:1.

Prevalence varies with latitude, and is < 1 per 100,000 near the equator, and is ≈ 30-80 per 100,000 in the northern U.S. and Canada.

CLINICAL

Causes exacerbations and remissions in various locations in the CNS (dissemination in space and time). Common symptoms: visual disturbances (diplopia, blurring, field cuts or scotoma), spastic paraparesis, and bladder disturbances. Nomenclature for the time course of MS is shown in *Table 4-2*[31]. Relapsing-remitting MS is the most common pattern (≥ 70%) at onset, and has the best response to therapy, but > 50% of cases eventually become secondary progressive MS. Only 10% have primary progressive MS, and these patients tend to be older at onset (40-60 years) and frequently develop progressive myelopathy[32]. Progressive relapsing MS is very uncommon.

Deficits present > 6 months usually persist.

Table 4-2 Clinical categories of MS

Category	Definition
relapsingremitting	episodes of acute worsening with recovery and a stable course between relapses
secondary progressive	gradual neurologic deterioration ± superimposed acute relapses in a patient who previously had relapsing-remitting MS
primary progressive	gradual, nearly continuous neurologic deterioration from the onset of symptoms
progressive relapsing	gradual neurologic deterioration from the onset of symptoms, but with subsequent superimposed relapses

Differential diagnosis

The plethora of possible signs and symptoms in MS causes the differential diagnosis to extend to almost all conditions causing focal or diffuse dysfunction of the CNS. Conditions that may closely mimic MS clinically and on diagnostic testing include:

1. acute disseminated encephalomyelitis **(ADEM)**: generally monophasic. May also have CSF-OCB. Corpus callosum involvement is uncommon
2. CNS lymphoma: *see page 673*
3. other closely related demyelinating diseases: e.g. Devic syndrome (*see page 1187*)
4. vasculitis
5. encephalitis: patients are usually very ill
6. chronic white matter changes: seen in older patients

Signs and symptoms

Visual disturbances: Disturbances of visual acuity may be caused by optic or retrobulbar neuritis which is the presenting symptom of MS in 15% of cases, and which occurs at some time in 50% of MS patients. The percentage of patients with an attack of optic neuritis and no prior attack that will go on to develop MS ranges from 17-87% depending on the series[33]. Symptoms: acute visual loss in one or both eyes with mild pain (often on eye movement).

Diplopia may be due to internuclear ophthalmoplegia **(INO)** (*see page 834*) from a plaque in the MLF. INO is an important sign because it rarely occurs in other conditions besides MS or brainstem stroke.

Motor findings: Extremity weakness (mono, para, or quadriparesis) and gait ataxia are among the most common symptoms of MS. Spasticity of the LEs is often due to pyramidal tract involvement. Scanning speech results from cerebellar lesions.

Sensory findings: Posterior column involvement often causes loss of proprioception. Paresthesias of extremities, trunk, or face occur. Lhermitte's sign (electric shock-like pain radiating down the spine on neck flexion) is common, but is not pathognomonic. Trigeminal neuralgia occurs in ≈ 2%, and is more often bilateral and occurs at a younger age than the population in general[34].

Mental disturbances: Euphoria (la belle indifference) and depression occur in ≈ 50% of patients.

Reflex changes: Hyperreflexia and Babinski signs are common. <u>Abdominal cutaneous reflexes</u> disappear in 70-80%.

GU symptoms: Urinary frequency, urgency, and incontinence are common. Impotence in males and reduced libido in either sex is often seen.

DIAGNOSTIC CRITERIA

No single clinical feature or diagnostic test is adequate for the accurate diagnosis of MS. Therefore, clinical information is integrated with paraclinical studies. Diagnosing MS after a single, acute remitting clinically isolated syndrome **(CIS)** is very risky. 50-70% of patients with a CIS suggestive of MS will have multifocal MRI abnormalities characteristic of MS. The presence of these MRI abnormalities increases the risk of developing MS in 1-3 years (with greater prognostic significance than CSF-OCB). The more MRI lesions, the higher the risk[35]. Criteria for the diagnosis of MS[36] follows.

DEFINITIONS[36, 37]

1. attack (exacerbation, relapse): neurologic disturbance lasting > 24 hrs[38] typical of MS when clinicopathological studies determine that the cause is demyelinating or inflammatory lesions
2. remission: ≥ 30 days should separate the onset of the first attack from the onset of a second
3. historical information: reporting of symptoms by the patient (confirmation by observer desirable), adequate to locate a lesion of MS, and has no other explanation (i.e. manifestations must not be attributable to another condition)
4. clinical evidence (signs): neuro dysfunction recorded by competent examiner
5. paraclinical evidence: tests or procedures demonstrating CNS lesion which has not produced signs; e.g. Uhthoff phenomenon or sign (worsening of symptoms with hot bath or shower), BAER, imaging procedures (CT, MRI), expert urological assessment
6. typical of MS: signs & symptoms **(S/S)** known to occur frequently in MS. Thus excludes gray matter lesions, peripheral nervous system lesions, and non-specific complaints such as H/A, depression, convulsive seizures, etc.
7. separate lesions: S/S cannot be explained on basis of single lesion (optic neuritis of both eyes simultaneously or within 15 days represents single lesion)
8. laboratory support: in this study, the only considerations were CSF oligoclonal bands **(CSF-OCB)** (*see below*) (OCB must not be present in serum) or increased CSF IgG production **(CSF-IgG)** (serum IgG must be normal). This assumes that syphilis, SSPE, sarcoidosis, etc. have been ruled out

Table 4-3 Diagnostic criteria for MS[36]

Clinical presentation	Additional data needed to diagnose MS
≥ 2 attacks; objective clinical evidence of ≥ 2 lesions	none*
≥ 2 attacks; objective clinical evidence of 1 lesion	demonstrate dissemination in *space* by: • MRI† or • ≥ 2 MS-compatible lesions on MRI PLUS positive CSF‡ or • await additional clinical attack implicating another site
1 attack; objective clinical evidence of ≥ 2 lesions	demonstrate dissemination in *time* by • MRI§ or • second clinical attack
1 attack; objective clinical evidence of 1 lesion (mono-symptomatic presentation; clinically isolated syndrome)	demonstrate dissemination in *space* by: • MRI† or • ≥ 2 MS-compatible lesions on MRI PLUS positive CSF‡ or and demonstrate dissemination in *time* by: • MRI§ or • second clinical attack
insidious neurological progression suggestive of MS	positive MCSF‡ and demonstrate dissemination in *space* by A. ≥ 9 T2WI lesions on MRI or B. ≥ 2 lesions in spinal cord or C. 4-8 brain + 1 spinal cord lesion or D. abnormal VEPΔ + (4-8 brain lesions or< 4 brain lesions + 1 spinal cord lesion on MRI) and demonstrate dissemination in *time* by A. MRI§ or B. continued progression for 1 year

* additional tests not required. If MRI or CSF test s are done and are negative, apply extreme caution in diagnosing MS

† must meet criteria in *Table 4-4*

‡ positive CSF showing oligoclonal bands, see *Table 4-6*

§ dissemination in *time* on MRI must meet the criteria in *Table 4-5*

Δ abnormal visual evoked potential as seen in MS (delay with well-preserved wave-form)

Diagnosis of MS

The “McDonald criteria” are shown in *Table 4-3*[36]. Preferred terms:

- MS
- possible MS (at risk for MS but diagnosis is equivocal)

• not MS

MRI

MRI is the preferred imaging study in evaluating MS[39] and can demonstrate dissemination of lesions in time and space. Recommended[36] brain MRI criteria for diagnosing MS are shown in *Table 4-4*[40, 41]. Lesions are normally > 3 mm diameter[36]. MRI shows multiple white matter abnormalities in 80% of patients with MS (compared to 29% for CT)[42, 43]. Lesions are high signal on T2WI, and acute lesions tend to enhance with gadolinium more than old lesions do. Periventricular lesions may blend in with the signal from CSF in the ventricles on T2WI, these lesions are shown to better advantage on proton density images as higher intensity than CSF. These lesions are ovoid and are oriented perpendicular to the ependymal surface and are sometimes called **Dawson's fingers**.

Spinal cord lesions normally show little or no swelling, should be ≥ 3 mm but < 2 vertebral segments, occupy only a portion of the cross-section of the cord, and must be hyperintense on T2WI[44].

Specificity of MRI is ≈ 94%[45], however, encephalitis as well as UBOs seen in aging may mimic MS lesions. DWI should be normal, however plaques can sometimes exhibit "shine through" (*see page 132*) so the ADC map must be checked to rule-out infarct.

Table 4-4 Brain MRI criteria for MS

3 of the following 4 criteria*
1. 1 gadolinium-enhancing lesion or, if no gadolinium enhancing lesions, then 9 T2WI lesions
2. ≥ 1 infratentorial lesion
3. ≥ 1 juxtacortical lesion (i.e. involving subcortical u fibers)
4. ≥ 3 periventricular lesions

* 1 spinal cord lesion can be substituted for 1 brain lesion

Focal **tumefactive demyelinating lesions (TDL)** may occur in isolation or, more commonly, in patients with established MS (concentric sclerosis of Balo). TDL may represent an intermediate position between MS and ADEM[46]. TDLs tend to be symmetric. TDLs may enhance, and show perilesional edema (but less than MS) and thus be mistaken for neoplasms. Biopsy results may be confusing. MRS may not be able to differentiate from neoplasm[47].

Table 4-5 MRI criteria for dissemination of lesions in time

1. if first MRI occurs ≥ 3 months after the onset of the clinical event, then a gadolinium enhancing lesion in a different location than

	that implicated by the event meets the criteria. If there is no enhancing lesion, a follow-up MRI is required*. A new enhancing or T2WI lesion meets the criteria
	2. if first MRI is < 3 months from onset, a second MRI ≥ 3 months from onset showing a new gadolinium enhancing lesion meets the criteria. If no enhancing lesion, a 3rd MRI ≥ 3 months from the first showing a new enhancing or T2WI lesion meets the criteria

* timing not critical, but 3 months is recommended[48]

CSF

CSF analysis can support the diagnosis in some cases, but cannot document dissemination of lesions in time or space. The CSF in MS is clear and colorless. The OP is normal. Total CSF protein is < 55 mg/dl in ≈ 75% of patients, and < 108 mg/dl in 99.7% (values near 100 should prompt a search for an alternative diagnosis). The WBC count is ≤ 5 cells/μl in 70% of patients, and only 1% have a count > 20 cells/μl (high values may be seen in the acute myelitis).

In ≈ 90% of patients with MS, CSF-IgG is increased relative to other CSF proteins, and a characteristic pattern occurs. Agarose gel electrophoresis shows a few IgG bands in the gamma region (**oligoclonal bands**) that are not present in the serum. CSF-OCB are not specific for MS, and can occur in CNS infections and less commonly with strokes or tumors. The predictive value of the absence of IgG in a patient with suspected MS has not been satisfactorily elucidated.

Recommended criteria have been published[49], most of which pertain to specifics of laboratory analysis, pertinent clinical excerpts are shown in *Table 4-6*.

Table 4-6 CSF criteria for MS

1. qualitative assessment of IgG is the most informative analysis
2. analysis should be performed on unconcentrated CSF and must be compared to simultaneously run serum sample in the same assay
3. quantitative analysis should be made in terms of one of the 5 recognized staining patterns for OCB
4. all other tests performed on the CSF (including WBC, protein & glucose, lactate) should be taken into consideration
5. if clinical suspicion is high but CSF results are equivocal, negative or show only a single band, consider repeating the LP
6. quantitative IgG is a complementary test, but is not a substitute for qualitative IgG testing

4.5. Motor neuron diseases

Degenerative diseases of motor neurons. For comparison of upper motor neuron **(UMN)** with lower motor neuron **(LMN)** and the paralysis they produce, *see page 786*.

Three patterns of involvement:

1. mixed UMN & LMN degeneration: amyotrophic lateral sclerosis **(ALS)** (*see below*). The most common of the motor neuron diseases
2. UMN degeneration: **primary lateral sclerosis**. Rare, onset after age 50. No LMN signs. Slower progression than ALS (yrs to decades). Pseudobulbar palsy is common[50]. Usually does not shorten longevity. May present with falling due to balance problems or low back and neck pain due to axial muscle weakness
3. LMN degeneration: progressive muscular atrophy **(PMA)** and spinal muscular atrophy **(SMA)**

4.5.1. Amyotrophic lateral sclerosis

Key concepts:

- degeneration of anterior horn cells and corticospinal tracts in the cervical spine and medulla (bulb) of unknown etiology
- a mixed upper and lower motor neuron disease (UMN → mild spasticity in LEs; LMN → atrophy and fasciculations in UEs)
- clinically: progressive muscle wasting, weakness, and fasciculations
- no cognitive, sensory, nor autonomic dysfunction

In the U.S. amyotrophic lateral sclerosis **(ALS)** is AKA Lou Gehrig's disease. Some-times AKA motor neuron *disease* (singular).

Epidemiology[33]

Prevalence: 4-6/100,000. Incidence: 0.8-1.2/100,000.

Familial in 8-10% of cases. Familial cases usually follow autosomal dominant inheritance, but occasionally demonstrate a recessive pattern.

Onset usually after 40 years of age.

Pathology

Etiology is not known with certainty. Histology: degeneration of anterior horn alpha-motoneurons (in the spinal cord and in brain stem motor nuclei) (LMNs) and corticospinal tracts (UMNs). Produces mixed UMN & LMN findings, with a great deal of variability depending on which predominates at any given time.

Clinical

Characterized by progressive muscle wasting, weakness, and fasciculations.

Involvement is of voluntary muscles, sparing the voluntary eye muscles and urinary sphincter.

Classically, presents initially with weakness and atrophy of the hands (lower motor neuron) with spasticity and hyperreflexia of the lower extremities (upper motor neuron). However, LEs may be hyporeflexic if the lower motor neuron deficits predominate.

Dysarthria and dysphagia are caused by a combination of upper and lower motor neuron pathology. Tongue atrophy and fasciculations may also occur.

Although cognitive deficits are generally considered to be absent in ALS, in actuality 1-2% of cases are associated with dementia, and cognitive changes may occasionally predate the usual features of ALS[51].

Differential diagnosis

At times, it may be very difficult to distinguish ALS from cervical spondylotic myelopathy. See *page 489* for a discussion of differentiating features.

Diagnostic studies

EMG: Not absolutely necessary to make diagnosis in most cases. Fibrillations and positive sharp waves are found in advanced cases (may be absent early, especially if upper motor neuron pathology predominates). LMN findings in the LE in the absence of lumbar spine disease, or fibrillation potentials in the tongue are suggestive of ALS.

LP (CSF): May have slightly elevated protein.

Treatment

Ongoing trials with riluzole (Rilutek®), which inhibits the presynaptic release of glutamate, indicate that doses of 50-200 mg/d increases tracheostomy-free survival at 9 & 12 months, but the improvement is more modest or may be non-existent by ≈ 18 months[52-54]. At the time of this writing, the drug is available only for premarketing trials, and cannot be procured commercially.

Much of care is directed towards minimizing disability:

1. aspiration may be treated with
    - A. tracheostomy
    - B. gastrostomy tube to allow continued feeding

C. vocal cord injection with Teflon

2. spasticity that occurs when upper motor neuron deficits predominate may be treated (usually with short-lived response) with:

   A. baclofen: also may relieve the commonly occurring cramps (*see page 537*)

   B. diazepam

Prognosis

Most patients die within 5 years of onset (median survival: 3-4 yrs). Those with prominent oropharyngeal symptoms may have a shorter life-span usually due to complications of aspiration.

4.6. Guillain-Barré syndrome

Key concepts:

> • acute onset of peripheral neuropathy with progressive muscle weakness (more severe proximally) with areflexia, reaches maximum over 3 days to 3 weeks
> • cranial neuropathy: also common, may include facial diplegia, ophthalmoplegia
> • little or no sensory involvement (paresthesias are not uncommon)
> • onset often 3 days-5 weeks following viral URI, immunization, *Campylobacter jejuni* enteritis, or surgery
> • pathology: focal segmental demyelination with endoneurial monocytic infiltrate
> • elevated CSF protein without pleocytosis (albuminocytologic dissociation)

Guillain-Barré syndrome **(GBS)** AKA acute polyradiculoneuritis, among others, is actually a collection of syndromes having inflammatory polyradiculoneuropathy in common. Its most frequent form is acute inflammatory demyelinating polyradiculoneuropathy **(AIDP)**. First described as an ascending paralysis, most forms are characterized by symmetric weakness and areflexia. Mild cases may present only with ataxia, whereas fulminant cases may ascend to complete tetraplegia with paralysis of respiratory muscles and cranial nerves. There are also a number of variants (*see page 67*).

GBS is the most common acquired demyelinating neuropathy. Incidence is ≈ 1-3/100,000. The lifetime risk for any one individual getting GBS is ≈ 1/1,000.

GBS is triggered by both humoral and cell mediated autoimmune response to an immune sensitizing event. Frequent (but not essential) antecedents: viral infection, surgery, immunization, mycoplasma infection, enteral infection with *Campylobacter jejuni* (≈ 4 days of intense diarrhea). Higher frequency in the following conditions than in general population: Hodgkin's disease, lymphoma, lupus.

Most cases involve antibodies to gangliosides and glycolipids in peripheral myelin (axon antibodies occur in some forms). For unknown reasons serum creatine kinase can be mildly elevated, and may correlate with muscle type pain[55].

Diagnostic criteria[56]

1. features required for diagnosis:
   A. progressive motor weakness of more than 1 limb (from minimal weakness ± ataxia to paralysis, may include bulbar or facial or EOM palsy). Unlike most neuropathies, proximal muscles are affected more than distal
   B. areflexia (usually universal, but distal areflexia with definite hyporeflexia of biceps and knee jerks suffices if other features consistent)
2. features strongly supportive of diagnosis:
   A. clinical features (in order of importance)
      1. progression: motor weakness peaks at 2 wks in 50%, by 3 wks in 80%, and by 4 wks in > 90%
      2. relative symmetry
      3. mild sensory symptoms/signs (e.g. mild paresthesias in hands or feet)
      4. cranial nerve involvement: facial weakness in 50%, usually bilateral. GBS presents initially in EOMs or other Cr. N. in < 5% of cases. Oropharyngeal muscles may be affected
      5. recovery usually by 2-4 wks after progression stops, may be delayed by months (most patients recover functionally)
      6. autonomic dysfunction (may fluctuate): tachycardia and other arrhythmias, postural hypotension, HTN, vasomotor symptoms
      7. afebrile at onset of neuritic symptoms
      8. variants (not ranked):

a. fever at onset of neuritic symptoms
b. severe sensory loss with pain
c. progression > 4 wks
d. cessation of progression without recovery
e. sphincter dysfunction (usually spared): e.g. bladder paralysis
f. CNS involvement (controversial): e.g. ataxia, dysarthria, Babinski signs

B. CSF: **albuminocytologic dissociation** (↑ protein without pleocytosis)
1. protein: elevated after 1 wk of symptoms, > 55 mg/dl
2. cells: 10 or fewer mononuclear leukocytes/ml
3. variants
a. no CSF protein rise 1-10 wks after onset (rare)
b. 11-50 monocytes/ml
c. electrodiagnostics: 80% have NCV slowing or block at some time (may take several weeks in some). NCV usually < 60% of normal, but not in all nerves

3. features casting doubt on diagnosis:
A. marked, persistent, asymmetry of weakness
B. persistent bowel or bladder dysfunction
C. > 50 monocytes/ml CSF
D. PMNs in CSF
E. sharp sensory level

4. features of conditions in the differential diagnosis (*see below*)

GUILLAIN-BARRÉ VARIANTS

A number of variants have been described (some may simply be incomplete forms of typical Guillain-Barré). Autonomic dysfunction may occur in some.

Miller-Fisher variant of GBS: Ataxia, areflexia and ophthalmoplegia. May also have ptosis. 5% of cases of GBS. Serum marker: anti-GQ1b antibodies.

Acute motor axonal neuropathy (AMAN): This variant and AIDP are the most common to follow *Campylobacter jejuni* enteritis.

Pharyngeal-cervical-brachial variant: Facial, oropharyngeal, cervical, and UE weakness, sparing the LEs.

Pure sensory variant: Sensory loss accompanied by areflexia.

Atypical GBS: May be accompanied by rhabdomyolysis[57].

DIFFERENTIAL DIAGNOSIS

Also see conditions in the differential diagnosis under *Myelopathy* on page 1185

1. Guillain-Barré syndrome (including one of its variants)
2. critical illness polyneuropathy: EMG: ↓ CMAP & SNAP (*see page 794*)
3. current hexacarbon abuse: volatile solvents (n-hexane, methyl n-butyl ketone), glue sniffing
4. **acute intermittent porphyria (AIP)**: a disorder of porphyrin metabolism. CSF protein is not elevated in AIP. Recurrent painful abdominal crises are common. Check urine delta-aminolevulinic acid or porphobilinogen
5. recent diphtheritic infection: diphtheritic polyneuropathy has a longer latency and a slower crescendo of symptoms
6. lead neuropathy: UE weakness with wrist drop. May be asymmetrical
7. poliomyelitis: usually asymmetric, has meningeal irritation
8. hypophosphatemia (may occur in chronic IV hyperalimentation)
9. botulism: difficult to distinguish clinically from GBS. Normal NCV and a facilitating response to repetitive nerve stimulation on electrodiagnostics
10. toxic neuropathy (e.g. from nitrofurantoin, dapsone, thallium or arsenic)
11. tick paralysis: may cause an ascending motor neuropathy without sensory impairment. Careful examination of the scalp for tick(s)
12. **chronic immune demyelinating polyradiculoneuropathy (CIDP)** AKA chronic relapsing GBS, chronic relapsing polyneuritis[58]. Similar to GBS, but long time course (symptoms must be present > 2 mos). CIDP produces progressive, symmetrical, proximal & distal weakness, depression of muscle stretch reflexes, and variable sensory loss. Cranial nerves are usually spared (facial muscles may be involved). Balance difficulties are common. Need for respiratory support is rare. Peak incidence: age 40-60 yrs. Electrodiagnostics and nerve biopsy findings are indicative of demyelination. CSF findings are similar to GBS (*see above*). Most respond to immunosuppressive therapy (especially prednisolone & plasmapheresis) but relapses are common. Refractory cases may be treated with IV gamma-globulin, cyclosporin-A[59], total body lymphoid irradiation or interferon-α[60]
13. critical illness *myopathy*: Muscles not excitable with direct stimulation. EMG: low or normal CMAP with normal SNAP. Muscle biopsy: abnormalities may range from Type II fiber atrophy to necrosis (severe necrosis may not recover)
14. motor neuron disease: AKA ALS. Hyperreflexia in LEs (*see page 65*)

15. myasthenia gravis: weakness worsens towards the end of the day and with repeat efforts. Positive assay for circulating anti-acetylcholine receptor antibodies
16. spinal cord injury

IMAGING

No characteristic finding, however, diffuse enhancement of cauda equina and nerve roots occurs in up to 95% of cases[61] (for Differential diagnosis, see *page 1230*). Thought to be due to disruption of the blood-nerve barrier from inflammation. Conspicuous nerve root enhancement correlates with pain, GBS disability grade, and duration of recovery[61].

TREATMENT

Immunoglobulins may be helpful. In severe cases, early plasmapheresis hastens the recovery and reduces the residual deficit. Its role in mild cases is uncertain. Steroids are not helpful[62]. Mechanical ventilation and measures to prevent aspiration are used as appropriate. In cases of facial diplegia, the eyes must be protected from exposure (neuroparalytic) keratitis.

OUTCOME

Recovery may not be complete for several months. 35% of untreated patients have residual weakness and atrophy. Recurrence of GBS after achieving maximal recovery occurs in ≈ 2%.

4.7. Myelitis

AKA acute transverse myelitis **(ATM)**. The terminology is confusing: myelitis overlaps with “myelopathy”. Both are pathologic conditions of the spinal cord. Myelitis indicates inflammation, and etiologies include: infectious/post-infectious, autoimmune, and idiopathic. Myelopathy is generally reserved for compressive, toxic, or metabolic etiologies[63] (*see page 1185* for differential diagnosis).

ETIOLOGY

Many so-called “causes” remain unproven. Immunologic response against the CNS (most likely via cell mediated component) is the probable common

mechanism. Animal model: experimental allergic encephalomyelitis (requires myelin basic protein of CNS, not peripheral).

Generally accepted etiologies include:

1. infectious and post-infectious
   - A. primary infectious myelitis
     1. viral: poliomyelitis, myelitis with viral encephalomyelitis, herpes zoster, rabies
     2. bacterial: including tuberculoma of spinal cord
     3. spirochetal: AKA syphilitic myelitis. Causes syphilitic endarteritis
     4. fungal (aspergillosis, blastomycosis, cryptococcosis)
     5. parasitic (Echinococcus, cysticercosis, paragonimiasis, schistosomiasis)
   - B. post-infectious: including post-exanthematous, influenza
2. post-traumatic
3. physical agents
   - A. decompression sickness (dysbarism)
   - B. electrical injury*
   - C. post-irradiation
4. paraneoplastic syndrome (remote effect of cancer): most common primary is lung, but prostate, ovary and rectum have also been described[64]
5. metabolic
   - A. diabetes mellitus*
   - B. pernicious anemia*
   - C. chronic liver disease*
6. toxins
   - A. cresyl phosphates*
   - B. intraarterial contrast agents*
   - C. spinal anesthetics
   - D. myelographic contrast agents
   - E. following chemonucleolysis[65]
7. arachnoiditis
8. autoimmune
   - A. multiple sclerosis **(MS)**, especially Devic syndrome (*see page 1187*)
   - B. following vaccination (smallpox, rabies)
9. collagen vascular disease
   - A. systemic lupus erythematosus

B. mixed connective tissue disease

* items with an asterisk may be more properly associated with myelopathy rather than myelitis

CLINICAL

PRESENTATION

34 patients with ATM[66]: age of onset ranged 15-55 yrs (66% occurred in 3rd & 4th decade). 12 patients (35%) had a viral-like prodrome. Presenting symptoms are shown in *Table 4-7*. Other presenting symptoms of unspecified frequency[68]: fever and rash.

Table 4-7 Presenting symptoms in myelitis

Symptom	Series A*	Series B†
pain (back or radicular)	35%	35%
muscle weakness	32%	13%
sensory deficit or paresthesias	26%	46%
sphincter disturbance	12%	6%

* series A: 34 patients with ATM[66]

† series B: 52 patients with acute or subacute transverse myelitis[67]

Table 4-8 Level of sensory deficit

Level	%
cervical	8%
high thoracic	36%
low thoracic	32%
lumbar	8%
unknown	16%

Presenting level

The levels at presentation in 62 patients with ATM are shown in *Table 4-8*[68]. The thoracic level is the most common sensory level. ATM is rarely the presenting symptom of MS (≈ 3-6% of patients with ATM develop MS).

PROGRESSION

Progression is usually rapid, with 66% reaching maximal deficit by 24 hrs, however the interval between first symptom and maximal deficit varies from 2 hrs-14 days[68]. Findings at the time of maximal deficit are shown in *Table 4-9*.

EVALUATION

Myelogram, CT & MRI: no characteristic finding. One paper reports 2 patients with fusiform cord enlargement[69]. High resolution MRI with thin cuts may be able to demonstrate area of involvement within the cord. Patient should have imaging to R/O compressive lesion.

CSF: normal during acute phase in 38% of LPs. Remainder (62%) had elevated protein (usually > 40 mg%) or pleocytosis (lymphocytes, PMNs, or both) or both.

Table 4-9 Symptoms at time of maximal deficit (62 patients with ATM[68])

Symptom	%
sensory deficit or paresthesias	100%
muscle weakness	97%
sphincter disturbance (hesitancy, retention, overflow incontinence)	94%
pain in back, abdomen, or limbs	34%
fever	27%
nuchal rigidity	13%

EVALUATION SCHEME

In a patient developing acute myelopathy/paraplegia, especially when ATM is considered likely, the first test of choice is an emergency MRI. If not readily available, a myelogram (with CT to follow) directed at the region of the sensory level is performed (CSF may be sent in this circumstance once block is ruled out).

TREATMENT

Suggested efficacy of high-dose steroid treatment in 1 patient with ATM[70] (methylprednisolone 250 mg IV q 6 hrs **x** 24 hrs, 125 mg IV q 6 hrs **x** 24 hrs, 125 mg IV q 12 hrs **x** 48 hrs, then 30 mg PO q 6 hrs, tapered gradually. Regimen should probably be individualized based on response).

PROGNOSIS

In a series of 34 ATM patients with ≥ 5 yrs follow-up **(F/U)**[66]: 9 patients (26%) had good recovery (ambulate well, mild urinary symptoms, minimal sensory and UMN signs); 9 (26%) had fair recovery (functional gait with some degree of spasticity, urinary urgency, obvious sensory signs, paraparesis); 11 (32%) poor (paraplegic, absent sphincter control); 5 (15%) died within 4 mos of illness. 18 patients (62% of survivors) became ambulatory (in these cases, all could walk with support by 3-6 mos).

In a series of 59 patients[68] (F/U period unspecified): 22 (37%) had good recovery; 14 (24%) poor; 3 died in acute stage (respiratory insufficiency in 2, sepsis in 1). Recovery occurred between 4 weeks and 3 mos after onset (no improvement occurred after 3 mos).

4.8. Neurosarcoidosis

Key concepts:

- neurologic involvement of sarcoidosis (a systemic granulomatous disease)
- may produce multiple cranial nerve palsies
- the most common neurologic manifestation is diabetes insipidus
- corticosteroids are beneficial for systemic as well as neurologic involvement

Sarcoidosis is a granulomatous disease that is usually systemic, and may include the CNS (so-called **neurosarcoidosis** AKA neurosarcoid). Only 1-3% of cases have CNS findings without systemic manifestations[71]. The cause of the disease is unknown. An exaggerated cellular immune response for unknown reasons is the currently favored hypothesis. Organs commonly involved include lungs, skin, lymph nodes, bones, eyes, muscles, and parotid glands[33].

PATHOLOGY

CNS sarcoidosis primarily involves the leptomeninges, however parenchymal invasion often occurs. Adhesive arachnoiditis with nodule formation may also occur (nodules have a predilection for the posterior fossa). Diffuse meningitis or meningoencephalitis may occur, and may be most pronounced at the base of the brain (basal meningitis) and in the subependymal region of the third ventricle (including the hypothalamus).

Constant microscopic features of neurosarcoidosis include noncaseating

granulomas with lymphocytic infiltrates. Langhans giant cells may or may not be present.

EPIDEMIOLOGY

Incidence of sarcoidosis is ≈ 3-50 cases/100,000 population; neurosarcoidosis occurs in ≈ 5% of cases (reported range: 1-27%). In one series, the median age of onset of neurologic symptoms was 44 years.

CLINICAL FINDINGS

Clinical findings include multiple cranial nerve palsies in 50-70% (particularly facial n., including diplegia), peripheral neuropathy, and myopathy[72]. Occasionally the lesions may produce mass effect[73], and hydrocephalus may result from adhesive basal arachnoiditis. Patients may have low grade fever. Intracranial hypertension is common and may be dangerous. Hypothalamic involvement may produce disorders of ADH (diabetes insipidus, disordered thirst). Rare involvement of the pituitary may produce pituitary insufficiency. Seizures occur in 15%.

0.4% of patients with sarcoidosis develop spinal cord involvement[74], and in 16% of these, the spinal cord was the only identifiable site of involvement.

LABORATORY

CBC: mild leukocytosis and eosinophilia may occur.

Serum angiotensin-converting enzyme (ACE): abnormally elevated in 83% of patients with active pulmonary sarcoidosis, but in only 11% with inactive disease[75]. False positive rate: 2-3%; may also be elevated in primary biliary cirrhosis.

CSF: similar to any subacute meningitis: elevated pressure, mild pleocytosis (10-200 cells/mm^3) mostly lymphocytes, elevated protein (up to 2,000 mg/dl), mild hypoglycorrhachia (15-40 mg/dl), CSF ACE is elevated in ≈ 55% of cases with neurosarcoidosis (normal in patients with sarcoidosis not involving the CNS)[76]. No organisms are recovered on culture or gram stain.

IMAGING

CXR

Usually demonstrates characteristic findings of sarcoidosis (hilar adenopathy, mediastinal lymph nodes…).

MRI

Gadolinium enhancement of the leptomeninges and/or optic nerve may be the only abnormal finding(s). Lesions may be solitary or multiple, and may be located intra- or extraparenchymal, periventricular, and/or in basal cisterns. Lesions may be seen on FLAIR that would otherwise have been missed. Hydrocephalus may occur.

Gallium scan

Nuclear medicine scan with 67Ga citrate (*see page 141*). Described findings include:

1. Panda sign[77]: uptake in lacrimal glands, parotid glands & nasopharynx (normal). Not specific for sarcoidosis
2. lambda distribution[78]: uptake in hilar lymph nodes
3. leopard man sign[79]: diffuse dappled pattern due to uptake in soft tissues, skin, muscles, mediastinum, and lacrimal glands

Diagnosis

Differentiating granulomatous angiitis **(GA)** from neurosarcoidosis that involves only the CNS can be done on histologic criteria: the inflammatory reaction in sarcoidosis is not limited to the region immediately surrounding blood vessels as it is in GA, where extensive disruption of the vessel wall may occur.

Making the diagnosis is relatively easy when systemic involvement occurs: characteristic findings on CXR, biopsy of skin or liver nodules, muscle biopsy, serum ACE assay.

Isolated neurosarcoidosis may be more difficult to diagnose, and may require biopsy (*see below*).

Table 4-10 Differential diagnosis of neurosarcoidosis

1. Hodgkin's disease
2. chronic granulomatous meningitis:
A. Hansen's disease (leprosy)
B. syphilis
C. cryptococcosis
D. tuberculosis
3. multiple sclerosis
4. CNS lymphoma
5. pseudotumor cerebri
6. granulomatous angiitis

BIOPSY

In uncertain cases, biopsy may be indicated. Whenever possible, MRI should be used to localize a supratentorial region of involvement, and biopsy should include all layers of meninges and cerebral cortex. Cultures and stains for fungus and acid-fast bacteria (TB) should be performed in addition to microscopic examination.

TREATMENT

Antibiotics have not been proven to be of benefit. Immunosuppression primarily with corticosteroids are beneficial for systemic as well as neurologic involvement. Therapy may be initiated with prednisone 60 mg PO qd in adults, and tapered based on response. Therapy with cyclosporine may allow a reduction in steroid dosage in refractory cases[80]. Treatment for unresponsive cases include: methotrexate, cytoxan, cyclophosphamide, azathioprine, low dose XRT. CSF shunting is indicated if hydrocephalus develops.

PROGNOSIS

Usually a benign disease. Peripheral and cranial nerve palsies recover slowly.

4.9. Vascular dysautoregulatory encephalopathy

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME (PRES)

AKA reversible posterior leukoencephalopathy syndrome **(RPLS)**. A group of encephalopathies with characteristic pattern of widespread vasogenic brain edema seen on CT or MRI with some predominance in the parietal and occipital regions[81]. The most common PRES pattern involves watershed zones with involvement of the cortex, subcortical and deep white matter to a variable extent[81]. A small number of patients with PRES will go on to infarction.

Patients may present with headache, seizures, mental status changes and focal neurologic deficit. Intracerebral hemorrhage **(ICH)** and SAH may occur in up to 15%[81].

Associated findings and conditions: Includes:

1. **hypertensive encephalopathy**: commonly seen in the setting of subacute blood pressure elevations (as may occur with malignant hypertension).

Imaging studies show symmetric confluent lesions with mild mass effect and patchy enhancement primarily in the subcortical white matter of the occipital lobes[82] which may produce cortical blindness

A. moderate to severe hypertension is seen in ≈ 75% of patients with PRES[81] although the upper limits of autoregulation are often not reached

B. in addition to hemispheric patterns of edema isolated brain stem and cerebellar edema have been described. Posterior fossa edema has been reported to cause obstructive hydrocephalus in a severe case[83]

2. **preeclampsia/eclampsia** associated with cerebral edema[84]. The condition is often temporary, but (permanent) infarctions also occur. Restricted diffusion on MR imaging is seen in 11-26% of cases. Abnormal DWI areas on MRI may be associated with a worse prognosis[85]
   A. may present (e.g. with blindness) during pregnancy complicated by preeclampsia or eclampsia[86]
   B. may develop 4-9 days post-partum and may be associated with vasospasm[87]
   C. toxemia is attributed to the placenta. Delivery and removal of the placenta is felt to be curative[88]
3. **infection, sepsis and shock**: blood pressure was normal in 40% (edema was greater in the normotensive patients). Gram positive organisms predominate[89]
4. autoimmune disease: PRES has been described in patients with lupus, scleroderma, Wegener's granulomatosis and polyarteritis nodosa[81]. These patients often receive regimens of immunosuppressive medications (tacrolimus, cyclosporine), which have also been linked to cases of PRES
5. cancer chemotherapy: PRES occurs in patients receiving multi-drug high dose chemotherapy most commonly for hematopoietic malignancies
6. transplantation: PRES has been reported both with bone marrow and solid organ transplantation
   A. incidence: 3-16% with bone marrow transplantation depending on the preconditioning regimen and whether or not it is myeloablative[81]
   B. highest incidence in the first month following allogeneic bone marrow transplant[81]
   C. lower incidence following solid organ transplants. Occurs earlier following liver transplantation, usually within 2 months. Occurs later

in renal transplants[81]

7. cyclosporine post-transplant neurotoxicity[89]

Treatment

Disordered autoregulation mandates tight control of blood pressure to reduce the risk of ICH. The underlying cause needs to be addressed (i.e. control HTN, hold immunosuppressives or chemotherapeutics, delivery of the placenta, etc.).

UREMIC ENCEPHALOPATHIES

Imaging studies show multiple areas of symmetric edema in the basal ganglia, with severe cases developing focal infarcts with or without hemorrhage[82]. These disorders are associated with elevated BUN and include:

1. uremia
2. glomerulonephritis
3. hemolytic-uremic syndrome (HUS)
4. thrombotic thrombocytic purpura (TTP)

CROSSED CEREBELLAR DIASCHISIS

Hypometabolism of cerebellar cortex contralateral to a cerebral hemispheric lesion (lesions include: stroke, brain tumor…). Lesions in the motor cortex, anterior corona radiata, and thalamus produce the most marked suppression of metabolism. Theory: hypometabolism is due to disconnection of cerebro-ponto-cerebellar pathways → decreased oxygen and glucose consumption → decreased CO_2 production → local arterial constriction (down-regulation of cerebellar blood flow).

4.10. Vasculitis and vasculopathy

The vasculitides are a group of disorders characterized by inflammation and necrosis of blood vessels. Vasculitis may be primary or secondary. Those that may affect the CNS are listed in *Table 4-11*, all of these cause tissue ischemia (even after the inflammation is quiescent) that may range in effect from neuropraxia to infarction.

Table 4-11 Vasculitides that may affect the CNS[90]

Vasculitis	Frequency of neuro involvement	—TYPE OF CNS INVOLVEMENT*—				
		Acute encephalopathy	Seizure	Cranial nerve	Spinal cord	ICH or SAH
periarteritis nodosa† **(PAN)**‡	20-40%	++	++	+	+	+
hypersensitivity vasculitis†	10%	+	+	0	0	+
giant cell (temporal) arteritis†	10%	+	0	++	0	0
Takayasu's arteritis	10-36%	+	++	++	+	+
Wegener's granulomatosis†	23-50%	+	++	++	+	+
lymphomatoid granulomatosis†	20-30%	++	+	++	+	0
isolated angiitis of the CNS†	100%	++	+	++	++	+
Behçet's disease†	10-29%	++	+	++	+	+

* KEY: 0 = uncommon or unreported; + = not uncommon; ++ = common; ICH = intracerebral hemorrhage; SAH = subarachnoid hemorrhage

† see section that follows for these topics

‡ PAN: a group of disorders, frequencies may vary by subgroup

4.10.1. Giant cell arteritis (GCA)

Key concepts:

- formerly often referred to as temporal arteritis
- a chronic vasculitis of large and medium caliber vessels, primarily involving cranial branches of the arteries arising from the aortic arch
- age > 50 years; affects women twice as often as men
- important possible late complications: blindness, stroke, thoracic aortic aneurysms and aortic dissections
- temporal artery biopsy is recommended for all patients suspected of GCA
- corticosteroids are the drug of choice for treatment

AKA **temporal arteritis (TA)**, AKA cranial arteritis. A chronic granulomatous arteritis of unknown etiology involving primarily the cranial branches of the aortic arch (especially the external carotid artery **(ECA)**)[91], which if untreated, may lead to blindness. Takayasu's arteritis is similar to GCA, but tends to affect large arteries in young women; it has 2 phases: inflammatory (treated with corticosteroids) and stenotic (treated with arterial bypasses).

EPIDEMIOLOGY

Seen almost exclusively in Caucasians > 50 yrs age (mean age of onset is 70). Incidence: 17.8 per 100,000 people ≥ 50 years old[92] (range: 0.49-23). Prevalence: ≈ 223 (autopsy incidence may be much higher)[93]. More common in

northern latitudes and among individuals of Scandinavian descent[91]. Female:male ratio is ≈ 2:1 (reported range: 1.05-7.4:1). 50% of GCA patients also have polymyalgia rheumatica **(PMR)** (*see* *page 77*).

PATHOLOGY

Discontinuous (so-called “skip lesions”) inflammatory reaction of lymphocytes, plasma cells, macrophages, ± giant cells (if absent, intimal proliferation may be prominent); predominantly in media of involved arteries. Arteries preferentially involved include the ophthalmic and posterior ciliary branches and the entire distribution of the external carotid system (of which the STA is a terminal branch). Other arteries in the body may be involved (reported involvement of abdominal aorta, femoral, brachial and mesenteric arteries are rarely symptomatic). Unlike PAN, GCA generally spares the renal arteries.

CLINICAL

Various combinations of symptoms of giant cell arteritis are listed in *Table 4-12*. Onset is usually insidious, although occasionally it may be abrupt[95].

Table 4-12 Signs and symptoms of GCA[91, 94]

Frequent (> 50% of cases)	Occasional (10-50% of cases)	Rare (< 10% of cases)
H/A: 66% temporal artery tenderness	visual symptoms weight loss fever (low grade) proximal myalgias jaw claudication facial pain scalp tenderness	blindness extremity claudication tongue claudication ear pain synovitis stroke angina

Details of some findings:

1. H/A: the most common presenting symptom. May be nonspecific or located in one or both temporal areas, forehead, or occiput. May be superficial or burning with paroxysmal lancinating pain
2. symptoms relating to ECA blood supply (strongly suggestive of GCA, but not pathognomonic[96]): jaw claudication, tongue, or pharyngeal muscles
3. ophthalmologic symptoms: due to arteritis and occlusion of branches of ophthalmic artery or posterior ciliary arteries
   A. symptoms include: amaurosis fugax (precedes permanent visual loss in 44%), blindness, visual field cuts, diplopia, ptosis, ocular pain, corneal edema, chemosis
   B. blindness: incidence is ≈ 7%, and once it occurs, recovery of sight is unlikely

4. systemic symptoms
   A. nonspecific constitutional symptoms: fever (may present as FUO in 15% of cases), anorexia, weight loss, fatigue, malaise
   B. 30% have neurologic manifestations. 14% are neuropathies including mononeuropathies and peripheral polyneuropathies of the arms or legs[97]
   C. musculoskeletal symptoms
      1. PMR is the most common (occurs in 40% of patients): *see page 77*
      2. peripheral arthritis, swelling & pitting edema of hands & feet in 25%
      3. arm claudication from stenosis of subclavian and axillary arteries
   D. thoracic aortic aneurysms: 17 times as likely in GCA. Annual CXRs are adequate for screening
5. temporal arteries on physical examination may exhibit tenderness, swelling, erythema, reduced pulsations, or nodularity. Normal in 33%
6. the presence of systemic symptoms correlates with a lower incidence of blindness or stroke

Differential diagnosis:
1. periarteritis nodosa (PAN): *see page 77*
2. hypersensitivity vasculitis
3. atherosclerotic occlusive disease
4. malignancy: symptoms of low grade fever, malaise and weight loss
5. infection
6. trigeminal neuralgia: *see page 551*[7]. ophthalmoplegic migraine
8. dental problems

EVALUATION

Laboratory studies

1. ESR > 40 mm/hr (usually > 50) by Westergren method (if > 80 mm/hr with above clinical syndromes, highly suggestive of GCA). ESR is normal in up to 22.5%[98]
2. C-reactive protein: another acute phase reactant that is more sensitive than ESR. Has the advantage that it can be performed on frozen sera
3. CBC: may show mild normochromic anemia[99]

4. rheumatoid factor, ANA, and serum complement usually normal
5. LFTs abnormal in 30% (usually elevated alkaline phosphatase)
6. tests for rheumatoid factor and ANA are usually negative
7. temporal artery angiography not helpful (angiography elsewhere indicated if suspicion of large artery involvement exists)
8. CT: usually not helpful, one report described calcified areas corresponding to the temporal arteries[100]
9. temporal artery biopsy: *see below*

TEMPORAL ARTERY BIOPSY

Sensitivity and specificity are shown in *Table 4-13*.

Table 4-13 Temporal artery biopsy

sensitivity	≈ 90% (reported range[94, 101] is 9-97%)
specificity	near 100%
predictive value	≈ 94%

Indications and timing

Current recommendations: temporal artery biopsy in all patients suspected of having GCA[91].

Preferably, biopsy should be done before treatment is initiated[91]. However, pathologic changes be seen after more than 2 weeks of therapy[102], therefore do not withhold steroids to await biopsy.

Technique of temporal artery biopsy

Biopsy side of involvement if laterality exists. The yield is increased by removing a portion of artery that is involved clinically (a tender or inflamed segment)[103]. Mark the frontal branch of the STA with a skin marker (spare the main trunk and parietal branch if possible). Infiltrate local anesthetic. The incision is made parallel to the artery and if possible behind the hairline. The incision is taken down to the fascia of the temporalis muscle, to which the STA is superficial[104]. Optimal length of STA biopsy: 4-6 cm (if an abnormal segment of STA can be palpated, some say that a smaller biopsy to include this area may be sufficient, but this is probably unreliable as the muscle may be tender, etc.). Step-sectioning by pathologist through the entire length of the biopsy specimen

also increases the yield.

Frozen sections can be performed. Biopsy of the contralateral side if the first side is negative in cases where clinical suspicion is high increases the yield by 5-10%.

TREATMENT

No known cure. Steroids can produce symptomatic relief and usually prevent blindness (progression of ocular problems 24-48 hrs after institution of adequate steroids is rare). Totally blind patients or those with longstanding partial visual loss are unlikely to respond to any treatment.

1. for most cases:
   A. start with prednisone, 40-60 mg/d PO divided BID-QID (qod dosing is usually not effective in initial management) (*see* *page 31* for dosing forms…)
   B. if no response after 72 hrs, and diagnosis certain, ↑ to 10-25 mg QID
   C. once response occurs (usually within 3-7 days), give entire dose as q AM dose for 3-6 weeks until symptoms resolved and ESR normalizes (occurs in 87% of patients within ≈ 4 weeks) or stabilizes at < 40-50 mm/hr
   D. once quiescent, a gradual taper is performed to prevent exacerbations: reduce by 10 mg/d q 2-4 weeks to 40 mg/d, then by 5 mg/d q 2-4 wks to 20 mg/d, then by 2.5 mg/d q 2-4 wks to 5-7.5 mg/d which is maintained for several months, followed by 1 mg/d decrements q 1-3 mos (usual length of treatment is 6-24 mos; do not D/C steroids when ESR normalizes)
   E. if symptoms recur during treatment, prednisone dose is temporarily increased until symptoms resolve (isolated rise in ESR is not sufficient reason to increase steroids[91])
   F. patients should be followed closely for ≈ 2 years
2. in severely ill patients: methylprednisolone, 15-20 mg IV QID
3. anticoagulant therapy: controversial
4. acute blindness (onset within 24-36 hrs) in a patient with giant cell arteritis:
   A. consider up to 500 mg methylprednisolone IV over 30-60 mins (no controlled studies show reversal of blindness)
   B. some have used intermittent inhalation of 5% carbon dioxide and oxygen

OUTCOME

Complications of steroid therapy occur in ≈ 50% of patients (most are not life threatening, and include vertebral compression fractures in ≈ 36%, peptic ulcer disease in ≈ 12%, proximal myopathy, cataracts, exacerbation of diabetes; also see *Possible deleterious side effects of steroids*, page 33).

30-50% of patients will have spontaneous exacerbations of GCA (especially during the first 2 years) regardless of the corticosteroid regimen[91].

Survival parallels that of the general population. Onset of blindness after initiation of steroid therapy is rare.

4.10.2. Polymyalgia rheumatica (PMR)

PMR and giant cell arteritis **(GCA)** (*see page 74*) may be different points on a continuum of the same disease. Both have in increased frequency of HLA-DR[4] and systemic monocyte activation. 15% of patients with PMR eventually develop GCA.

Epidemiology[91]

Both GCA & PMR occur in people ≥ 50 years old. The incidence increases with age and peaks between 70-80 years and is higher at higher latitudes[91].

PMR is more common than GCA. Prevalence: 500/100,000)[105]. Incidence: 52.5 per 100,000 people ≥ age 50, higher in females (61.7) than males (39.9)[106].

Features[91]

- an inflammatory condition of unknown etiology
- clinical characteristics
    - A. aching and morning stiffness in the cervical region and shoulder & pelvic girdles lasting > 1 month. The pain usually increases with movement
        1. shoulder pain: present in 70-95% of patients. Radiates toward elbow
        2. hip & neck pain: 50-70%. Hip pain radiates towards knees
    - B. age ≥ 50 years
    - C. ESR ≥ 40 mm/hr (7-20% have normal ESR[107])
    - D. usually responds rapidly to low dose corticosteroids (≤ 20 mg

prednisone/day) *see below*

E. systemic symptoms (present in ≈ 33%): fever, malaise or fatigue, anorexia and weight loss

- favorable prognosis: usually remits in 1-3 years

Treatment

PMR responds to either to low doses of steroids[105] (10-20 mg prednisone/day) or sometimes to NSAIDs (response to steroids is much more rapid). The initial dose of steroids is maintained for 2-4 weeks, and then by ≤ 10% of the daily dose every 1-2 weeks[91] while observing for signs of GCA.

4.10.3. Other vasculitides

PERIARTERITIS NODOSA

AKA polyarteritis nodosa. Actually a group of necrotizing vasculitides, including:

- classic periarteritis nodosa **(PAN)**: a multisystem disease with inflammatory necrosis, thrombosis (occlusion), and hemorrhage of arteries and arterioles in every organ except lung & spleen. Nodules may be palpated along medium sized muscular arteries. Commonly produces mononeuritis multiplex, weight loss, fever, and tachycardia. Peripheral nerve manifestations are attributed to arteritic occlusion of vasa nervorum. CNS manifestations are uncommon and include H/A, seizures, SAH, retinal hemorrhages, and stroke in ≈ 13%
- allergic angiitis and granulomatosis (Churg-Strauss syndrome)
- systemic necrotizing vasculitis

These patients do better when treated with cyclophosphamide rather than steroids.

WEGENER'S GRANULOMATOSIS

A systemic necrotizing granulomatous vasculitis involving the respiratory tract (lung → cough/hemoptysis, and/or nasal airways → serosanguinous nasal drainage ± septal perforation → characteristic "saddle nose deformity") and frequently the kidneys (no reported cases of kidney involvement without respiratory)[108].

Nasal obstruction and crusting are the usual initial findings. Arthralgia (not true arthritis) is present in > 50%.

Neurologic involvement usually consists of cranial nerve dysfunction (usually II, III, IV, & VI; less often V, VII, & VIII; and least commonly IX, X, XI, & XII) and peripheral neuropathies, with diabetes insipidus (occasionally preceding other symptoms by up to 9 months). Focal lesions of the brain and spinal cord occur less frequently.

Differential diagnosis includes:

- "**lethal midline granuloma**" (may be similar or identical to polymorphic reticulosis) may evolve into lymphoma. May cause fulminant local destruction of the nasal tissue. Differentiation is crucial as this condition is treated by radiation; one should avoid immune suppression (e.g. cyclophosphamide). Probably does not involve true granulomas. Renal and tracheal involvement do not occur
- fungal disease: *Sporothrix schenckii* & Coccidioides may cause identical syndrome
- other vasculitides: especially Churg-Strauss syndrome (asthma and peripheral eosinophilia usually seen), and PAN (granulomas usually lacking)

LYMPHOMATOID GRANULOMATOSIS

Rare; affects mainly the lungs, skin (erythematous macules or indurated plaques in 40%) and nervous system (CNS in 20%, peripheral neuropathies in 15%). Sinuses, lymph nodes, and spleen are usually spared.

BEHÇET'S SYNDROME

Relapsing ocular lesions and recurrent oral and genital ulcers, with occasional skin lesions, thrombophlebitis, and arthritis 90. H/A occur in > 50%. Neurologic involvement includes pseudotumor, cerebellar ataxia, paraplegia, seizures, and dural sinus thrombosis. Only 5% have neurologic symptoms as the presenting complaint.

86% have CSF pleocytosis and protein elevation. Cerebral angiography is usually normal. CT may show focal areas of enhancing low density.

Steroids usually ameliorate ocular and cerebral symptoms, but usually have no effect on skin and genital lesions. Uncontrolled trials of cytotoxic agents → some benefit. Thalidomide may be effective (uncontrolled studies), but carries risk of serious adverse effects (teratogenicity, peripheral neuropathy…)[109].

Although painful, the disease is usually benign. Neurologic involvement portends a worse prognosis.

ISOLATED CNS VASCULITIS

AKA **isolated angiitis of the CNS**. Rare (≈ 20 cases reported[110] as of 1983); limited to vessels of CNS. Small vessel vasculitis is ≈ always present → segmental inflammation and necrosis of small leptomeningeal and parenchymal blood vessels with surrounding tissue ischemia or hemorrhage[90].

PRESENTATION

Combinations of H/A, confusion, dementia, and lethargy. Occasionally seizures. Focal and multifocal brain disturbance occurs in > 80%. Visual symptoms are frequent (secondary either to involvement of choroidal and retinal arteries, or to involvement of visual cortex → visual hallucinations).

EVALUATION

ESR & WBC count are usually normal. CSF may be normal or have pleocytosis and/or elevated protein. CT may show enhancing areas of low density.

Angiography (required for diagnosis): characteristically shows multiple areas of symmetrical narrowing ("string of pearls" configuration). If normal, it does not exclude diagnosis.

Histological diagnosis (recommended): all biopsy material should be cultured. Brain parenchyma biopsy infrequently shows vasculitis. Leptomeningeal biopsy invariably shows involvement.

HYPERSENSITIVITY VASCULITIS

Neurologic involvement is not a prominent feature of this group of vasculitides, which include:

- drug induced allergic vasculitis
- cutaneous vasculitis
- serum sickness: may → encephalopathy, seizures, coma, peripheral neuropathy and brachial plexopathy
- Henoch-Schönlein purpura

DRUG INDUCED VASCULITIS

A number of drugs are associated with the development of cerebral

vasculitis. These include methamphetamines (“speed”), cocaine (frank vasculitis occurs[111] but is rare), heroin and ephedrine.

4.10.4. Fibromuscular dysplasia

A vasculopathy (angiopathy) affecting primarily branches of the aorta, with renal artery involvement in 85% of cases (the most common site) and commonly associated with hypertension. The disease has an incidence of ≈ 1%, and results in multifocal arterial constrictions and intervening regions of aneurysmal dilatation.

The second most commonly involved site is the cervical internal carotid (primarily near C1-2), with fibromuscular dysplasia **(FMD)** appearing on 1% of carotid angiograms, making FMD the second most common cause of extracranial carotid stenosis[112]. Bilateral cervical ICA involvement occurs in ≈ 80% of cases. 50% of patients with carotid FMD have renal FMD. Patients with FMD have an increased risk of intracranial aneurysms and neoplasms, and are probably at higher risk of carotid dissection.

Table 4-14 Previous symptoms in 37 cases of aortocranial FMD[113]

Symptom	%
H/A	78%
mental distress	48%
tinnitus	38%
vertigo	34%
cardiac arrhythmia	31%
TIA	31%
syncope	31%
carotidynia	21%
epilepsy	15%
hearing impairment	12%
abdominal angina	8%
angina/MI	8%

Etiology

The actual etiology remains unknown, although congenital defects of the

media (muscular layer) and internal elastic layer of the arteries has been identified which may predispose the arteries to injury from otherwise well-tolerated trauma. A high familial rate of strokes, HTN, and migraine have supported the suggestion that FMD is an autosomal dominant trait with reduced penetrance in males[113].

Aneurysms and fibromuscular dysplasia

The reported incidence of aneurysms with FMD[114] ranges from 20-50%.

PRESENTATION

Most patients have recurrent, multiple symptoms shown in *Table 4-14*.

Up to 50% of patients present with episodes of transient cerebral ischemia or infarction. However, FMD may also be an incidental finding and some cases have been followed for 5 years without recurrence of ischemic symptoms suggesting that FMD may be a relatively benign condition.

Headaches are commonly unilateral and may be mistaken for typical migraine. Syncope may be caused by involvement of the carotid sinus.

Horner's syndrome occurs in ≈ 8% of cases. T-wave changes on EKG may be seen in up to one third of cases, and may be due to involvement of the coronary arteries.

Diagnosis

The "gold-standard" for the diagnosis of FMD is the angiogram. The three angiographic types of FMD[115] are shown in *Table 4-15*.

Treatment

Medical therapy including antiplatelet medication (e.g. aspirin) has been recommended.

Direct surgical treatment is problem ridden due to the difficult location (high carotid artery, near the base of the skull), and the friable nature of the vessels making anastomosis or arteriotomy closure difficult.

Transluminal angioplasty has achieved some degree of success. Carotid cavernous fistulas and arterial rupture have been reported as complications.

Table 4-15 Angiographic classification of FMD

Type	Findings
1	most common (80-100% of reported cases). Multiple, irregularly spaced, concentric narrowings with normal or dilated intervening segments giving rise to the so-called "**string of pearls**"

	appearance. Corresponds with arterial medial fibroplasia
2	focal tubular stenosis, seen in ≈ 7% of cases. Less characteristic for FMD than Type 1, and may also be seen in Takayasu's arteritis and other conditions
3	"atypical FMD". Rare. May take on various appearances, most commonly consisting of diverticular outpouchings of one wall of the artery

4.10.5. Miscellaneous vasculopathies

CADASIL

Key concepts:

- clinical: migraines, dementia, TIAs, psychiatric disturbances
- MRI: white matter abnormalities
- autosomal dominant inheritance
- anticoagulants controversial, generally discouraged

An acronym for Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy[116]. A familial disease with onset in early adulthood (mean age at onset: 45 ± 11 yrs), mapped to chromosome 19. Clinical and neuroradiologic features are similar to those seen with multiple subcortical infarcts from HTN, except there is no evidence of HTN. The vasculopathy is distinct from that seen in lipohyalinosis, arteriosclerosis and amyloid angiopathy, and causes thickening of the media of leptomeningeal and perforating arteries measuring 100-400 µm in diameter.

Clinical involvement: recurrent subcortical infarcts (84%), progressive or stepwise dementia (31%), migraine with aura (22%), and depression (20%). All symptomatic and 18% of asymptomatic patients had prominent subcortical white-matter and basal ganglia hyperintensities on T2WI MRI.

Treatment: Coumadin® is used by some.

NOTES

5. Neuroanatomy and physiology

5.1. Surface anatomy

5.1.1. Cortical surface anatomy

Lateral cortical surface (*Figure 5-1*)

For abbreviations, *see Table 5-2* and *Table 5-1*. The MFG is usually more sinuous than the IFG or SFG, and it often connects to the pre-central gyrus via a thin isthmus[1]. The central sulcus joins the Sylvian fissure in only 2% of cases (i.e. in 98% of cases there is a "subcentral" gyrus). The intraparietal sulcus **(ips)** separates the superior and inferior parietal lobules. The IPL is composed primarily of the AG and SMG. The Sylvian fissure terminates in the SMG (Brodmann's area 40). The superior temporal sulcus terminates in the AG.

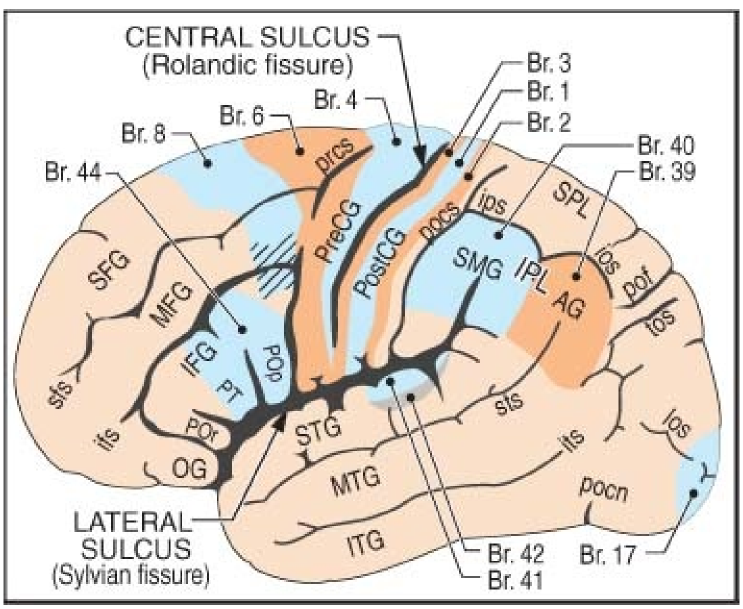

Figure 5-1 Left lateral cerebral cortical surface anatomy*

* Br. = Brodmann's area (shaded). See *Table 5-1* and *Table 5-2* for abbreviations (lowercase = sulci, UPPERCASE = gyri)

Brodmann’s areas

Figure 5-1 also identifies the clinically significant areas of Brodmann’s **(Br.)** map of the cytoarchitectonic fields of the human brain. Functional significance of these areas is as follows:

- Br. areas 3,1,2: primary somatosensory cortex
- Br. areas 41 & 42: primary auditory areas (transverse gyri of Heschl)
- Br. area 4: precentral gyrus, primary motor cortex (AKA “**motor strip**”). Large concentration of giant pyramidal cells of Betz
- Br. area 6: premotor area or supplemental motor area. Immediately anterior to motor strip, it plays a role in contralateral motor programming
- Br. area 44: (dominant hemisphere) **Broca’s area** (motor speech)[A]
- Br. area 17: primary visual cortex
- **Wernicke’s area** (language)[A]: in the dominant hemisphere, most of Br. area 40 and a portion of Br. area 39 (may also include ≈ posterior third of STG)
- the striped portion of Br. area 8 in *Figure 5-1* (frontal eye field) initiates voluntary eye movements to the opposite direction

A. language function cannot be reliably localized on anatomic grounds due to individual variability in its exact location; in order to perform maximal brain resections with minimal risk of aphasia, techniques such as intraoperative brain mapping[2] or looking for phase reversal on intraoperative cortical SSEP[3] should be employed (*see page 150*)

Medial surface

(*Figure 5-2*)

The cingulate sulcus terminates posteriorly in the **pars marginalis (pM)** (plural: partes marginales). On axial imaging, the pMs: are visible on 95% of CTs and 91% of MRIs[4], are usually the most prominent of the paired grooves straddling the midline, and they extend a greater distance into the hemispheres[4]. On axial CT, the pM is located slightly posterior to the widest biparietal diameter[4]; on the typically more horizontally oriented MRI slices the pM assumes a more posterior position. The pMs curve posteriorly in lower slices and anteriorly in higher slices (here, the paired pMs form the “**pars bracket**” - a characteristic “handlebar” configuration straddling the mid-line).

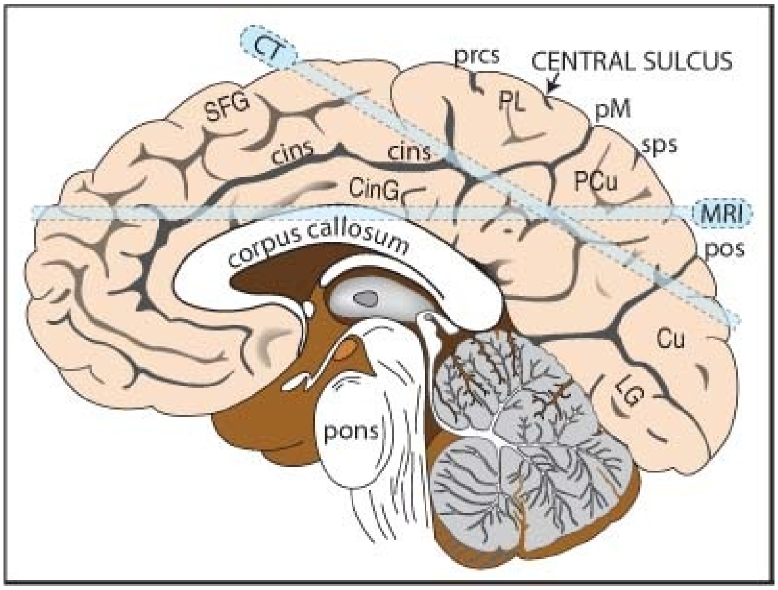

Figure 5-2 Medial aspect of the right hemisphere "CT" & "MRI" bars depict typical axial slice orientation for CT & MRI scans. See *Table 5-1* and *Table 5-2* for abbreviations

Central sulcus on axial imaging

See *Figure 5-3*. Identification is important to localize the motor strip (contained in the PreCG). The central sulcus **(CS)** is visible on 93% of CTs and 100% of MRIs[4]. It curves posteriorly as it approaches the interhemispheric fissure **(IHF)**, and often terminates in the paracentral lobule, just anterior to the pars marginalis **(pM)** within the pars bracket (*see above*)[4] (i.e. the CS often does not reach the midline).

Pointers:

- parieto-occipital sulcus **(pos)** (or fissure): more prominent over the medial surface, and on axial imaging is longer, more complex, and more posterior than the pars marginalis[5]
- post-central sulcus **(pocs)**: usually bifurcates and forms an arc or parenthesis ("lazy-Y") cupping the pM. The anterior limb does not enter the pM-bracket and the posterior limb curves behind the pM to enter the IHF

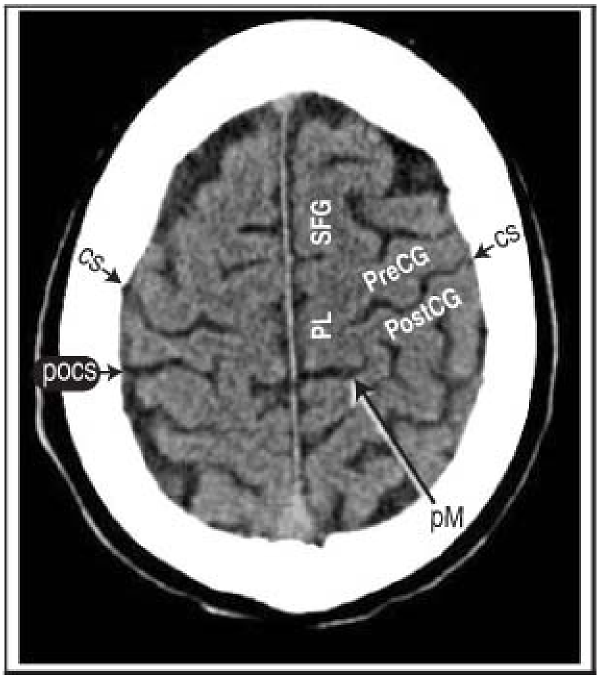

Figure 5-3 CT scan (upper cut) showing gyri/sulci. See *Table 5-1* and *Table 5-2* for abbreviations

Table 5-1 Cerebral sulci (abbreviations)

cins	cingulate sulcus
cs	central sulcus
ips-ios	intraparietal-intraoccipital sulcus
los	lateral occipital sulcus
pM	pars marginalis
pocn	pre-occipital notch
pocs	post-central sulcus
pof	parieto-occipital fissure
pos	parieto-occipital sulcus

AG	angular gyrus
CinG	cingulate gyrus
Cu	cuneus
LG	lingual gyrus
MFG, SFG	middle & superior frontal gyrus
OG	orbital gyrus
PCu	precuneous
PreCG, PostCG	pre- and post-central gyrus
PL	paracentral lobule (upper SFG and PreCG and PostCG)
IFG POp PT POr	inferior frontal gyrus pars opercularis pars triangularis pars orbitalis
STG, MTG, ITG	superior, middle & inferior temporal gyrus
SPL, IPL	superior & inferior parietal lobule
SMG	supramarginal gyrus

5.1.2. Surface anatomy of the cranium

CRANIOMETRIC POINTS

See *Figure 5-4*.

Pterion: region where the following bones are approximated: frontal, parietal, temporal and sphenoid (greater wing). Estimated as 2 fingerbreadths above the zygomatic arch, and a thumb's breadth behind the frontal process of the zygomatic bone (blue circle in *Figure 5-4*).

Asterion: junction of lambdoid, occipitomastoid and parietomastoid sutures. Usually lies within a few millimeters of the posterior-inferior edge of the junction of the transverse and sigmoid sinuses (not always reliable[6] - may overlie either sinus).

Vertex: the top-most point of the skull.

Lambda: junction of the lambdoid and sagittal sutures.

Stephanion: junction of coronal suture and superior temporal line.

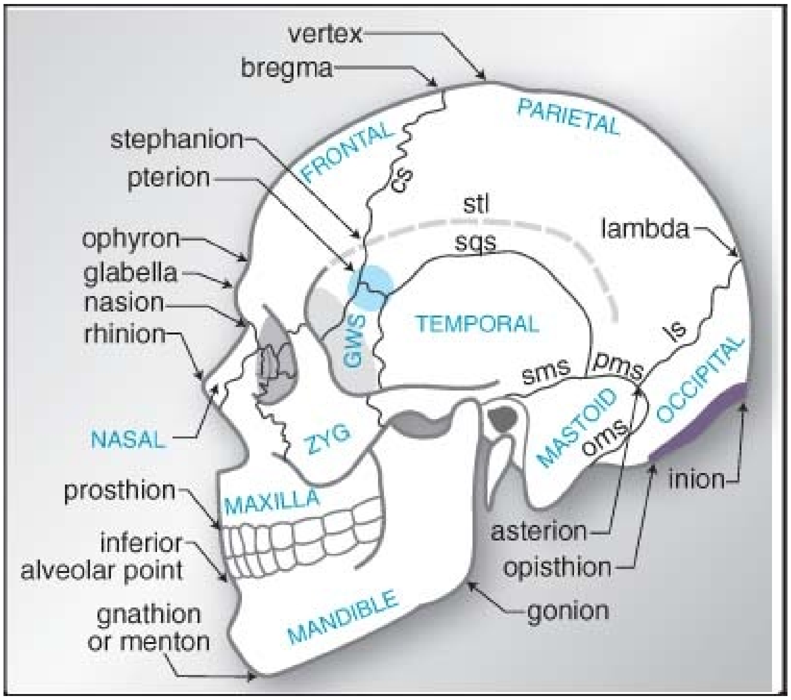

Figure 5-4 Craniometric points & cranial sutures.

Named bones appear in all upper case letters.
Abbreviations: GWS = greater wing of sphenoid bone, NAS = nasal bone, stl = superior temporal line, ZYG = zygomatic.
Sutures: cs = coronal, ls = lambdoid, oms = occipitomastoid, pms = parietomastoid, sms = squamomastoid, sqs = squamosal

Glabella: the most forward projecting point of the forehead at the level of the supraorbital ridge in the midline.

Opisthion: the posterior margin of the foramen magnum in the midline.

Bregma: the junction of the coronal and sagittal sutures.

Sagittal suture: midline suture from coronal suture to lambdoid suture. Although often assumed to overlie the superior sagittal sinus **(SSS)**, the SSS lies to the right of the sagittal suture in the majority of specimens[7] (but never by > 11 mm).

The most anterior mastoid point lies just in front of the sigmoid sinus[8].

RELATION OF SKULL MARKINGS TO CEREBRAL ANATOMY

Taylor-Haughton lines

Taylor-Haughton **(T-H)** lines can be constructed on an angiogram, CT scout film, or skull x-ray, and can then be re-constructed on the patient in the O.R.

based on visible external landmarks[9]. T-H lines are shown as dashed lines in *Figure 5-5*.

1. **Frankfurt plane**, AKA baseline: line from inferior margin of orbit through the upper margin of the external auditory meatus **(EAM)** (as distinguished from **Reid's base line**: from inferior orbital margin through the *center* of the EAM)[10 (p 313)]
2. the distance from the nasion to the inion is measured across the top of the calvaria and is divided into quarters (can be done simply with a piece of tape which is then folded in half twice)
3. posterior ear line: perpendicular to the baseline through the mastoid process
4. condylar line: perpendicular to the baseline through the mandibular condyle
5. T-H lines can then be used to approximate the sylvian fissure (*see below*) and the motor cortex (also *see below*)

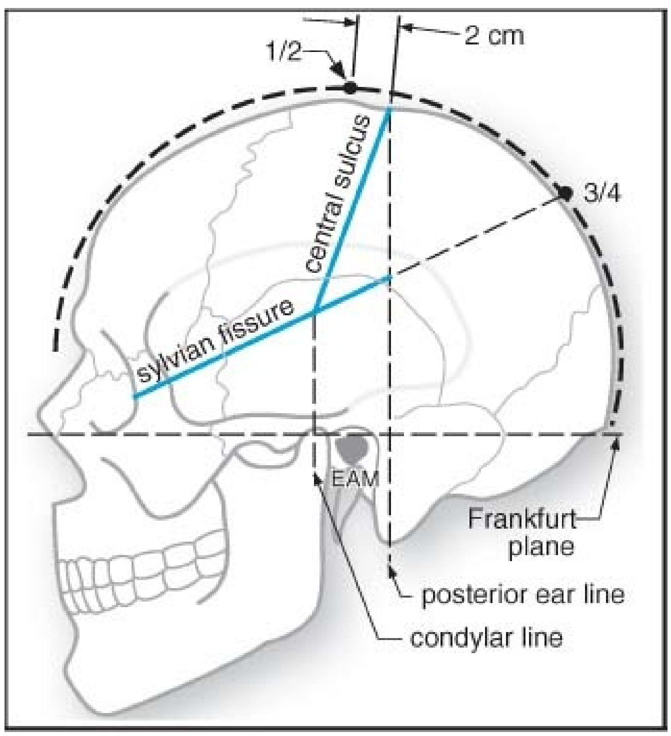

Figure 5-5 Taylor-Haughton lines and other localizing methods

Sylvian fissure AKA lateral fissure

Approximated by a line connecting the lateral canthus to the point 3/4 of the

way posterior along the arc running over convexity from nasion to inion (T-H lines).

Angular gyrus

Located just above the pinna, important on the dominant hemisphere as part of Wernicke's area. Note: there is significant individual variability in the location[2].

Angular artery

Located 6 cm above the EAM.

Motor cortex

Numerous methods utilize external landmarks to locate the motor strip (pre-central gyrus) or the central sulcus (Rolandic fissure) which separates motor strip anteriorly from primary sensory cortex posteriorly. These are just approximations since individual variability causes the motor strip to lie anywhere from 4 to 5.4 cm behind the coronal suture[11]. The central sulcus cannot even be reliably identified visually at surgery[12].

- method 1: the superior aspect of the motor cortex is almost straight up from the EAM near the midline
- method 2[13]: the central sulcus is approximated by connecting:
  - A. the point 2 cm posterior to the midposition of the arc extending from nasion to inion (illustrated in *Figure 5-5*), to
  - B. the point 5 cm straight up from the EAM
- method 3: using T-H lines, the central sulcus is approximated by connecting:
  - A. the point where the "posterior ear line" intersects the circumference of the skull (*see Figure 5-5*) (usually about 1 cm behind the vertex, and 3-4 cm behind the coronal suture), to
  - B. the point where the "condylar line" intersects the line representing the sylvian fissure
- method 4: a line drawn 45° to Reid's base line starting at the pterion points in the direction of the motor strip[14 (p 584-5)]

RELATIONSHIP OF VENTRICLES TO SKULL

Figure 5-6 shows the relationship of non-hydrocephalic ventricles to the skull in the lateral view. Some dimensions of interest are shown in *Table 5-3*[15].

In the non-hydrocephalic adult, the lateral ventricles lie 4-5 cm below the outer skull surface. The center of the body of the lateral ventricle sits in the midpupillary line, and the frontal horn is intersected by a line passing perpendicular to the calvaria along this line[16]. The anterior horns extend 1-2 cm anterior to the coronal suture.

Average length of third ventricle ≈ 2.8 cm.

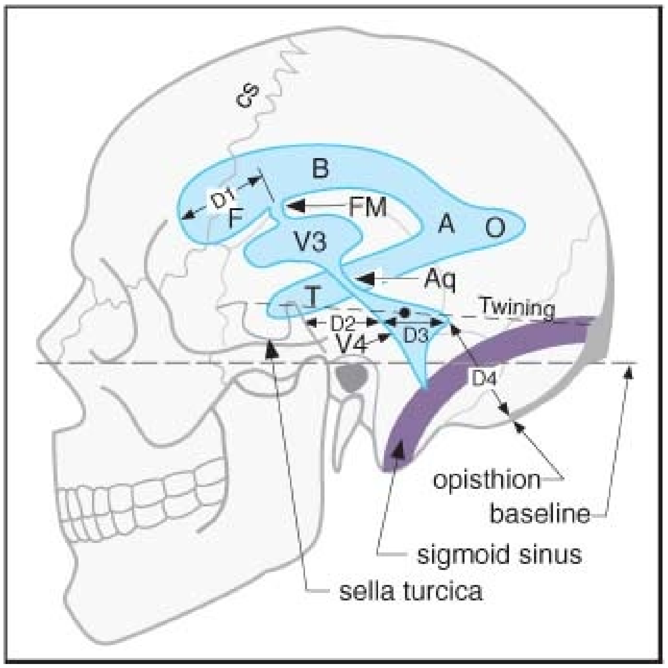

Figure 5-6 Relationship of ventricles to skull landmarks*

* Abbreviations: (F = frontal horn, B = body, A = atrium, O = occipital horn, T = temporal horn) of lateral ventricle. FM = foramen of Monro. Aq = sylvian aqueduct. V3 = third ventricle. V4 = fourth ventricle. cs = coronal suture. Dimensions D1-4 → *see Table 5-3*

Table 5-3 Dimensions from *Figure 5-6*

Dimension (*see Figure 5-6*)	Description	Lower limit (mm)	Average (mm)	Upper limit (mm)
D1	length of frontal horn anterior to FM		25	
D2	distance from clivus to floor of 4th ventricle at level of fastigium*	33.3	36.1	40.0
D3	length of 4th ventricle at level of fastigium*	10.0	14.6	19.0
D4	distance from fastigium* to opisthion	30.0	32.6	40.0

* the fastigium is the apex of the 4th ventricle within the cerebellum

5.1.3. Surface landmarks of spine levels

Estimates of cervical levels for anterior cervical spine surgery may be made using the landmarks shown in *Table 5-4*. Intraoperative C-spine x-rays are essential to verify these estimates.

The scapular spine is located at about T2-3.

The inferior scapular pole is ≈ T6 posteriorly.

Intercristal line: a line drawn between the highest point of the iliac crests across the back will cross the midline either at the interspace between the L4 and L5 spinous processes, or at the L4 spinous process itself.

Table 5-4 Cervical levels[17]

Level	Landmark
C1-2	angle of mandible
C3-4	1 cm above thyroid cartilage (≈ hyoid bone)
C4-5	level of thyroid cartilage
C5-6	crico-thyroid membrane
C6	carotid tubercle
C6-7	cricoid cartilage

5.2. Cranial foramina & their contents

Table 5-5 Cranial foramina and their contents*

Foramen	Contents
nasal slits	anterior ethmoidal nn., a. & v
superior orbital fissure	Cr. Nn. III, IV, VI, all 3 branches of V1 (ophthalmic division divides into nasociliary, frontal, and lacrimal nerves); superior ophthalmic vv.; recurrent meningeal br. from lacrimal a.; orbital branch of middle meningeal a.; sympathetic filaments from ICA plexus
inferior orbital fissure	Cr. N. V-2 (maxillary div.), zygomatic n.; filaments from pterygopalatine branch of maxillary n.; infraorbital a. & v.; v. between inferior ophthalmic v. & pterygoid venous plexus
foramen lacerum	usually nothing (ICA traverses the upper portion but doesn't enter, 30% have vidian a.)
carotid canal	internal carotid a., ascending sympathetic nerves
incisive	descending septal a.; nasopalatine nn.

foramen	
greater palatine foramen	greater palatine n., a., & v.
lesser palatine foramen	lesser palatine nn.
internal acoustic meatus	Cr. N. VII (facial); Cr. N. VIII (stato-acoustic) - (*see text* & *Figure 5-7* below)
hypoglossal canal	Cr. N. XII (hypoglossal); a meningeal branch of the ascending pharyngeal a.
foramen magnum	spinal cord (medulla oblongata); Cr. N. XI (spinal accessory nn.) entering the skull; vertebral aa.; anterior & posterior spinal arteries
foramen cecum	occasional small vein
cribriform plate	olfactory nn.
optic canal	Cr. N. II (optic); ophthalmic a.
foramen rotundum	Cr. N. V2 (maxillary div.), a. of foramen rotundum
foramen ovale	Cr. N. V3 (mandibular div.) + portio minor (motor for CrN V)
foramen spinosum	middle meningeal a. & v.
jugular foramen	internal jugular v. (beginning); Cr. Nn. IX, X, XI
stylomastoid foramen	Cr. N. VII (facial); stylomastoid a.
condyloid foramen	v. from transverse sinus
mastoid foramen	v. to mastoid sinus; branch of occipital a. to dura mater

* Abbreviations: a. = artery, aa. = arteries, v. = vein, vv. = veins, n. = nerve, nn. = nerves, br. = branch, Cr. N. = cranial nerve, fmn. = foramen, div. = division

Porus acusticus

AKA internal auditory canal (*see Figure 5-7*)

The filaments of the acoustic portion of VIII penetrate tiny openings of the lamina cribrosa of the cochlear area[18].

Transverse crest: separates superior vestibular area and facial canal (above) from the inferior vestibular area and cochlear area (below)[18].

Vertical crest (AKA Bill's bar): separates the meatus to facial canal anteriorly (containing VII and nervus intermedius) from the vestibular area posteriorly (containing the superior division of vestibular nerve).

The "5 nerves" of the IAC:

1. facial nerve (VII) (mnemonic: "7-up" as VII is in superior portion)
2. nervus intermedius: the somatic sensory branch of the facial nerve primarily innervating mechanoreceptors of the hair follicles on the inner surface of the pinna and deep mechanoreceptors of nasal and buccal cavities and chemoreceptors in the taste buds on the anterior 2/3 of the tongue
3. acoustic portion of the VIII nerve (mnemonic: "Coke down" for cochlear portion)
4. superior branch of vestibular nerve: passes through the superior vestibular area to terminate in the utricle and in the ampullæ of the superior and lateral semi-circular canals
5. inferior branch of vestibular nerve: passes through inferior vestibular area to terminate in the saccule

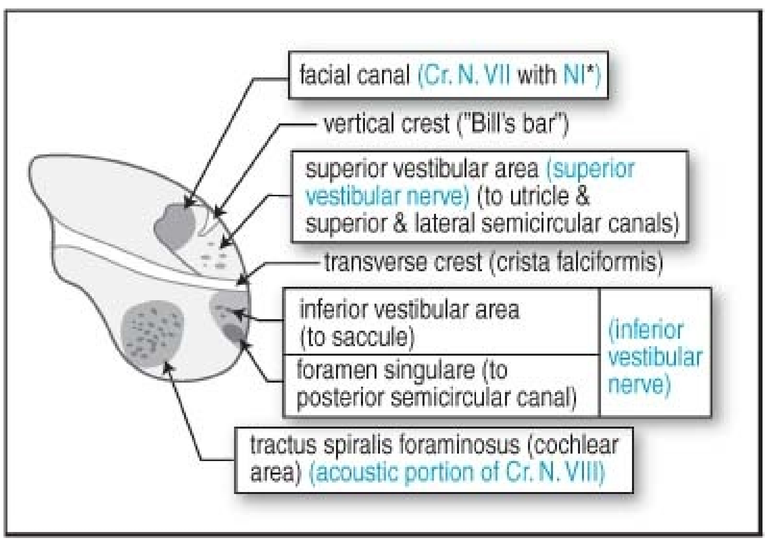

Figure 5-7 Right internal auditory canal (porus acusticus) & nerves

* NI = nervus intermedius

5.3. Cerebellopontine angle anatomy

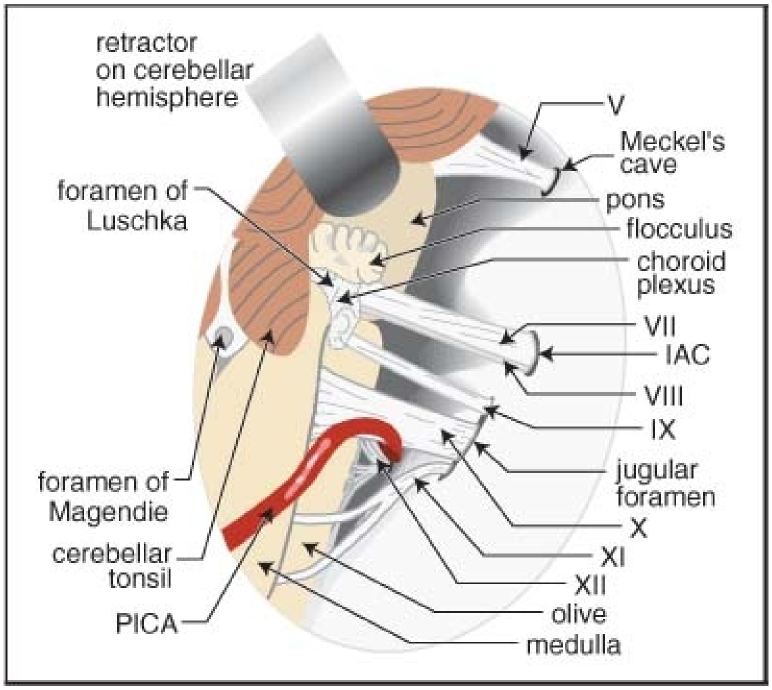

Figure 5-8 Normal anatomy of right cerebellopontine angle viewed from behind (as in a suboccipital approach)[18]

5.4. Occiptoatlantoaxial-complex anatomy

≈ 50% of head rotation occurs at the C1-2 (atlantoaxial) joint.

Ligaments of the occipito-atlanto-axial complex

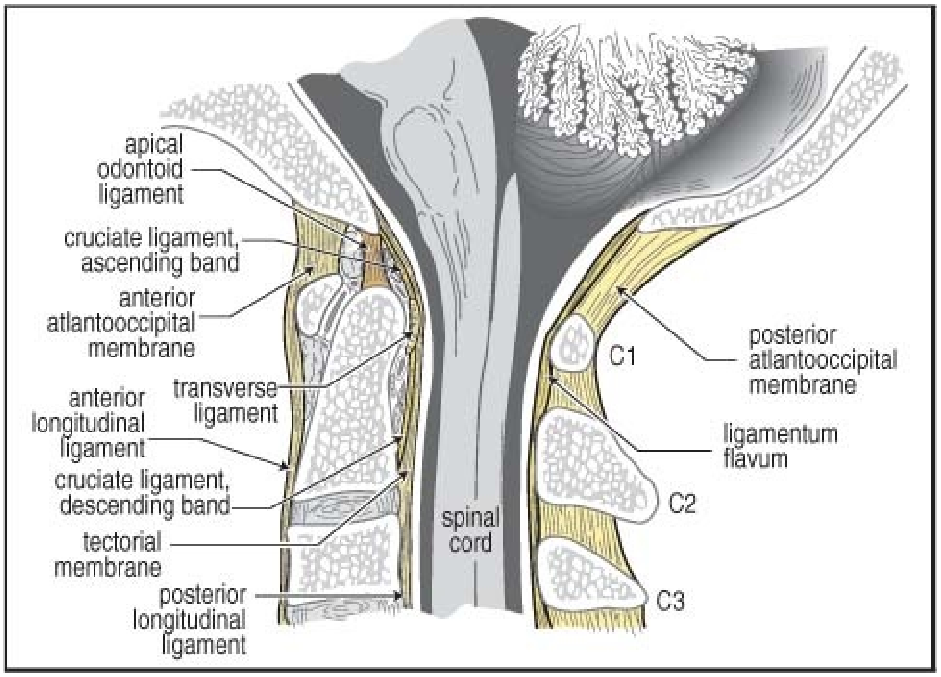

Figure 5-9 Sagittal view of the ligaments of the craniovertebral junction Modified with permission from "In Vitro Cervical Spine Biomechanical Testing" BNI Quarterly, Vol.9, No. 4, 1993

Stability of this joint complex is primarily due to ligaments, with little contribution from bony articulations and joint capsules (*see Figure 5-9* through *Figure 5-11*):

1. ligaments that connect the atlas to the occiput:
   A. anterior atlanto-occipital membrane: cephalad extension of the anterior longitudinal ligament. Extends from anterior margin of foramen magnum **(FM)** to anterior arch of C1
   B. posterior atlanto-occipital membrane: connects the posterior margin of the FM to posterior arch of C1
   C. the ascending band of the cruciate ligament

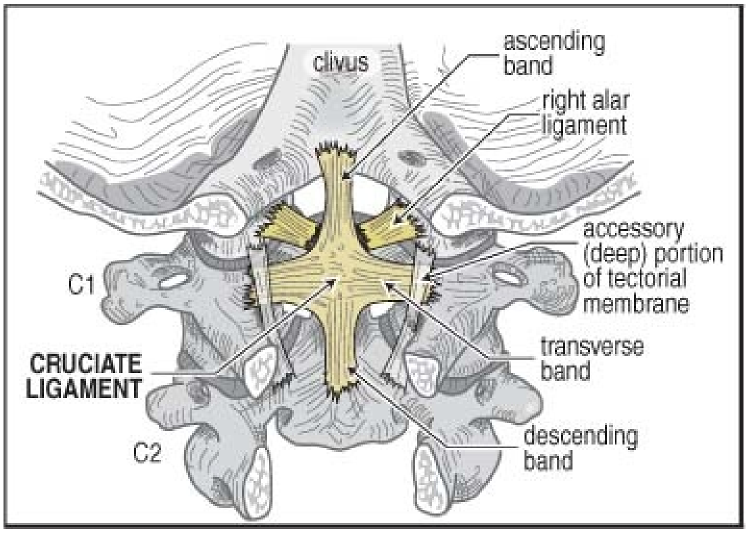

Figure 5-10 Dorsal view of the cruciate and alar ligaments Viewed with tectorial membrane removed. Modified with permission from "In Vitro Cervical Spine Biomechanical Testing" BNI Quarterly, Vol.9, No. 4, 1993

2. ligaments that connect the axis (viz. the odontoid) to the occiput:
   A. **tectorial membrane**: some authors distinguish 2 components
      1. superficial component: cephalad continuation of the posterior longitudinal ligament. A strong band connecting the dorsal surface of the dens to the ventral surface of the FM above, and dorsal surface of C2 & C3 bodies below
      2. accessory (deep) portion: located laterally, connects C2 to occipital condyles
   B. alar ("check") ligaments[19]
      1. occipito-alar portion: connects side of the dens to occipital condyle
      2. atlanto-alar portion: connects side of the dens to the lateral mass of C1
   C. apical odontoid ligament: connects tip of dens to the FM. Little mechanical strength
3. ligaments that connect the axis to the atlas:
   A. **transverse (atlanto-axial) ligament**: the horizontal component of the **cruciate** ligament. Traps the dens against the anterior atlas via a strap-like mechanism (*see Figure 5-11*). Provides the majority of the strength ("the strongest ligament of the spine"[20])
   B. atlanto-alar portion of the alar ligaments (*see above*)
   C. descending band of the cruciate ligament

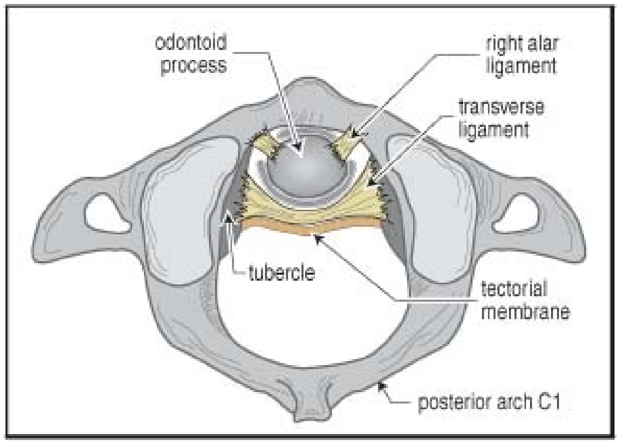

Figure 5-11 C1 viewed from above, showing the transverse and alar ligaments Modified with permission from "In Vitro Cervical Spine Biomechanical Testing" BNI Quarterly, Vol.9, No. 4, 1993

The most important structures in maintaining atlanto-occipital stability are the tectorial membrane and the **alar ligaments**. Without these, the remaining cruciate ligament and apical dentate ligament are insufficient.

5.5. Spinal cord anatomy

5.5.1. Spinal cord tracts

Figure 5-12 depicts a cross-section of a typical spinal cord segment, combining some elements from different levels (e.g. the intermediolateral grey nucleus is only present from T1 to ≈ L1 or L2 where there are sympathetic (thoracolumbar outflow) nuclei). It is schematically divided into ascending and descending halves, however, in actuality, ascending and descending paths coexist on both sides.

Table 5-6 Descending (motor) tracts (↓) in *Figure 5-12*

Number (*see Figure 5-12*)	Path	Function	Side of body
1	anterior corticospinal tract	skilled movement	opposite
2	medial longitudinal fasciculus	?	same
3	vestibulospinal tract	facilitates extensor muscle tone	same
4	medullary (ventrolateral) reticulospinal tract	automatic respirations?	same
5	rubrospinal tract	flexor muscle tone	same
6	lateral corticospinal (pyramidal) tract	skilled movement	same

Table 5-7 Bi-directional tracts in *Figure 5-12*

Number (*see Figure 5-12*)	Path	Function
7	dorsolateral fasciculus (of Lissauer)	
8	fasciculus proprius	short spinospinal connections

Table 5-8 Ascending (sensory) tracts (↑) in *Figure 5-12*

Number (*see Figure 5-12*)	Path	Function	Side of body
9	fasciculus gracilis	joint position, fine touch, vibration	same
10	fasciculus cuneatus		
11	posterior spinocerebellar tract	stretch receptors	same
12	lateral spinothalamic tract	pain & temperature	opposite
13	anterior spinocerebellar tract	whole limb position	opposite
14	spinotectal tract	unknown, ? nociceptive	opposite
15	anterior spinothalamic tract	light touch	opposite

Figure 5-12 also depicts some of the laminae according to the scheme of Rexed. Lamina II is equivalent to the substantia gelatinosa. Laminae III and IV are the nucleus proprius. Lamina VI is located in the base of the posterior horn.

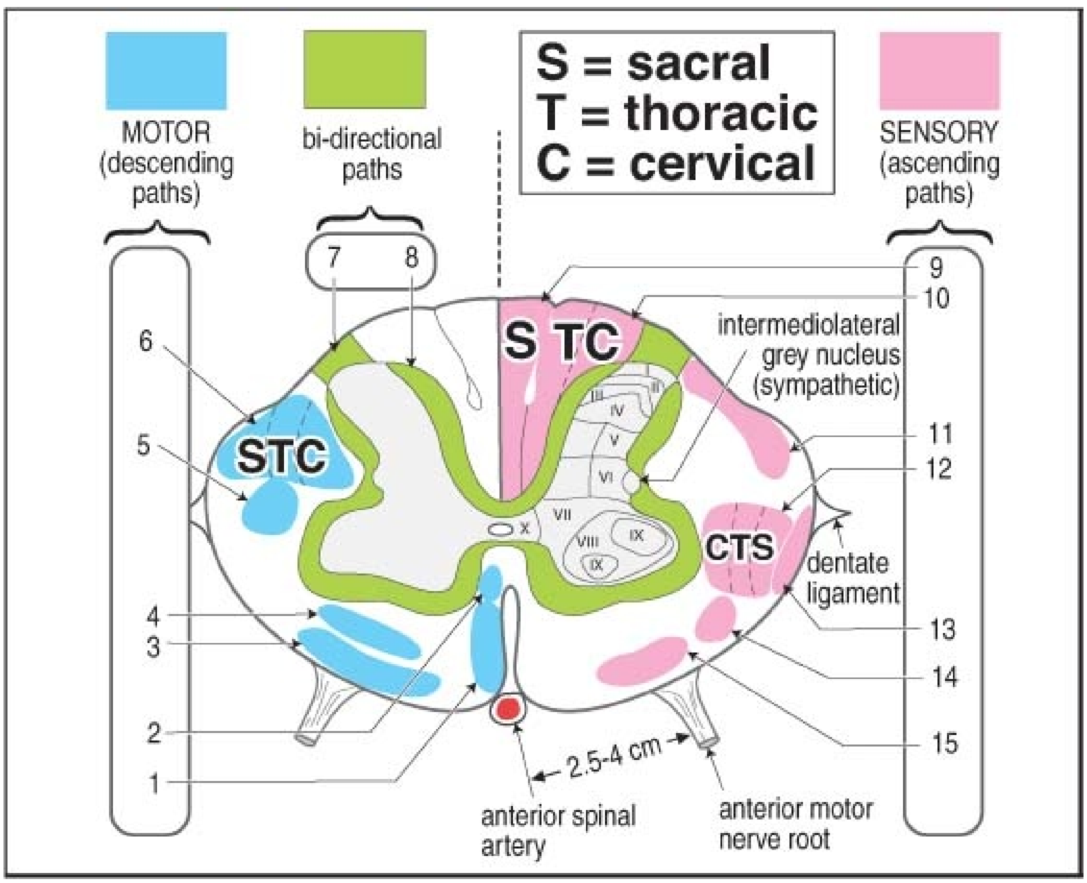

Figure 5-12 Schematic cross-section of cervical spinal cord

SENSATION

PAIN & TEMPERATURE: BODY

Receptors: free nerve endings (probable).

1st order neuron: small, finely myelinated afferents; soma in dorsal root ganglion (no synapse). Enter cord at dorsolateral tract (zone of Lissauer). Synapse: substantia gelatinosa (Rexed II).

2nd order neuron axon cross obliquely in the anterior white commissure ascending ≈ 1-3 segments while crossing to enter the lateral spinothalamic tract.

Synapse: VPL thalamus. 3rd order neurons pass through IC to postcentral gyrus (Brodmann's areas 3, 1, 2).

FINE TOUCH, DEEP PRESSURE & PROPRIOCEPTION: BODY

Fine touch AKA discriminative touch. Receptors: Meissner's & pacinian corpuscles, Merkel's disks, free nerve endings.

1st order neuron: heavily myelinated afferents; soma in dorsal root ganglion (no synapse). Short branches synapse in nucleus proprius (Rexed III & IV) of posterior gray; long fibers enter the ipsilateral posterior columns without synapsing (below T6: fasciculus gracilis; above T6: fasciculus cuneatus).

Synapse: nucleus gracilis/cuneatus (respectively), just above pyramidal decussation. 2nd order neuron axons form internal arcuate fibers, decussate in lower medulla as **medial lemniscus**.

Synapse: VPL thalamus. 3rd order neurons pass through IC primarily to postcentral gyrus.

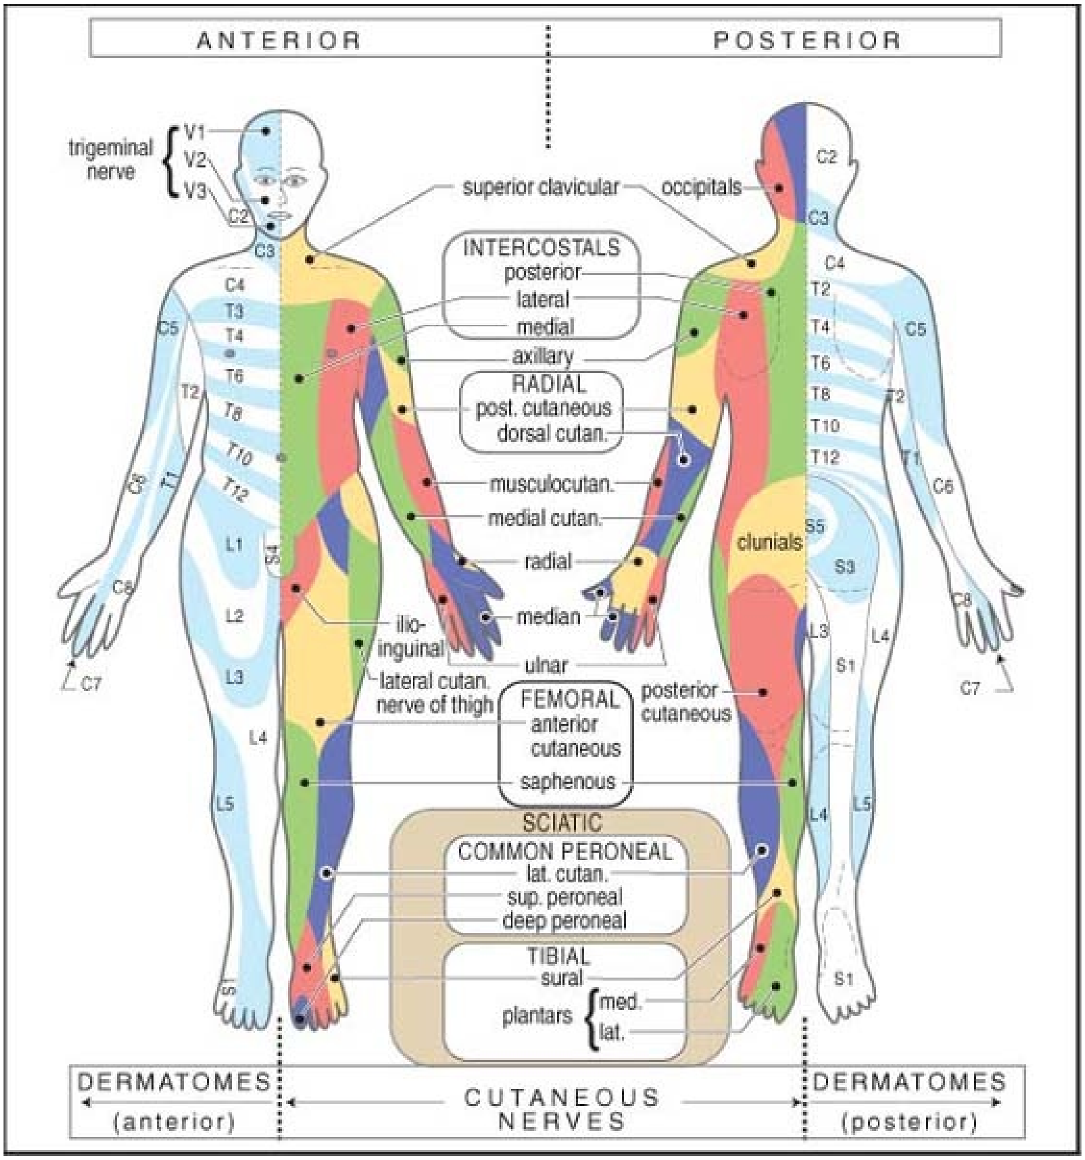

Figure 5-13 Dermatomal and sensory nerve distribution
(Redrawn from "Introduction to Basic Neurology", by Harry D. Patton, John W. Sundsten, Wayne E. Crill and Phillip D. Swanson, © 1976, pp 173, W. B. Saunders Co., Philadelphia, PA, with permission)

LIGHT (CRUDE) TOUCH: BODY

Receptors: as fine touch (*see above*), also peritrichial arborizations.

1st order neuron: large, heavily myelinated afferents (Type II); soma in dorsal root ganglion (no synapse). Some ascend uncrossed in post. columns

(with fine touch); most synapse in Rexed VI & VII.

2nd order neuron axons cross in anterior white commissure (a few don't cross); enter anterior spinothalamic tract.

Synapse: VPL thalamus. 3rd order neurons pass through IC primarily to postcentral gyrus.

5.5.2. Dermatomes and sensory nerves

Figure 5-13 shows anterior and posterior view, each schematically separated into sensory dermatomes (segmental) and peripheral sensory nerve distribution.

5.5.3. Spinal cord vasculature

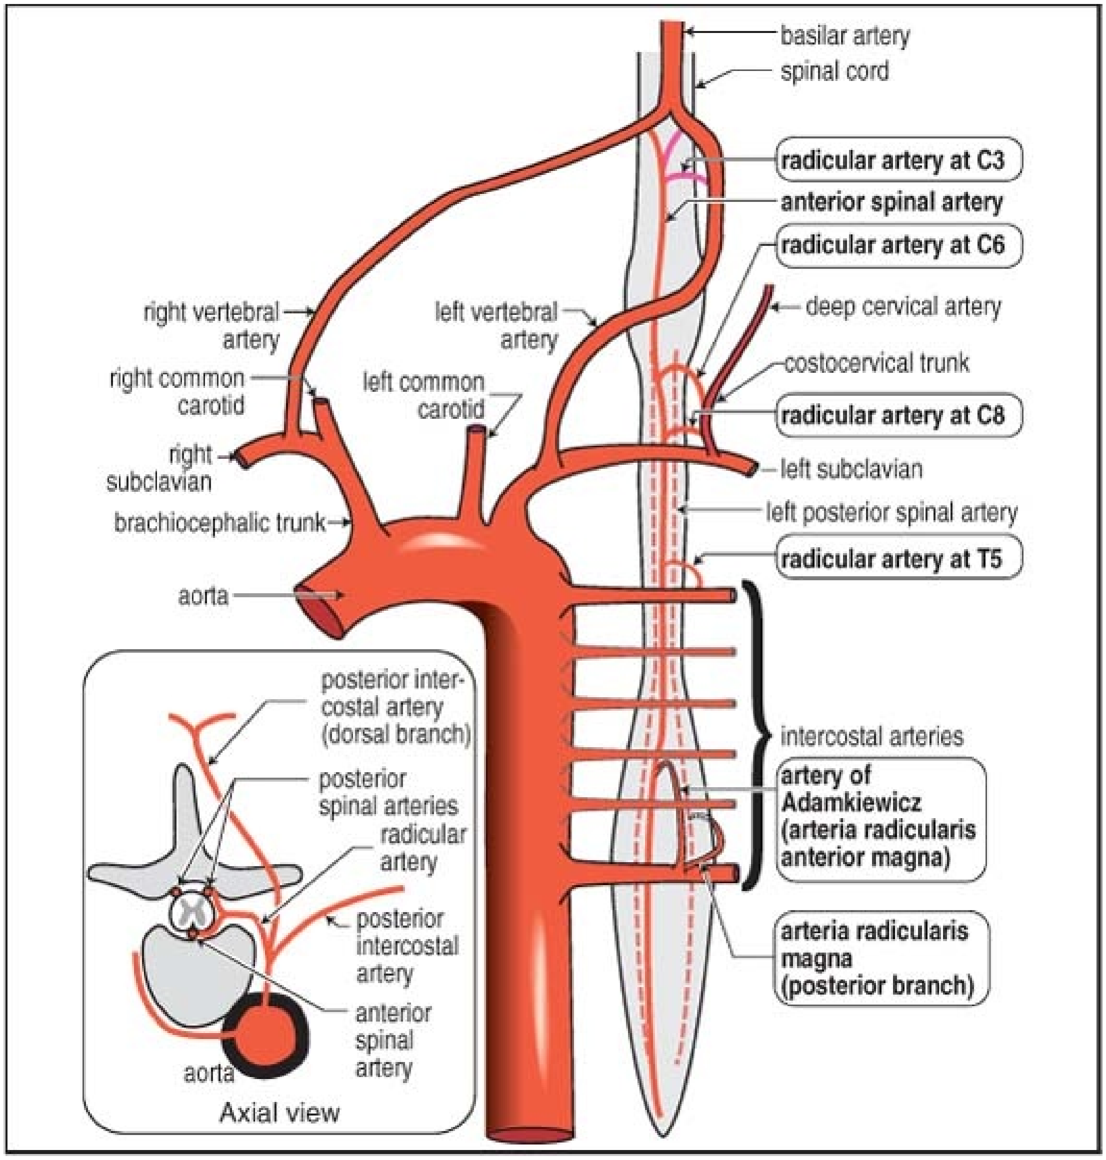

Figure 5-14 Schematic diagram of spinal cord arterial supply
Modified from **Diagnostic Neuroradiology**, 2nd ed., Volume II, pp. 1181, Taveras J M, Woods EH, editors, © 1976, the Williams and Wilkins Co., Baltimore, with permission)

Although a radicular artery from the aorta accompanies the nerve root at many levels, most of these contribute little flow to the spinal cord itself. The anterior spinal artery is formed from the junction of two branches, each from one of the vertebral arteries. Major contributors of blood supply to the anterior spinal cord is from 6-8 radicular arteries at the following levels ("radiculomedullary arteries", the levels listed are fairly consistent, but the side varies[21] (p 1180-1)):

- C3 - arises from vertebral artery
- C6 - usually arises from deep cervical artery } ≈ 10% of population lack an

anterior radicular artery in lower cervical spine[22]

- C8 - usually from costocervical trunk } ≈ 10% of population lack an anterior radicular artery in lower cervical spine[22]
- T4 or T5
- **artery of Adamkiewicz** AKA arteria radicularis anterior magna
  A. the main arterial supply for the spinal cord from ≈ T8 to the conus
  B. located on the left in 80%[23]
  C. situated between T9 & L2 in 85% (between T9 & T12 in 75%); in remaining 15% between T5 & T8 (in these latter cases, there may be a supplemental radicular artery further down)
  D. usually fairly large, gives off cephalic and caudal branch (latter is usually larger) giving a characteristic hair-pin appearance on angiography

The paired posterior spinal arteries are less well defined than the anterior spinal artery, and are fed by 10-23 radicular branches.

The midthoracic region has a tenuous vascular supply (“watershed zone”), possessing only the above noted artery at T4 or T5. It is thus more susceptible to vascular insults.

ANATOMIC VARIANTS

Arcade of Lazorthes: normal variant where the anterior spinal artery joins with the paired posterior spinal arteries at the conus medullaris.

5.6. Cerebrovascular anatomy

5.6.1. Cerebral vascular territories

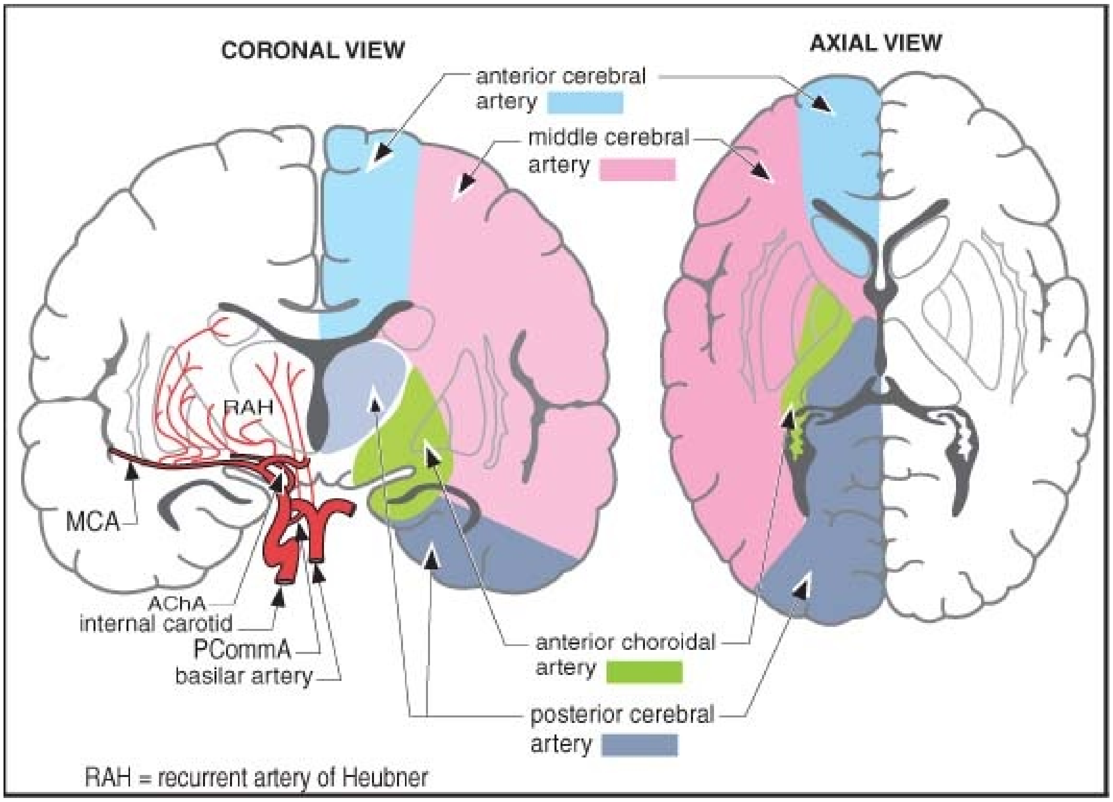

Figure 5-15 Vascular territories of the cerebral hemispheres

Figure 5-15 depicts approximate vascular distributions of the major cerebral arteries. There is considerable variability of the major arteries[24] as well as the central distribution. The lenticulostriates may have origins off of different segments of the middle or anterior cerebral artery). Recurrent artery of Heubner **(RAH)** (AKA medial striate artery) origin: junction of the ACA and a-comm in 62.3%, proximal A2 in 23.3%, A1 in 14.3%[25].

5.6.2. Cerebral arterial anatomy

The symbol "⇒" is used to denote a region supplied by the indicated artery. See *Angiography (cerebral)* on page 134 for angiographic diagrams of the following anatomy.

CIRCLE OF WILLIS

A balanced configuration of the Circle of Willis is present in only 18% of the population. Hypoplasia of 1 or both p-comms occurs in 22-32%, absent or

hypoplastic A1 segments occurs in 25%.

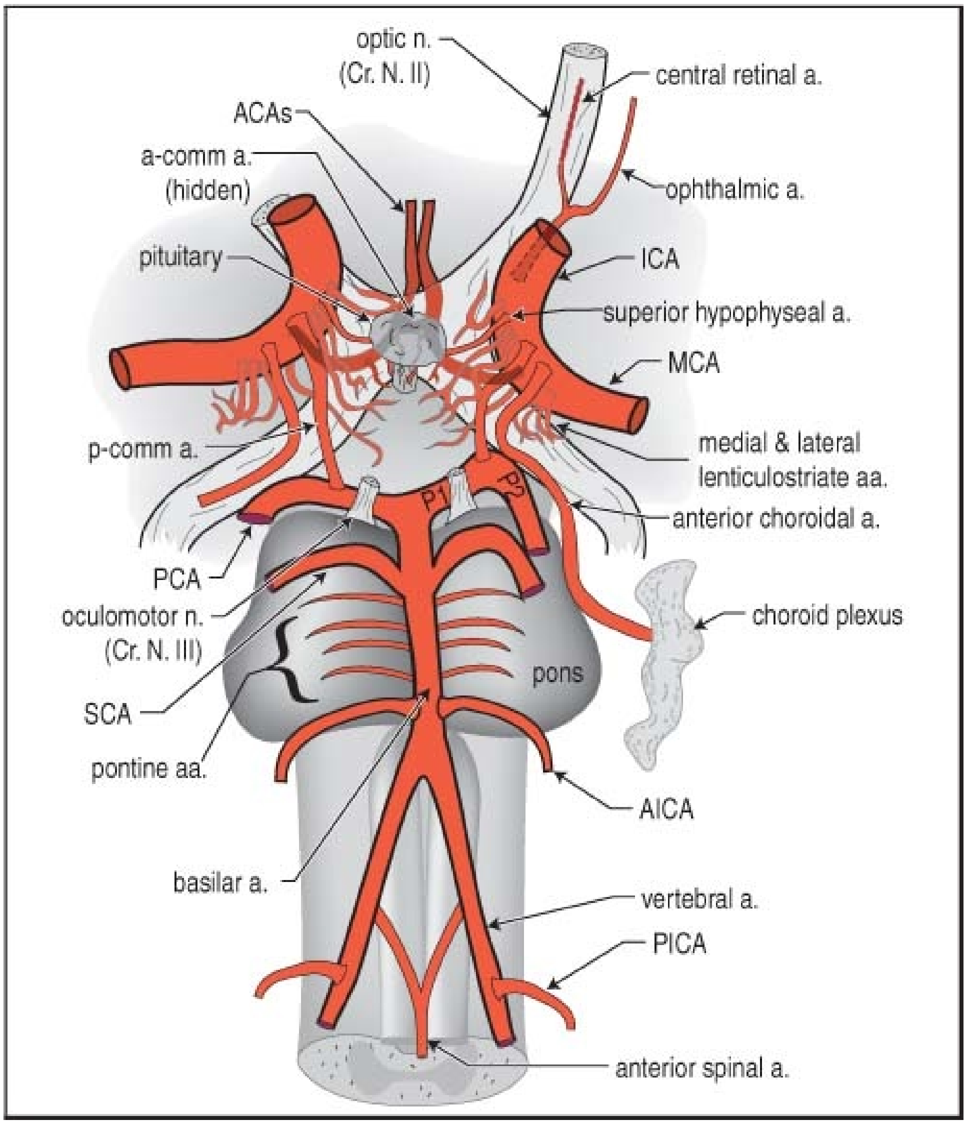

Figure 5-16 Circle of Willis viewed from in front of and below the brain

Key point: the anterior cerebral arteries pass over the superior surface of the optic chiasm.

Anatomical segments of intracranial cerebral arteries

- carotid artery: the traditional numbering system[26] was from rostral to caudal (counter to the direction of flow, and to the numbering scheme of the other arteries). A number of systems have been described to addresses this inconsistency and also to identify anatomically important segments of the

ICA that were not originally delineated (e.g. *see Table 5-9*[27]). Also *see below* for more detail

- anterior cerebral[28]:
  - A1: ACA from origin to ACoA
  - A2: ACA from ACoA to branch-point of callosomarginal
  - A3: from branch-point of callosomarginal to superior surface of corpus callosum 3 cm posterior to the genu
  - A4: pericallosal
  - A5: terminal branch
- middle cerebral[28]:
  - M1: MCA from origin to bifurcation (horizontal segment on AP angiogram). A classical bifurcation into relatively symmetrical superior and inferior trunks is seen in 50%, no bifurcation occurs in 2%, 25% have a very proximal branch (middle trunk) arising from the superior (15%) or the inferior (10%) trunk creating a “pseudo-trifurcation”, a pseudo-tetrafurcation occurs in 5%
    1. lateral fronto-orbital and prefrontal branches arise from M1 or superior M2 trunk
    2. precentral, central, anterior and posterior parietal arteries arise from a superior (60%) or middle (25%) or inferior (15%) trunk
    3. the superior M2 trunk does not give any branches to the temporal lobe
  - M2: MCA trunks from bifurcation to emergence from Sylvian fissure
  - M3-4: distal branches
  - M5: terminal branch
- posterior cerebral (PCA) (several nomenclature schemes exist[29, 30]):
  - P1: PCA from the origin to posterior communicating artery (AKA mesencephalic, precommunicating, circular, peduncular, basilar…). The long and short circumflex and thalamoperforating arteries arise from P1
  - P2: PCA from origin of p-comm to the origin of inferior temporal arteries (AKA ambient, postcommunicating, perimesencephalic), P2 traverses the ambient cistern, Hippocampal, anterior temporal, peduncular perforating and medial posterior choroidal arteries arise from P2
  - P3: PCA from the origin of the inferior temporal branches to the origin of the terminal branches (AKA quadrigeminal segment). P3 traverses

the quadrigeminal cistern

- P4: segment after the origin of the parieto-occipital and calcarine arteries, includes the cortical branches of the PCA

Table 5-9 Segments of the ICA

Cincinnati system	System of Fischer
C1 (cervical)	not described
C2 (petrous)	
C3 (lacerum)	C5
C4 (cavernous)	C4 + part of C5
C5 (clinoid)	C3
C6 (ophthalmic)	C2
C7 (communicating)	C1

ANTERIOR CIRCULATION

ANATOMIC VARIANTS

Bovine circulation: the common carotids arise from a common trunk off the aorta.

EXTERNAL CAROTID

1. superior thyroid a.: 1st anterior branch
2. ascending pharyngeal a.
   A. neuromeningeal trunk of the ascending pharyngeal a.: supplies IX, X & XI
   B. pharyngeal branch: usually the primary feeder for jugular foramen tumors (essentially the <u>only</u> cause of hypertrophy of the ascending pharyngeal a.)
3. lingual a.
4. facial a.: branches anastamose with ophthalmic a. (important in collateral flow with ICA occlusion - *see page 1027*)
5. occipital a. ⇒ posterior scalp
6. posterior auricular
7. superficial temporal
   A. frontal branch
   B. parietal branch

8. (internal) maxillary a. - initially within parotid gland
   A. middle meningeal a.
      1. anterior branch
      2. posterior branch
   B. accessory meningeal
   C. inferior alveolar
   D. infraorbital
   E. others: distal branches of which may anastomose with branches of ophthalmic artery in the orbit

INTERNAL CAROTID ARTERY (ICA)
Lies posterior & medial to the external carotid **(ECA)**.

Segments of the ICA and its branches[27]

- **C1 (cervical)**: begins in neck at carotid bifurcation where the common carotid artery divides into internal and external carotids. Travels in carotid sheath with IJV and vagal nerve, encircled with postganglionic sympathetic nerves **(PGSN)**. C1 ends where the ICA enters carotid canal of petrous bone. No branches
- **C2 (petrous)**: still surrounded by PGSNs. Ends at the posterior edge of the foramen lacerum **(f-Lac)** (inferomedial to the edge of the Gasserian ganglion in Meckel's cave). Three divisions:
   A. vertical segment: ICA ascends then bends as the…
   B. **posterior loop**: anterior to cochlea, bends antero-medially becoming the…
   C. horizontal segment: deep and medial to greater and lesser superficial petrosal nerves, anterior to tympanic membrane **(TM)**
- **C3 (lacerum)**: the ICA passes over (but not through) the f-Lac forming the lateral loop. Ascends in the canalicular portion of the f-Lac to juxtasellar position, piercing the dura as it passes the petrolingual ligament to become the cavernous segment. Branches (usually not visible angiographically):
   A. caroticotympanic (inconsistent) ⇒ tympanic cavity
   B. pterygoid (vidian) branch: passes through foramen lacerum, present in only 30%, may continue as artery of pterygoid canal
- **C4 (cavernous)**: covered by vascular membrane lining sinus, still surrounded by PGSNs. Passes anteriorly then supero-medially, bends

posteriorly (**medial loop** of ICA), travels horizontally, and bends anteriorly (part of **anterior loop** of ICA) to anterior clinoid process. Ends at the **proximal dural ring** (incompletely encircles ICA). Many branches, main ones include:

A. meningohypophyseal trunk **(MHT)** (largest & most proximal). 2 causes of a prominent MHT: 1) tumor (usually petroclival meningioma - *see below*), 2) dural AVM (*see page 1109*)
   1. a. of tentorium (AKA **artery of Bernasconi & Cassinari**): the blood supply of petroclival meningiomas
   2. dorsal meningeal a. (AKA dorsal clival a.)
   3. inferior hypophyseal a. (⇒ posterior lobe of pituitary): post-partum occlusion causes pituitary infarcts (Sheehan's necrosis), however, DI is rare because the stalk is spared

B. anterior meningeal a.

C. a. to inferior portion of cavernous sinus (present in 80%)

D. capsular aa. of McConnell (in 30%): supply the capsule of the pituitary[31]

- **C5 (clinoid)**: begins at proximal dural ring, ends at **distal dural ring** (which completely encircles ICA) where the ICA becomes intradural
- **C6 (ophthalmic)**: begins at distal dural ring, ends just proximal to p-comm. Branches:

A. ophthalmic a.: the origin from the ICA is distal to the cavernous sinus in 89% (intracavernous in 8%, absent in 3%[32]) and can vary from 5 mm anterior to 7 mm posterior to the anterior clinoid[31]. Passes through the optic canal into the orbit. Has a characteristic bayonet-like "kink" on lateral angiogram

B. superior hypophyseal a. branches ⇒ anterior lobe of pituitary & stalk (1st branch of supraclinoid ICA)

- **C7 (communicating)**: begins just proximal to p-comm origin, travels between Cr. N. II & III, terminates just below anterior perforated substance where it bifurcates into the ACA & MCA

A. posterior communicating a. (p-comm)
   1. few anterior **thalamoperforators** (⇒ optic tract, chiasm & posterior hypothalamus): see *Posterior circulation* below
   2. plexal segment: enters supracornual recess of temporal horn, ⇒ only this portion of choroid plexus
   3. cisternal segment: passes through crural cistern

B. **anterior choroidal artery** 33: takeoff 2-4 mm distal to p-comm ⇒ (variable) portion of optic tract, medial globus pallidus, genu of internal capsule **(IC)** (in 50%), inferior half of posterior limb of IC, uncus, retrolenticular fibers (optic radiation), lateral geniculate body (see *page 1028* for occlusion syndromes)

Differentiating p-comm from ACh on arteriogram

1. p-comm origin is proximal to that of the anterior choroidal artery **(ACh)**
2. p-comm is usually larger than ACh
3. p-comm usually goes up or down a little, then straight back & usually bifurcates
4. ACh usually has a superior "hump" (plexal point) where it pass through the choroidal fissure to enter the ventricle

- "**Carotid siphon**": not a segment, but a region incorporating the cavernous, ophthalmic and communicating segments. Begins at the posterior bend of the cavernous ICA, and ends at the ICA bifurcation

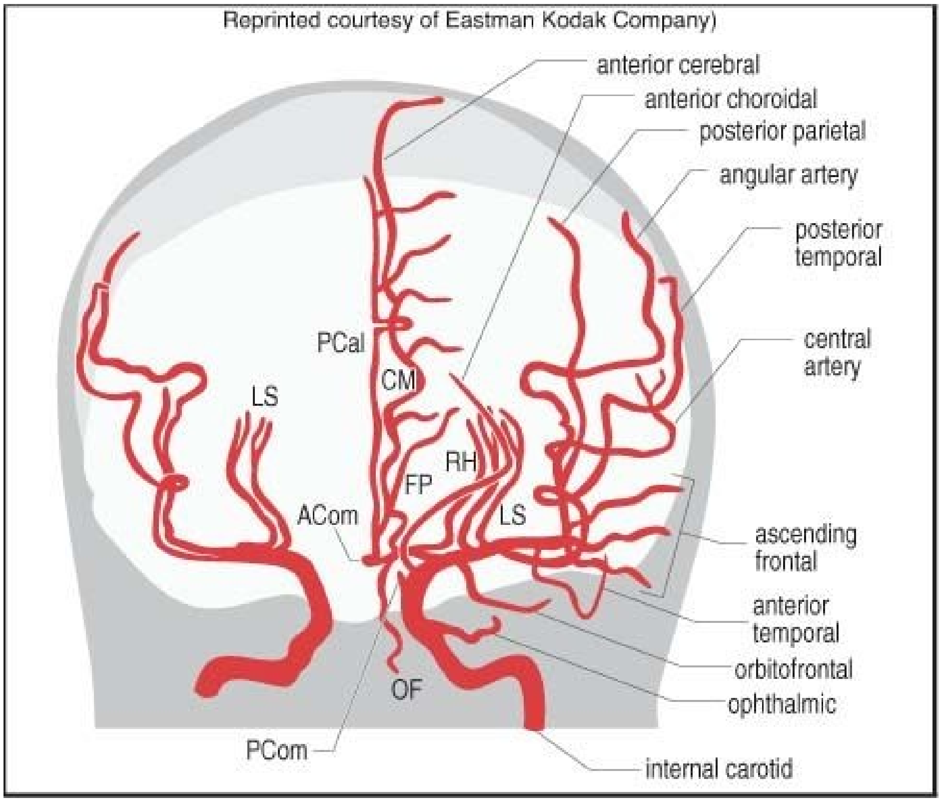

Figure 5-17 Internal carotid arteriogram (AP view)

ANTERIOR CEREBRAL ARTERY (ACA)

Passes between Cr. N. II and anterior perforated substance. See *Figure 5-18*. Branches:

1. recurrent artery (of **Heubner**): 80% arise from A1 (one of the larger

medial lenticulostriates, remainder of lenticulostriates may arise from this artery) ⇒ head of caudate, putamen, and anterior internal capsule

2. medial orbitofrontal artery
3. frontopolar artery
4. callosomarginal
    A. internal frontal branches
        1. anterior
        2. middle
        3. posterior
    B. paracentral artery
5. pericallosal artery (continuation of ACA)
    A. superior internal parietal (precuneate) artery
    B. inferior internal parietal artery

Abbreviations from *Figure 5-17*

ACom	anterior communicating artery
CM	callosomarginal artery
FP	frontopolar artery
LS	lenticulostriate arteries
OF	orbitofrontal artery
PCal	pericallosal artery
PCom	posterior communicating artery
RH	recurrent artery of Heubner

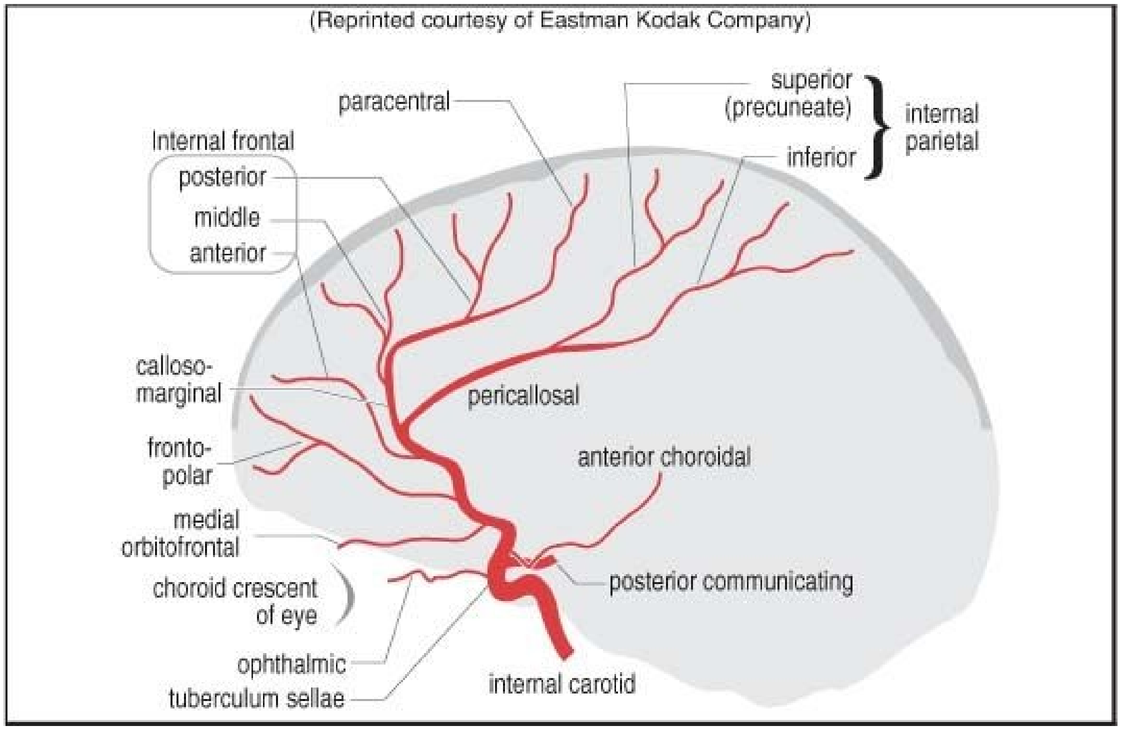

Figure 5-18 Anterior cerebral arteriogram (lateral view)

ANATOMIC VARIANTS

Hypoid: having only one anterior cerebral artery (as in a horse).

MIDDLE CEREBRAL ARTERY (MCA)

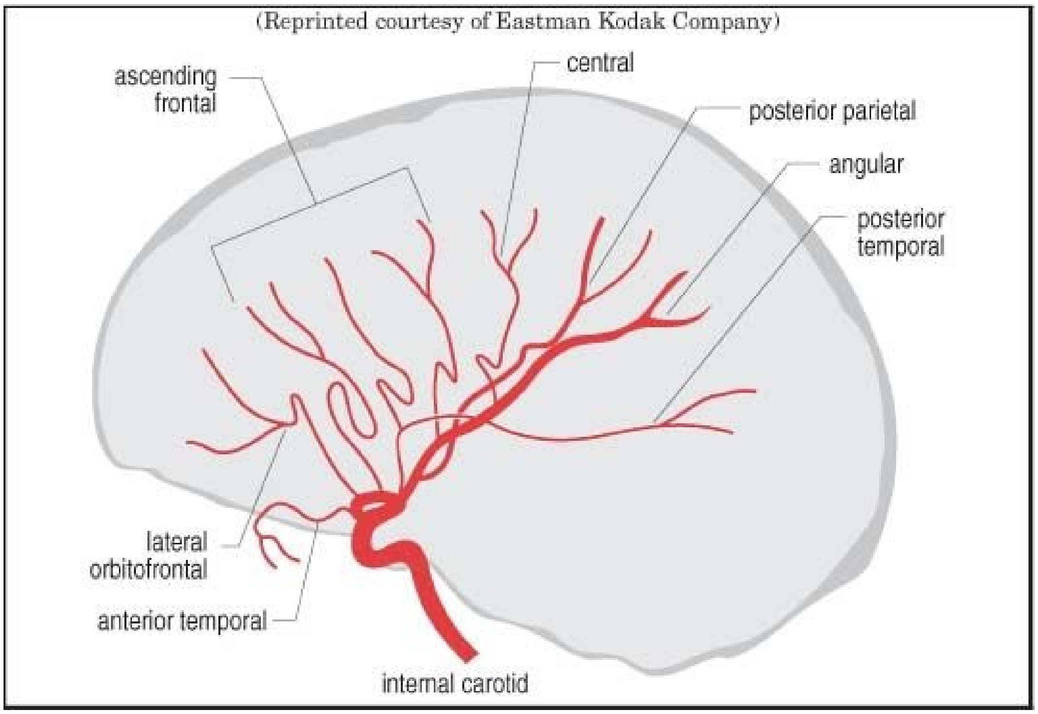

Figure 5-19 Middle cerebral arteriogram (lateral view)

See *Figure 5-19* (*see page 98* for anatomy). Branches vary widely, 10 common ones:

1. medial (3-6 per side) and lateral lenticulostriate arteries
2. anterior temporal
3. posterior temporal
4. lateral orbitofrontal
5. ascending frontal (candelabra)
6. precentral (prerolandic)
7. central (rolandic)
8. anterior parietal (postrolandic)
9. posterior parietal
10. angular

POSTERIOR CIRCULATION

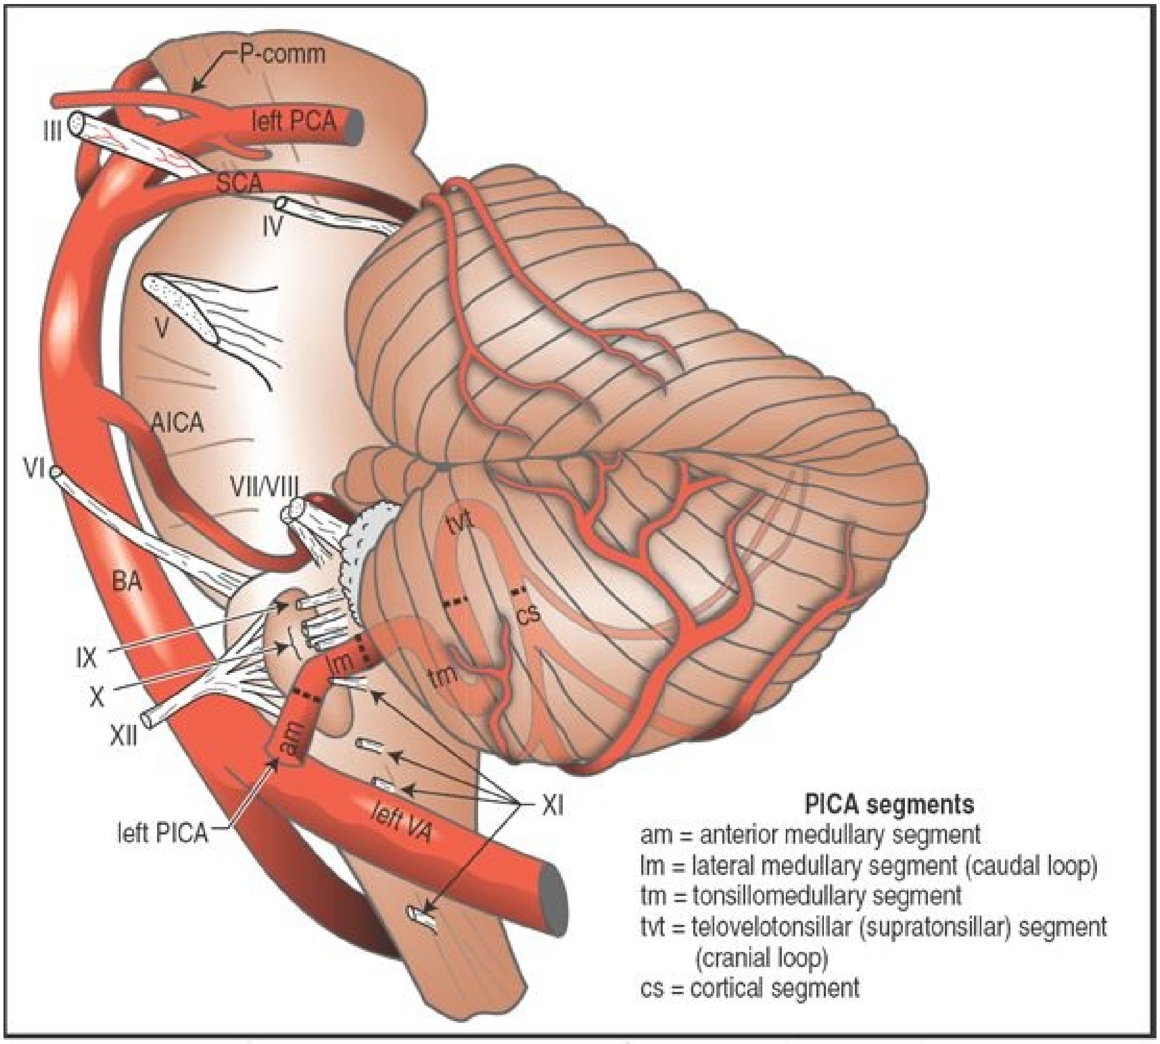

Figure 5-20 Intradural VA and PICA segments (lateral view) Modified with permission from: Lewis SB, Chang DJ, Peace DA, Lafrentz PJ, Day AL. Distal posterior inferior cerebellar artery aneurysms: clinical features and management. J Neurosurg 2002;97(4):756-66.

VERTEBRAL ARTERY (VA)

The VA is the first and usually the largest branch of the subclavian artery. Variant: the left VA arises off the aortic arch in ≈ 4%. Diameter ≈ 3 mm. Mean blood flow ≈ 150 ml/min. The left VA is dominant in 60%. The right VA will be hypoplastic in 10%, and the left will be hypoplastic in 5%. The VA is atretic and does not communicate with the BA on the left in 3%, and on the right in 2% (the VA may terminate in PICA).

Four segments:

V1 prevertebral: from subclavian artery, courses superiorly and posteriorly and enters the foramen transversarium, usually of the 6th vertebral body

V2 ascends vertically within the transverse foramina of the cervical vertebrae surrounded by sympathetic fibers (from the stellate ganglion) and a venous plexus. It is situated anterior to the cervical roots. It turns laterally to enter the foramen within the transverse process of the axis

V3 exits the foramen of the axis and curves posteriorly and medially in a groove on the upper surface of the atlas and enters the foramen magnum

V4 pierces the dura (location somewhat variable) and immediately enters the subarachnoid space. Joins the contralateral VA at the **vertebral confluens** located at the lower pontine border to form the basilar artery **(BA)**

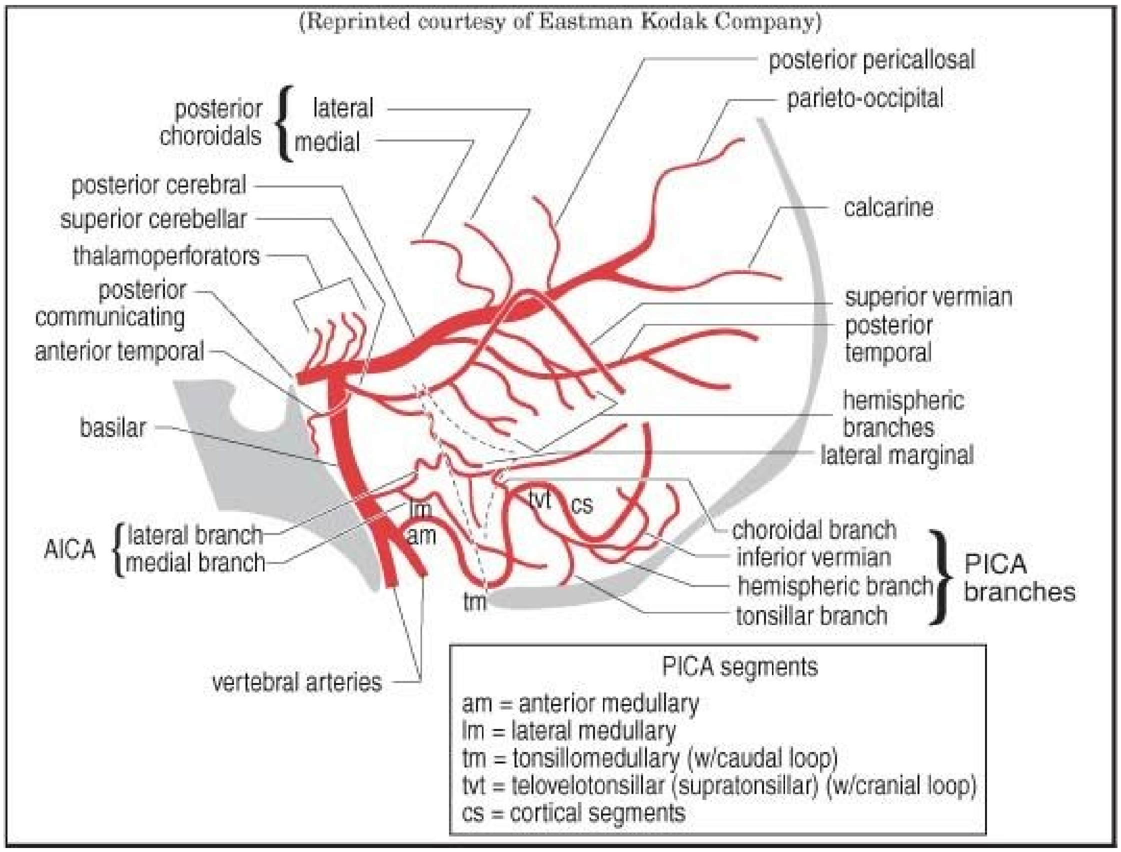

Figure 5-21 Vertebrobasilar arteriogram (lateral view)

Branches:

1. anterior meningeal: arises at body of C_2 (axis), may feed chordomas or foramen magnum meningiomas, may also act as collateral in vascular occlusion
2. posterior meningeal: may a source of blood for some dural AVMs (*see* *page 1109*)
3. medullary (bulbar) aa.

4. posterior spinal
5. posterior inferior cerebellar artery **(PICA)** (largest branch): (*see Figure 5-20*) usually arises ≈10 mm distal to point where VA becomes intradural, ≈ 15 mm proximal to the vertebrobasilar junction
   A. anatomic variants:
      1. in 5-8% the PICA has an extradural origin
      2. "AICA-PICA": origin is off basilar trunk (where AICA would usually originate)
   B. 5 segments[34] (some systems some describe only 4). During surgery, the first three must be preserved, but the last 2 may usually be sacrificed with minimal deficit[35]:
      1. anterior medullary: from PICA origin to inferior olivary prominence. 1 or 2 short medullary short circumflex branches ⇒ ventral medulla
      2. lateral medullary: to origin of nerves IX, X & XI. Up to 5 branches that supply brainstem
      3. tonsillomedullary: to tonsillar midportion (contains caudal loop on angio)
      4. telovelotonsillar (supratonsillar): ascends in tonsillomedullary fissure (contains cranial loop on angio)
      5. cortical segments
   C. 3 branches
      1. **choroidal** a. (BRANCH 1) arises from cranial loop (choroidal point), ⇒ choroid plexus of 4th ventricle
      2. terminal branches:
         a. **tonsillohemispheric** (BRANCH 2)
         b. **inferior vermian** (BRANCH 3) inferior inflection = copular point on angio
6. anterior spinal

ANATOMIC VARIANTS

Fetal circulation: 15-35% of patients supply their posterior cerebral artery on one or both sides from the carotid (via p-comm) instead of via the vertebrobasilar system.

BASILAR ARTERY (BA)

Formed by the junction of the 2 vertebral arteries. Branches:

1. anterior inferior cerebellar artery **(AICA)**: from lower part of BA, runs

postero-laterally anterior to VI, VII & VIII. Often gives off a loop that runs into the IAC and gives off the labyrinthine artery and then emerges to supply the anterolateral inferior cerebellum and then anastomoses with PICA

2. internal auditory (labyrinthine)
3. pontine branches
4. superior cerebellar a. **(SCA)**
   A. sup. vermian
5. **posterior cerebral**: joined by p-comms ≈ 1 cm from origin (the p-comm is the major origin of the PCA in 15% and is termed “fetal” circulation, bilateral in 2%). 3 segments (named for surrounding cistern) and their branches:
   A. peduncular segment (P1)
      1. mesencephalic perforating aa. (⇒ tectum, cerebral peduncles, and these nuclei: Edinger-Westphal, oculomotor and trochlear)
      2. interpeduncular **thalamoperforators** (1st of 2 groups of posterior thalamoperforating aa.)
      3. medial post. choroidal (most from P1 or P2)
      4. “artery of Percheron”: a rare anatomic variant[36] in which a solitary arterial trunk arising from the proximal segment of one PCA supplies the paramedian thalami and rostral midbrain bilaterally
   B. ambient segment (P2)
      1. lateral post. choroidal (most from P2)
      2. thalamogeniculate **thalamoperforators** (2nd of 2 groups of posterior thalamoperforating aa.) ⇒ geniculate bodies + pulvinar
      3. anterior temporal (anastomoses with anterior temporal br. of MCA)
      4. posterior temporal
      5. parieto-occipital
      6. calcarine
   C. quadrigeminal segment (P3)
      1. quadrigeminal & geniculate branches ⇒ quadrigeminal plate
      2. post. pericallosal (splenial) (anastomoses with pericallosal of ACA)

5.6.3. Cerebral venous anatomy

SUPRATENTORIAL VENOUS SYSTEM

See *Figure 5-22*, page 105 for angiogram and branches.

The left and right internal jugular veins **(IJVs)** are the major source of outflow of blood from the intracranial compartment. The right IJV is usually dominant. Other sources of outflow include orbital veins and the venous plexuses around the vertebral arteries. Diploic and scalp veins may act as collateral pathways, e.g. with superior sagittal sinus obstruction[38]. The following outline traces the venous drainage back from the IJVs.

A. inferior petrosal sinus: terminates (i.e. drains to) ≤ 1 cm of junction of sigmoid and transverse sinuses
B. sigmoid sinus
  1. superior petrosal sinus: drains to IJV near junction with sigmoid sinus
  2. transverse sinus (R > L in 65%)
    A. v. of Labbe (inferior anastomotic v.)
    B. confluens of sinuses (torcular herophili)
      1. occipital sinus
      2. superior sagittal sinus
        a. v. of Trolard (superior anastomotic v.): the prominent superficial vein on the non-dominant side (Labbé is more prominent on the dominant side)
      3. straight sinus
        a. inferior sagittal sinus
        b. great cerebral v. (of Galen)
          i. pre-central cerebellar v.
          ii. basal vein of Rosenthal
          iii. internal cerebral v.: joined at the foramen of Monro (venous angle) by:
            1. anterior septal v.
            2. thalamostriate v.

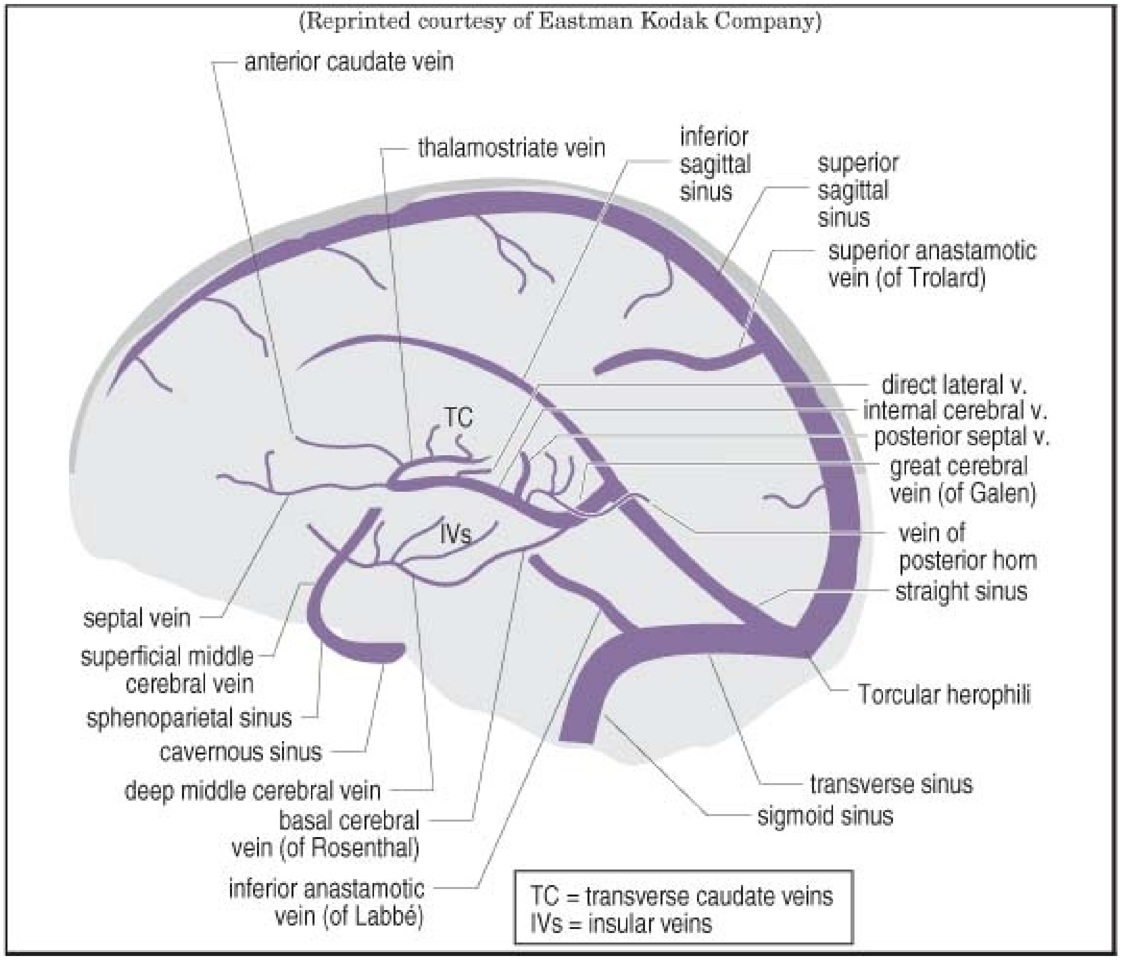

Figure 5-22 Internal carotid venogram (lateral view)

CAVERNOUS SINUS

Although classical teaching depicts the cavernous sinus as a large venous space with multiple trabeculations, injection studies[39] and surgical experience[40] supports the concept of the cavernous sinus as a plexus of veins. It is highly variable between individuals and from side-to-side. *Figure 5-23* is an oversimplified schematic of one section through the right cavernous sinus.

1. inflowing veins:
   - A. superior & inferior ophthalmic veins
   - B. superficial middle cerebral veins
   - C. sphenoparietal sinus
   - D. superior & inferior petrosal sinus
2. outflow:
   - A. sphenoparietal sinus
   - B. superior petrosal sinus

C. basilar plexus (which drains to the inferior petrosal sinus)
D. pterygoid plexus
E. the right and left cavernous sinuses communicate anteriorly and posteriorly via the circular sinus

3. contents[41]
   - **O**culomotor n. (III)
   - **T**rochlear n. (IV)
   - **O**phthalmic division of trigeminal (V1)
   - **M**axillary division of trigeminal (V2): the only nerve of the cavernous sinus that doesn't exit the skull through the superior orbital fissure (it exits through foramen rotundum)
   - **C**arotid artery (ICA). 3 segments within the cavernous sinus
     1. posterior ascending segment: immediately after ICA enters the sinus
     2. horizontal segment: after ICA turns anteriorly (the longest segment of the intracavernous ICA)
     3. anterior ascending segment: ICA turns superiorly
   - **A**bducens n. (VI): the only nerve NOT attached to lateral dural wall, some-times referred to as the only cranial nerve *inside* the cavernous sinus

3. **triangular space** (of Parkinson): superior border formed by Cr. N. III & IV, and the lower margin formed by V_1 & VI (a landmark for surgical entrance to the cavernous sinus)[42, 43 (p 3007)]

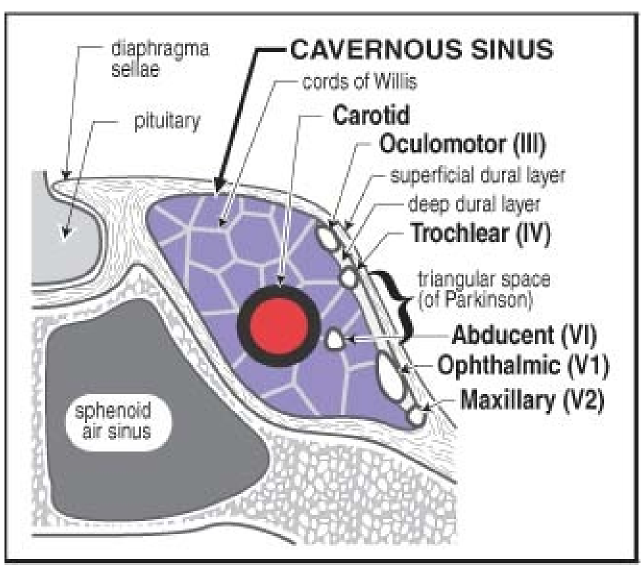

Figure 5-23 Right cavernous sinus (coronal section) Modified from the **Journal of Neurosurgery**,

Umansky F and Nathan H, Vol. 56, pp. 228-34, 1982, with permission)

POSTERIOR FOSSA VENOUS ANATOMY

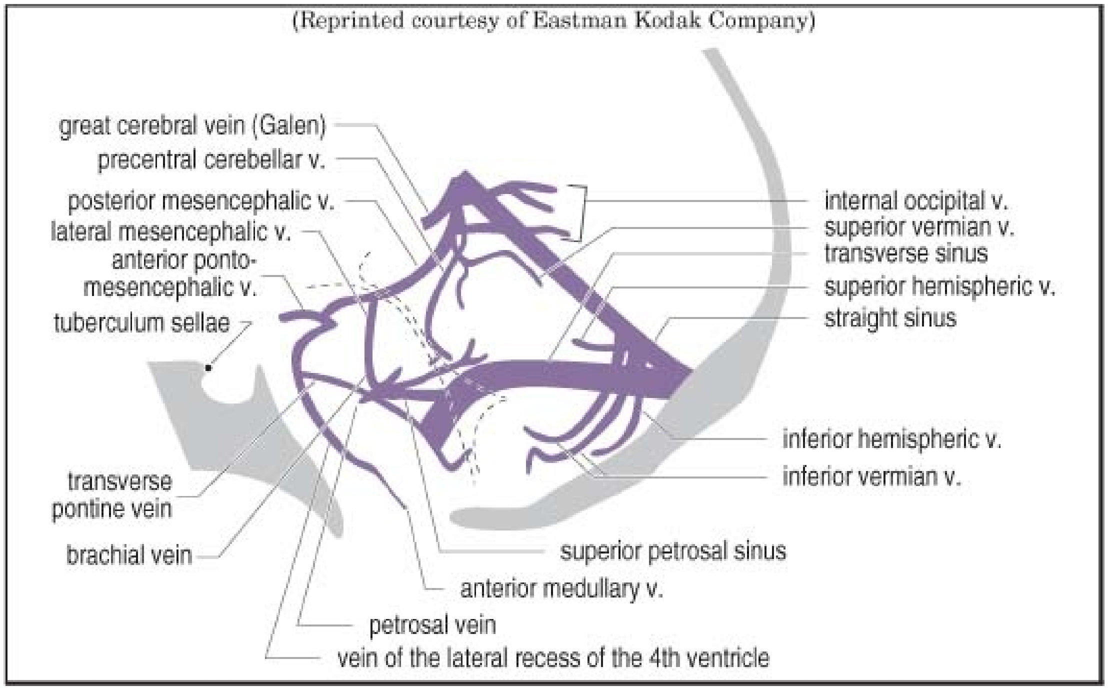

Figure 5-24 Vertebrobasilar venogram (lateral view)

5.6.4. Carotid-vertebrobasilar anastomoses

P-comm artery: the "normal" (most common) anastomosis.

Persistent fetal anastomoses[37]: (*see Figure 5-25*) result from failure to involute as the VAs and p-comms develop (order of involution: otic, hypoglossal, primitive trigeminal, proatlantal). Most are asymptomatic. However, some may be associated with vascular anomalies such as aneurysms or AVMs, and occasionally cranial nerve symptoms (e.g. trigeminal neuralgia with PPTA) can occur.

Four types (from cranial to caudal - the 1st 3 are named for the associated cranial nerve):

1. **persistent primitive trigeminal artery (PPTA)**: seen in ≈ 0.6% of cerebral angiograms. The most common of the persistent fetal anastomoses (83%). May be associated with trigeminal neuralgia (*see page 551*). Connects the cavernous carotid to the basilar artery. Arises from the ICA proximal to the origin of the meningohypophyseal trunk

(50% go through sella, 50% exit the cavernous sinus & course with the trigeminal nerve) and connects to the upper basilar artery between AICA & SCA. The VAs may be small. Saltzman type 1 variant: the p-comms are hypoplastic and the PPTA provides significant blood supply to the distributions of the distal BA, PCA and the SCAs (the basilar artery is often hypoplastic). Saltzman type 2: p-comm supplies PCA. Saltzman type 3: PPTA joins the SCA (instead of the BA). It is critical to recognize a PPTA before doing a Wada test (*see page 421*) because of the risk anesthetizing the brainstem, and in doing transsphenoidal surgery because of risk of arterial injury. May rarely be an explanation of posterior fossa symptoms in a patient with carotid disease

2. **otic**: the first to involute, and the rarest to persist (8 cases reported). Passes through IAC to connect petrous carotid to basilar artery
3. **hypoglossal**: connects petrous or distal cervical ICA (origin usually between C1-C3) to VA. Traverses the hypoglossal canal. Does not cross foramen magnum
4. **proatlantal intersegmental**: connects cervical ICA to VA. May arise from: bifurcation of common carotid, ECA, or ICA from C2-C4. Anastomosis with VA in suboccipital region. 50% have hypoplastic proximal VA. 40 cases reported

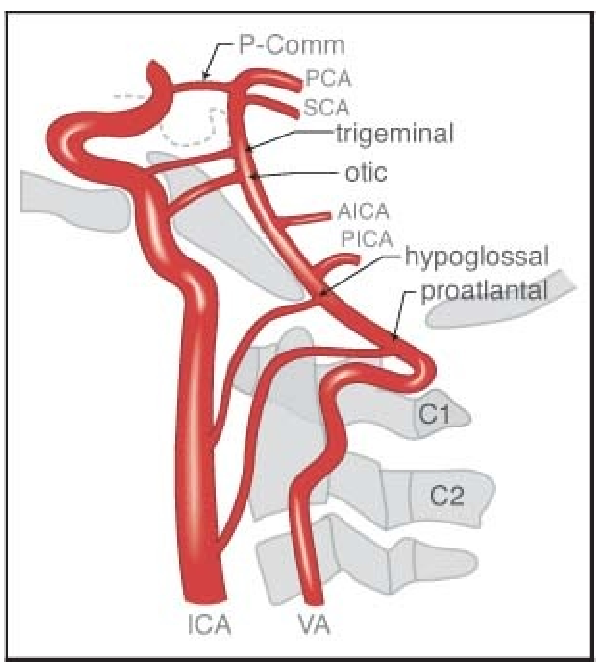

Figure 5-25 Carotid-vertebrobasilar anastomoses

5.7. Internal capsule

For a schematic diagram, *see Figure 5-26*. *Table 5-10* delineates the thalamic sub-radiations. Most IC lesions are caused by vascular accidents (thrombosis or hemorrhage).

Vascular supply of the internal capsule (IC)

1. anterior choroidal: ⇒ all of retrolenticular part (includes optic radiation) and ventral part of posterior limb of IC
2. lateral striate branches (AKA capsular branches) of middle cerebral artery: ⇒ most of anterior AND posterior limbs of IC
3. genu usually receives some direct branches of the internal carotid artery

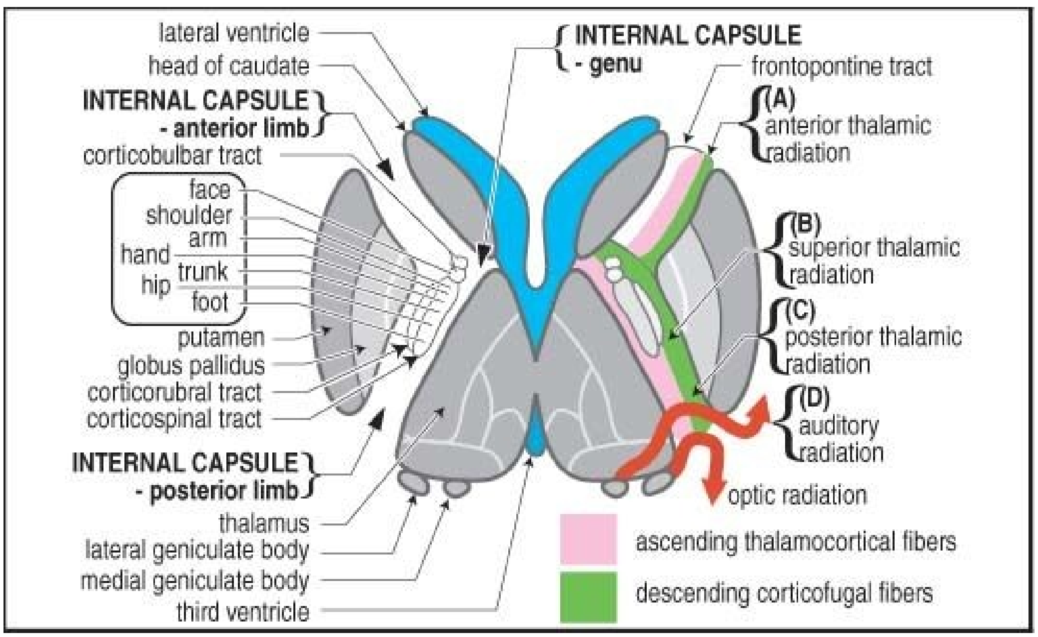

Figure 5-26 Internal capsule schematic diagram (left side shows tracts, right side shows radiations)

Table 5-10 Four Thalamic "subradiations" (AKA thalamic peduncles)
(labeled A-D in *Figure 5-26*)

Radiation	Connection			Comments
anterior (**A**)	medial & anterior thalamic nucleus	↔	frontal lobe	
superior (**B**)	rolandic areas	↔	ventral thalamic nuclei	general sensory fibers from body & head to terminate in postcentral gyrus (areas 3,1,2)
posterior (**C**)	occipital & posterior parietal	↔	caudal thalamus	
inferior (**D**)	transverse temporal gyrus of Heschl	↔	MGB	(small) includes auditory radiation

5.8. Miscellaneous

Obersteiner-Redlich zone (ORZ)

Transition from CNS myelin to peripheral myelin of cranial nerves = area where pressure from intracranial structures can cause cranial nerve symptoms (trigeminal neuralgias, hemifacial spasm, disabling positional vertigo, etc.)[44]. Also, zone where neoplasms tend to occur, especially vestibular schwannoma. On Cr. N. VIII, the ORZ is 8-12 mm distal to exit point from brainstem, and is close to porus acusticus (especially common on vestibular division)[14 (p 695)].

Dentate ligament

The dentate ligament separates dorsal from ventral nerve roots in the spinal nerves. The spinal accessory nerve (Cr. N. XI) is dorsal to the dentate ligament.

5.9. Neurophysiology

5.9.1. Blood-brain barrier

The passage of water-soluble substances from the blood to the CNS is limited by tight junctions (zonulae occludentes) which are found between cerebral capillary endothelial cells, limiting penetration of the cerebral parenchyma (blood-brain barrier, **(BBB)**), as well as between choroid plexus epithelial cells (blood-CSF barrier)[45]. A number of specialized mediated transport systems allow transmission of, among other things, glucose and certain

amino acids (especially precursors to neurotransmitters).

The efficacy of the BBB is compromised in certain pathological states (e.g. tumor, infection, trauma, stroke, hepatic encephalopathy…), and can also be manipulated pharmacologically (e.g. hypertonic mannitol increases the permeability, whereas steroids reduce the penetration of small hydrophilic molecules).

The BBB is absent in the following areas: choroid plexus, hypophysis, tuber cinereum, area postrema, pineal and preoptic recess.

CEREBRAL EDEMA

Three basic types (diffusion-weighted MRI may be able to differentiate, *see page 132*):

1. **cytotoxic**: BBB is closed, therefore no protein extravasation, therefore no enhancement on CT or MRI. Cells swell then shrink. Seen e.g. in head injury
2. **vasogenic**: BBB disrupted. Protein (serum) leaks out of vascular system, and therefore may enhance on imaging. Extracellular space **(ECS)** expands. Cells are stable. Responds to corticosteroids (e.g. dexamethasone). Seen e.g. surrounding metastatic brain tumor
3. **ischemic**: a combination of the above. BBB closed initially, but then may open. ECS shrinks then expands. Fluid extravasates late. May cause delayed deterioration following intracerebral hemorrhage (*see page 1125*)

5.9.2. Pituitary embryology & neuroendocrinology

The **posterior pituitary** (neurohypophysis) derives from downward evagination of neural crest cells (brain neuroectoderm) from the floor of the third ventricle. The residual recess in the floor of the third ventricle is called the median eminence. The **anterior pituitary** gland (adenohypophysis) develops from an evagination of epithelial ectoderm of the oropharynx, the evagination is known as Rathke's pouch and is eventually separated from the oropharynx by the sphenoid bone. Cleft-like remnants of Rathke's pouch separates the adenohypophysis and neurohypophysis. The adenohypophysis is comprised of the pars distalis (anterior lobe), the pars intermedia (intermediate lobe) and the pars tuberalis (extension of adenohypophyseal cells on the anterior aspect of the pituitary stalk). The pituitary gland is functionally <u>outside</u> the blood-brain barrier.

PITUITARY HORMONES AND THEIR CONTROLS

The pituitary gland releases 8 hormones, 6 from the anterior pituitary, 2 from the posterior pituitary (*see Figure 5-27*). The anterior pituitary is one of only two sites in the body having a portal circulation (the other being the liver). 6 hypothalamic hormones released in a pulsatile fashion are conveyed in blood from hypothalamic capillaries through this portal circulation via the pituitary stalk to a second capillary bed in the anterior pituitary where they control release of hormones by adenohypophyseal gland cells.

Hormones released from the posterior pituitary (ADH & oxytocin) are synthesized in <u>neurons</u> in the hypothalamus (<u>not</u> gland cells) and are conveyed along their <u>axons</u> also in the pituitary stalk to the posterior pituitary gland where they are released.

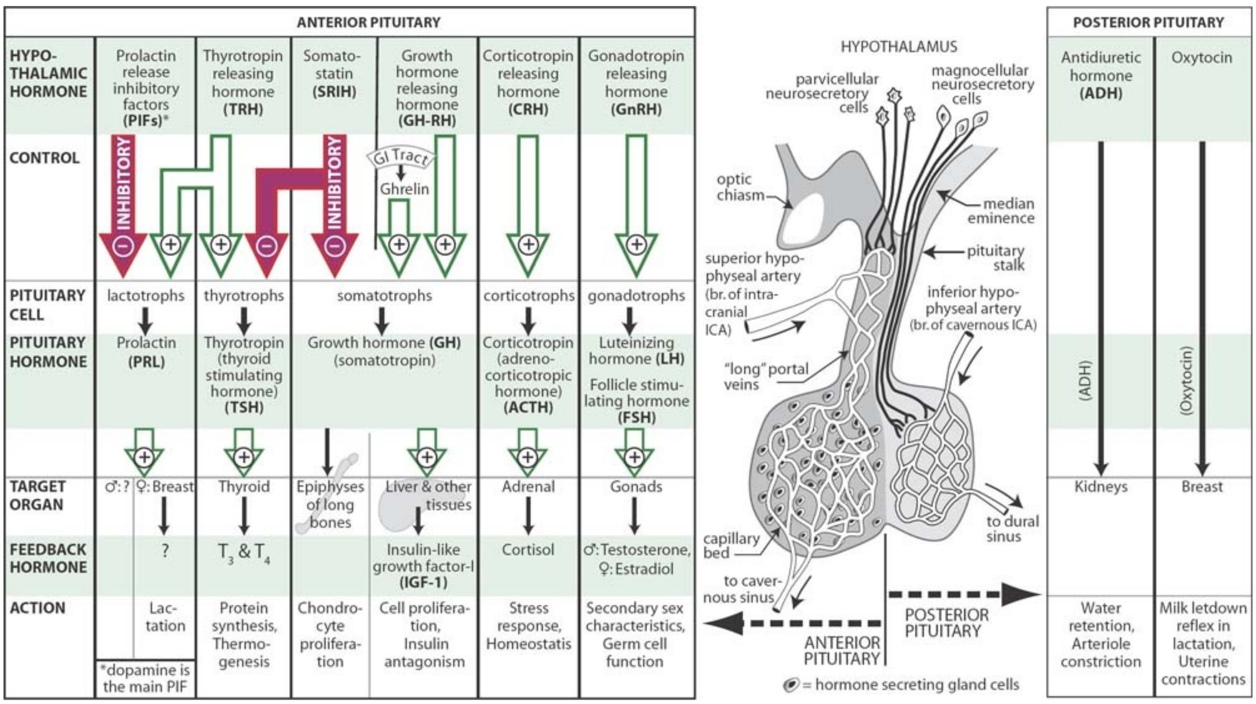

Figure 5-27 Pituitary neuroendocrinology

The complete homeostatic loop (including negative feedback of the hypothalamic hormones) will not be covered here, and the reader is referred to physiology texts.

Propiomelanocortin (POMC) AKA proopiomelanocortin

241 amino acid polypeptide hormone precursor synthesized primarily in

corticotroph cell of the anterior pituitary (but also found in the hypothalamus). Contains amino acid sequences for ACTH, alpha–melanocyte–stimulating hormone **(α-MSH)**, ß-lipotropin, γ-lipotropin, ß-endorphin and met-enkephalin.

Corticotropin AKA adrenocorticotrophic hormone (ACTH)

A 39 amino acid trophic hormone synthesized from POMC (*see above*). The first 13 amino acids at the amino terminal of ACTH are identical to α-MSH. Active half-life is ≈ 10 minutes. Produces a diurnal peak in cortisol (the highest peak occurs in the early morning, with a second, lesser peak in the late afternoon) and also increases in response to stress.

Control: CRH from the hypothalamus stimulates the release of ACTH.

Prolactin (PRL)

AKA somatomammotropin. 199 amino-acid protein weighing 23,000 daltons. Levels are higher in females than males, and are higher still in pregnancy (*see page 643*). Secreted in pulsatile fashion with a frequency and amplitude that varies during menstrual cycle (range: 5-27 ng/ml). There is also diurnal variation: levels begin to rise 1 hour after the onset of sleep, peak ≈ 5:00-7:00 AM, and nadir in midmorning after awakening. Heterogeneity of the molecule may produce different results between bioassays and immunoassays.

Control: PRL is the only pituitary hormone predominantly under inhibitory control from the hypothalamus by prolactin inhibitory factors **(PRIFs)**, with dopamine being the primary PRIF. Prolactin releasing factors **(PRFs)** include: thyrotropin-releasing hormone (TRH) and vasoactive intestinal peptide (VIP). The physiologic role of PRFs is not established. For differential diagnosis of hyperprolactinemia *see page 644*.

Growth hormone (GH)

A 191 amino-acid polypeptide trophic hormone. GH normally has pulsatile secretion (≈ 5-10 pulses/24 hours, primarily at night, up to 30 μg/L), levels may be undetectable (< 0.2 μg/L) by standard assays between pulses[46]. Insulin-like growth factor-1 **(IGF-1)** (formerly AKA somatomedin-C) is the protein secreted primarily by the liver in response to GH that is responsible for most of GH's systemic effects (*see page 648* for levels). GH also acts directly on epiphyseal end-plates of long bone to stimulate chondrocyte proliferation.

Control: GH is under dual hypothalamic control via the hypophysial portal system. GH-releasing hormone **(GHRH)** from the arcuate nucleus stimulates pituitary secretion and synthesis of GH and induces GH gene transcription. **Somatostatin** from the periventricular nucleus suppresses GH release only. GH release is also stimulated by **ghrelin**[47], a peptide synthesized primarily in the GI tract in response to certain nutrients (may act partially or totally via hypothalamic GHRH).

Thyrotropin AKA thyroid stimulating hormone (TSH)

Glycoprotein trophic hormone secreted by thyrotroph cells of the anterior pituitary.

Control: TSH is also under dual hypothalamic control. TRH stimulates production and release of TSH. Somatostatin inhibits the release of TSH.

Gonadotropins

Follicle stimulating hormone **(FSH)** and leuteinizing hormone **(LH)** (AKA lutropin) are released from the pituitary in response to gonadotropin releasing hormone 1 **(GnRH)** (formerly leuteinizing hormone releasing hormone **(LH-RH)**) synthesized primarily in the preoptic area of the hypothalamus.

Antidiuretic hormone (ADH)

AKA arginine vasopressin **(AVP)**. The major source of this nanopeptide hormone is the magnocellular portion of the supraoptic nucleus of the hypothalamus. It is conveyed along axons in the supraoptic-hypophyseal tract to the posterior pituitary gland where it is released into the systemic circulation. All actions of ADH result from binding of the hormone to specific membrane bound receptors on the surface of target cells[48]. One of the major effects of ADH is to increase the permeability of the distal renal tubules resulting in increased reabsorption of water, diluting the circulating blood and producing a concentrated urine. The most powerful physiologic stimulus for ADH release is an increase in serum osmolality, a less potent stimulus is a reduction of intravascular volume. ADH is also released in glucocorticoid deficiency, and is inhibited by exogenous glucocorticoids and adrenergic drugs. ADH is also a potent vasoconstrictor.

Oxytocin

A nonapeptide. The hypothalamus is the main source of pituitary oxytocin which is stored in nerve endings in the neurohypophysis and is involved in the milk letdown reflex for breastfeeding as well as in uterine contraction during labor.

5.9.3. Regional brain syndromes

This section serves to briefly describe typical syndrome associated with lesions in various areas of the brain. Unless otherwise noted, lesions considered are destructive.

1. frontal lobe
   A. unilateral injury:
      1. may produce few clinical findings except with very large lesions
      2. bilateral or large unilateral lesions: apathy, abulia
      3. the frontal eye field (for contralateral gaze) is located in the posterior frontal lobe (Br. area 8, shown as the striped area in *Figure 5-1*, page 84). Destructive lesions impair gaze to the contralateral side (patient looks towards the side of the lesion), whereas irritative lesions (i.e. seizures) cause the center to activate, producing contralateral gaze (patient looks away from the side of the lesion). Also *see page 834*
   B. bilateral injury: may produce apathy, abulia
   C. olfactory groove region: may produce Foster Kennedy syndrome (*see below*)
   D. prefrontal lobes control "executive function": planning, prioritizing, organizing thoughts, suppressing impulses, understanding the consequences of decisions
2. parietal lobe: major features (*see below* for details)
   A. either side: cortical sensory syndrome, sensory extinction, contralateral homonymous hemianopia, contralateral neglect
   B. *dominant* parietal lobe lesion (left in most): language disorders (aphasias), Gerstmann's syndrome (*see page 113*), bilateral astereognosis
   C. *non-dominant* parietal lobe lesions: topographic memory loss, anosognosia and dressing apraxia
3. occipital lobe: homonymous hemianopsia
4. cerebellum

A. lesions of the cerebellar *hemisphere* cause ataxia in the ipsilateral limbs

B. lesions of the cerebellar vermis cause truncal ataxia

5. brainstem: usually produces a mixture of cranial nerve deficits and long tract findings (*see below* for some specific brainstem syndromes)
6. pineal region

A. Parinaud's syndrome: *see page 114*

FOSTER KENNEDY SYNDROME

Usually from olfactory groove or medial third sphenoid wing tumor (usually meningioma). Now rare due to earlier detection by CT scan. Classic triad:

1. ipsilateral anosmia
2. ipsilateral central scotoma (with optic atrophy due pressure on optic nerve)
3. contralateral papilledema (from elevated ICP)

Occasionally ipsilateral proptosis will also occur due to orbital invasion of tumor.

5.9.3.1. Parietal lobe syndromes[49] (p 308-12)

PARIETAL LOBE ANATOMY

The parietal lobe is located behind the central sulcus, above the Sylvian fissure, merging posteriorly into the occipital lobe (the border on the medial surface of brain is defined by a line connecting the parieto-occipital sulcus to the pre-occipital notch).

PARIETAL LOBE NEUROPHYSIOLOGY

- either side: anterior parietal cortex organizes tactile precepts (probably contralateral) and integrates with visual and auditory sensation to build awareness of body and its spatial relations
- dominant side (on left in 97% of adults): understanding language, includes "cross-modal matching" (auditory-visual, visual-tactile, etc.). Dysphasia present with dominant lobe lesions often impedes assessment
- non-dominant side: integrates visual and proprioceptive sensation to allow manipulation of body and objects, and for certain constructional activities

CLINICAL SYNDROMES OF PARIETAL LOBE DISEASE

1. <u>unilateral</u> parietal lobe disease (dominant or non-dominant):
   A. cortical sensory syndrome (*see below*) and sensory extinction (neglecting 1 of 2 simultaneously presented stimuli). Large lesion → hemianesthesia
   B. congenital injury → mild hemiparesis & contralateral muscle atrophy
   C. homonymous hemianopia or visual inattentiveness
   D. occasionally: anosognosia
   E. neglect of contralateral half of body and visual space (more common with right side lesions)
   F. abolition of <u>optokinetic nystagmus</u> to one side
2. additional effects of *dominant* parietal lobe lesion (left in most):
   A. language disorders (aphasias)
   B. speech-related or verbally mediated functions, e.g. cross-modal matching (e.g. patient understands spoken words and can read, but cannot understand sentences with elements of relationships)
   C. **Gerstmann's syndrome**, classically:
      1. agraphia without alexia (patients can read but cannot write)
      2. left-right confusion
      3. digit agnosia: inability to identify finger by name
      4. acalculia
   D. tactile agnosia (bilateral astereognosis)
   E. bilateral ideomotor apraxia (inability to carry out verbal commands for activities that can otherwise be performed spontaneously with ease)
3. additional effects of *non-dominant* parietal lobe lesions (usually right):
   A. topographic memory loss
   B. anosognosia and dressing apraxia

CORTICAL SENSORY SYNDROME

Lesion of postcentral gyrus, especially area that maps to hand.

- sensory deficits:
  A. loss of position sense and of passive movement sense
  B. inability to localize tactile, thermal, and noxious stimuli
  C. astereognosis (inability to judge object size, shape, and identity by feel)
  D. agraphesthesia (cannot interpret numbers written on hand)
  E. loss of two point discrimination
- preserved sensations: pain, touch, pressure, vibration, temperature

• other features
    A. easy fatigability of sensory perceptions
    B. difficulty distinguishing simultaneous stimulations
    C. prolongation of superficial pain with hyperpathia
    D. touch hallucinations

ASOMATAGNOSIAS

ANTON-BABINSKI SYNDROME

Unilateral asomatagnosia. May seem more common with non-dominant (usually right) parietal lesions because it may be obscured by the aphasia that occurs with dominant (left) sided lesions.

1. anosognosia (indifference or unawareness of deficits, patient may deny that paralyzed extremity is theirs)
2. apathy (indifference to failure)
3. allocheiria (one-sided stimuli perceived contralaterally)
4. dressing apraxia: neglect of one side of body in dressing and grooming
5. extinction: patient is unaware of contralateral stimulus when presented with double-sided simultaneous stimulation
6. inattention to an entire visual field (with or without homonymous hemianopia), with deviation of head, eyes, and torsion of body to unaffected side

APHASIAS

As related to parietal lobe lesions:

1. **Wernicke's aphasia**: lesion of auditory association areas or their separation from angular gyrus and primary auditory cortex. A fluent aphasia (normal sentence length & intonation, devoid of meaning). May include paraphasias. Lesion in region of Wernicke's area (Brodmann areas 40 & 39, see *Figure 5-1*, page 84)
2. **Broca's (motor) aphasia**: in reality, "apraxia" of motor sequencing for speech (speech and phonation muscles aren't paralyzed, and function for other activities), producing faltering, dysarthric speech. Lesion in region of Broca's area (Brodmann area 44, see *Figure 5-1*, page 84)
3. **global aphasia**: usually due to lesion that destroys large portion of language center; all aspects of speech and language affected
    A. unable to speak except for some clichés, habitual phrases, or

expletives

B. anomia (inability to name objects or parts of objects)

C. verbal and motor perseveration

D. unable to understand all except for a few words

E. inability to read or write

4. conduction aphasia: due to disruption of connections between frontal and temporal speech areas, usually involving supramarginal gyrus. Similar to Wernicke's (fluent spontaneous speech and paraphasias), but patients understand spoken or written words, and are aware of their deficit. Repetition is severely affected
5. pure word blindness: AKA **alexia without agraphia** (rare) due to lesion in parieto-occipital lobe that interrupts connections between left angular gyrus and both occipital lobes. Patients can write, but are unable to read what they've written, and frequently seem unconcerned about this. Often accompanied by loss of ability to name colors. Reading and naming numbers usually preserved

---

5.9.3.2. Brain stem and related syndromes

WEBER'S SYNDROME

Cr. N. III palsy with contralateral hemiparesis (also see *Lacunar strokes*, page 1026). Third nerve palsies from parenchymal lesions may be relatively pupil sparing.

BENEDIKT'S SYNDROME

Similar to Weber's, plus red nucleus lesion. Cr. N. III palsy with contralateral hemiparesis except arm which has hyperkinesia, ataxia, & a coarse intention tremor. Lesion: midbrain tegmentum involving red nucleus, brachium conjunctivum, and fascicles of III.

MILLARD-GUBLER SYNDROME

Facial (VII) & abducens (VI) palsy + contralateral hemiplegia (corticospinal tract) from lesion in base of pons (usually ischemic infarct, occasionally tumor).

PARINAUD'S SYNDROME

AKA dorsal midbrain syndrome, AKA pretectal syndrome. As originally described, a supranuclear paralysis of vertical gaze resulting from damage to the

mesencephalon[50]. There are a number of variations, most include:

1. supranuclear upward gaze palsy (i.e. upgaze palsy affecting both voluntary saccadic and pursuit movements, with preservation of vestibulo-ocular or oculocephalic (doll's eyes) reflexes in most cases). Horizontal eye movements are spared
2. lid retraction (Collier's sign): NB: upgaze palsy + lid retraction produces the "**setting sun sign**"
3. convergence palsy
4. accommodation palsy
5. less common associations: pseudoabducens palsy (AKA thalamic esotropia), seesaw nystagmus, fixed pupils, dissociated light-near response (pseudo-Argyll Robertson), convergence spasm, nystagmus retractorius, internuclear ophthalmoplegia (INO)

Skew deviation may be a unilateral variant.

When combined with downgaze palsy, Parinaud's syndrome **(PS)** is known as the **syndrome of the Sylvian aqueduct**.

Differential diagnosis

Etiologies

1. masses pressing directly on quadrigeminal plate (e.g. pineal region tumors)
2. elevated ICP: secondary to compression of mesencephalic tectum by dilated suprapineal recess, e.g. in hydrocephalus
3. stroke or hemorrhage in upper brainstem
4. multiple sclerosis (MS)
5. occasionally seen with toxoplasmosis

Conditions affecting ocular motility that could mimic the upgaze palsy of PS:

1. Guillain-Barré syndrome
2. myasthenia gravis
3. botulism
4. hypothyroidism
5. there may be a gradual benign loss of upgaze with senescence

---

5.9.4. Jugular foramen syndromes

Contents of jugular foramen **(JF)**: Cr. N. IX, X, XI, petrosal sinus, sigmoid sinus, some meningeal branches from the ascending pharyngeal and occipital arteries[51].

Nearby: Cr. N. XII passes through the hypoglossal canal just above the occipital condyle. The carotid artery with the sympathetic plexus enters the carotid canal.

See *Table 5-11* for a summary and *Figure 5-28* for a schematic diagram of deficits in various JF syndromes.

AKA syndrome of the jugular foramen. Damage of nerves in JF itself (IX, X, XI), usually due to intracranial lesion.

Collet-Sicard syndrome: More likely with lesion outside skull. If caused by an intracranial lesion, it would have to be of such a large size that it would usually produce brain stem compression → long tract findings.

Vernet's syndrome: Villaret's syndrome: AKA posterior retropharyngeal syndrome.

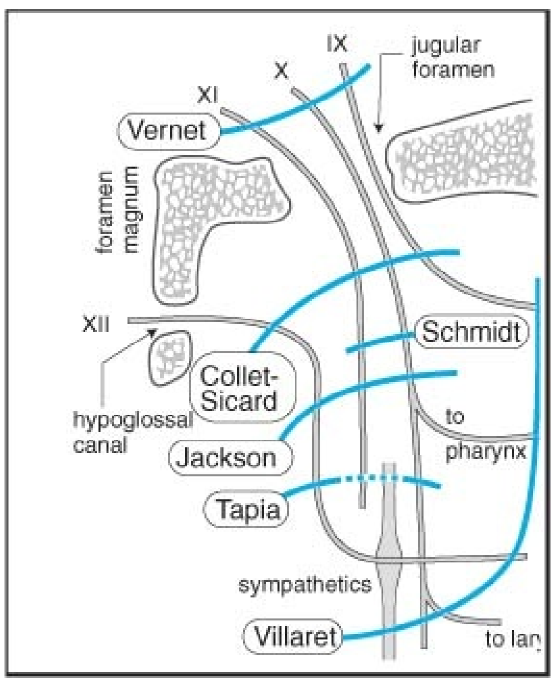

Figure 5-28 Schematic diagram of jugular foramen syndromes (coronal section through left jugular foramen viewed from the front) Solid line through a nerve indicates a deficit, dashed line indicates ± involvement.

Table 5-11 Cranial nerve dysfunction in jugular foramen syndromes

Nerve	Result of lesion	------- SYNDROME* -------					
		Vernet	Collet Sicard	Villaret	Tapia	Jackson	Schmidt
IX	loss of taste and sensation in posterior third of tongue	✖	✖	✖			
X	paralysis of vocal cords & palate, anesthesia of pharynx & larynx	✖	✖	✖	✖	✖	✖
XI	weak trapezius & SCM	✖	✖	✖	±	✖	✖
XII	tongue paralysis & atrophy		✖	✖	✖	✖	
sympathetics	Horner's syndrome			✖	±		

* KEY: ✖ indicates dysfunction of that nerve; ± indicates involvement may or may not occur

5.9.5. Babinski sign

Although regarded as the most famous sign in neurology, there is still disagreement over what constitutes a normal response and when abnormal responses should occur[52]. The following represents one interpretation.

The **plantar reflex (PR)** (AKA Babinski sign) is a primitive reflex, present in infancy, consisting of extension of the great toe in response to a noxious stimulus applied to the foot. The small toes may fan, but this is not consistent nor clinically important. The PR disappears usually at ≈ 10 months age (range: 6 mos to 12 yrs), presumably under inhibitory control as myelination of the CNS occurs, and the normal response then converts to plantarflexion of the great toe. An upper motor neuron **(UMN)** lesion anywhere along the pyramidal (corticospinal) tract from the motor strip down to ≈ L4 will result in a loss of inhibition, and the PR will be "unmasked" producing *extension* of the great toe. With such an UMN lesion, there may also be exaggeration of flexor synergy resulting in dorsiflexion of the ankle, and flexion of the knee and hip (AKA **triple flexor response**).

Neuroanatomy

The afferent limb of the reflex originates in cutaneous receptors restricted to the first sacral dermatome (S1) and travels proximally via the tibial nerve. The spinal cord segments involved in the reflex-arc lie within L4-S2. The efferent limb to the toe extensors travels via the peroneal nerve.

Etiologies

Lesions producing a PR need not be structural, but may be functional and

reversible. etiologies are listed in *Table 5-12*.

Table 5-12 Differential diagnosis of the PR

- spinal cord injuries*
- cervical spinal myelopathy
- lesions in motor strip or internal capsule (CVA, tumor, contusion…)
- subdural or epidural hematoma
- hydranencephaly
- toxic-metabolic coma
- seizures
- trauma
- TIAs
- hemiplegic migraine
- motor neuron disease (ALS)

* in spinal cord injuries, the PR may initially be absent during the period of spinal "shock" (*see page 930*)

Eliciting the PR, and variations

The optimal stimulus consists of stimulation of the lateral plantar surface and transverse arch in a single movement lasting 5-6 seconds[53]. Other means for applying noxious stimuli may also elicit the plantar reflex (even outside the S1 dermatome, although these do not produce toe flexion in normals). Described maneuvers include: **Chaddock** (scratch the lateral foot; positive in 3% where plantar stimulation was negative), **Schaeffer** (pinch the Achilles tendon), **Oppenheim** (slide knuckles down shin), **Gordon** (momentarily squeeze lower gastrocnemius), **Bing** (light pinpricks on dorsolateral foot), **Gonda** or **Stronsky** (pull the 4th or 5th toe down and out and allow it to snap back).

Hoffman's (or Hoffmann's or Hoffmann) sign

May signify a similar UMN interruption to the upper extremities. Elicited by flicking downward on the nail of the middle or ring finger: a positive (pathologic) response consists of involuntary flexion of the adjacent fingers and/or thumb (may be weakly present in normals)[54]. Differs from the plantar reflex since it is monosynaptic (synapse in Rexed lamina IX).

Can sometimes be seen as normal in young individual with diffusely brisk reflexes & positive jaw jerk, usually symmetric. When present pathologically, represents disinhibition of a C8 reflex, ∴ indicates lesion above C8.

Was observed in 68% of patients operated for cervical spondylotic

myelopathy[54]. In 11 patient's presenting with lumbar symptoms but no myelopathy, a bilateral Hoffman sign was associated with occult cervical spinal cord compression in 10 (91%)[54].

5.9.6. Bladder neurophysiology

Central pathways

The primary coordinating center for bladder function resides within the nucleus locus coeruleus of the pons. This center synchronizes bladder contraction with relaxation of the urethral sphincter during voiding[55].

Voluntary cortical control primarily involves inhibition of the pontine reflex, and originates in the anteromedial portion of the frontal lobes and in the genu of the corpus callosum. In an uninhibited bladder (e.g. infancy) the pontine voiding center functions without cortical inhibition and the detrusor muscle contracts when the bladder reaches a critical capacity. Voluntary suppression from the cortex via the pyramidal tract may contract the external sphincter and may also inhibit detrusor contraction. Cortical lesions in this location → urgency incontinence with inability to suppress the micturition reflex[43 (p 1031)].

Efferents to the bladder travel in the dorsal portion of the lateral columns of the spinal cord (blue areas in *Figure 5-29*).

Motor

There are two sphincters that prevent the flow of urine from the bladder: internal (autonomic, involuntary control), and external (striated muscle, voluntary control).

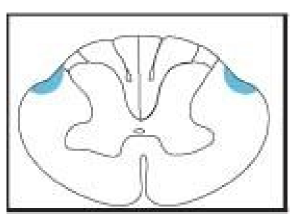

Figure 5-29 Location of spinal cord bladder efferents (blue)

Parasympathetics (PSN): the detrusor muscle of the bladder contracts and the internal sphincter relaxes under PSN stimulation. PSN preganglionic cell bodies reside in the intermediolateral grey of spinal cord segments S2-4. Fibers exit as ventral nerve roots and travel via pelvic splanchnic nerves (nervi

erigentes) to terminate on ganglia within the wall of the detrusor muscle.

Somatic nerves: somatic voluntary control descends in the pyramidal tract to synapse on motor nerves in S2-4, and then travels via the **pudendal nerve** to the external sphincter. This sphincter may be voluntarily contracted, but relaxes reflexly with opening of the internal sphincter at the initiation of micturition. Primarily maintains continence during ↑ vesical pressure (e.g. valsalva).

Sympathetics: sympathetic cell bodies lie within the intermediolateral gray column of lumbar spinal cord from segments T12 - L2. Preganglionic axons pass through the sympathetic chain (without synapsing) to the inferior mesenteric ganglion. Postganglionic fibers pass through the inferior hypogastric plexus to the bladder wall and internal sphincter. Sympathetics heavily innervate the bladder neck and trigone. Sympathetics have little effect on bladder motor activity, but alpha adrenergic stimulation results in bladder neck closure which is necessary for bladder filling.

Pelvic nerve stimulation → increased sympathetic tone → detrusor relaxation & increased bladder neck tone (allowing larger volume to be accommodated).

SENSORY

Less well understood than motor innervation. Bladder wall stretch receptors sense bladder filling and send afferent signals via pelvic, pudendal and hypogastric nerves to spinal cord segments T10-L2 & S2-4. Fibers ascend primarily in the spinothalamic tract.

URINARY BLADDER DYSFUNCTION

The term **neurogenic bladder** describes bladder dysfunction due to lesions within the central or peripheral nervous systems. Some use the term synonymously with detrusor areflexia.

Dorsal (sensory) roots lesions interrupt the afferent limb, producing an atonic bladder that fills until dribbling and overflow incontinence occur. No sensation of bladder fullness is appreciated. Voluntary voiding is still possible, but is usually incomplete.

Detrusor hyperreflexia: Can result from interruption of efferents anywhere from cortex to sacral cord. When a critical volume is attained, reflex bladder emptying occurs. Clinically associated with frequent, uncontrollable, precipitous voiding. Cerebral lesions include: CVA, head injury, brain tumors, hydrocephalus, Parkinson's disease, various dementias, and MS. Cord lesions include anything that causes myelopathy (see *Myelopathy*, page 1185).

Detrusor areflexia: Clinically correlates with difficulty initiating micturition, interrupted flow, and significant residual urine. Incontinence may result from over-distention of the bladder (**overflow incontinence**), or may be associated with absence of sphincter tone. Etiologies include: chronic infection, long-term bladder catheterization, certain drugs (especially phenothiazines), injury or tumor of the cauda equina or conus medullaris, myelomeningocele, and diabetes mellitus (autonomic neuropathy).

In general, regarding discrete neurologic lesions affecting the bladder[56]:

1. **supraspinal** (lesions above the brain stem): loss of centrally mediated inhibition of the pontine voiding reflex. Usually produces involuntary bladder contractions with smooth and striated sphincter synergy, often with preserved sensation and voluntary striated sphincter function. Symptoms: urinary frequency or urgency, urgency incontinence, and nocturia[55]. If sensory pathways are interrupted, unconscious incontinence occurs (incontinence of the unawares type). Since muscles are coordinated, normal bladder pressures are maintained and there is low risk of high-pressure related renal dysfunction. Voluntary bladder emptying is usually maintained, and timed voiding together with anticholinergic medications are used in management. Areflexia may sometimes occur
2. complete (or near complete) **spinal cord lesions**:
   A. **suprasacral** (lesion above the S2 spinal cord level, which is ≈ T12/L1 vertebral body level in an adult): the sacral voiding center is located in the conus medullaris. Etiologies: spinal cord injuries (after spinal shock has subsided[A]), tumors, transverse myelitis. Usually develop detrusor hyperreflexia → involuntary bladder contractions without sensation (**automatic bladder**), smooth sphincter synergy, but striated dyssynergy (involuntary contraction of the external sphincter during voiding which produces a functional outlet obstruction with poor emptying and high vesical pressures). Bladder fills and empties spontaneously (or in response to lower extremity cutaneous stimulation). Bladder compliance is often reduced. Managed by intermittent catheterizations + anticholinergics
   B. **infrasacral lesions** (lesion below the S2 spinal cord level): includes injury to conus medullaris, cauda equina or peripheral nerves (formerly referred to as lower motor neuron lesions). Etiologies: large HLD, trauma with compromise of spinal canal. Usually develop detrusor areflexia, and do not have involuntary bladder contractions. Reduced urinary flow rate or retention results, and voluntary voiding

may be lost. Overflow incontinence develops. There may be reduced compliance during filling, and paralysis of the smooth sphincter. Usually associated with loss of bulbocavernosus and anal wink reflex (preserved in suprasacral lesions) and perineal sensory loss

3. **interruption of the peripheral reflex arc**: may produce disturbances similar to low spinal cord injury with detrusor areflexia, low compliance and inability to relax the striated sphincter
4. herniated lumbar disc: (*see page 443*) most consist initially of difficulty voiding, straining, or urinary retention. Later, irritative symptoms may develop
5. spinal stenosis (lumbar or cervical): urologic symptoms vary, and depend on the spinal level(s) involved and the type of involvement
6. cauda equina syndrome: usually produces urinary retention, although sometimes incontinence may occur (some cases are overflow incontinence) (*see page 446*)
7. peripheral neuropathies: e.g. with diabetes, usually → impaired detrusor activity
8. neurospinal dysraphism: most myelodysplastic patients have an areflexic bladder with an open bladder neck. The bladder usually fills until the resting residual fixed external sphincter pressure is exceeded and the leakage occurs
9. **multiple sclerosis**: 50-90% of patients develop voiding symptoms at some time. The demyelination primarily involves the posterior and lateral columns of the cervical spinal cord. Detrusor hyperreflexia is the most common urodynamic abnormality (in 50-99% of cases), with bladder areflexia being less common (5-20%)

A. during spinal shock (*see page 930*), the bladder is acontractile and areflexic (detrusor areflexia); sphincter tone usually persists and urinary retention is the rule (urinary incontinence generally does not occur except with overdistention)

URINARY RETENTION

Etiologies of urinary retention:

1. bladder outlet obstruction (a brief differential diagnosis list is presented here)
    A. urethral stricture: retention tends to be progressive over time

B. prostatic enlargement in males:
   1. benign prostatic hypertrophy **(BPH)** & prostate cancer: retention tends to be progressive over time
   2. acute prostatitis: onset of retention may be <u>sudden</u>
   3. rare: extruded prostatic stone

C. women may develop a cystocele which can produce a urethral kink

D. rare: urethral cancer

2. detrusor areflexia (*see page 117*) or hypotonia
   A. spinal cord injury
   B. cauda equina syndrome (*see page 446*)
   C. chronic infectinon
   D. long-term bladder catheterization
   E. certain drugs (narcotics, phenothiazines)
   F. injury of the cauda equina or conus medullaris, or of the spinal cord at or below the sacrum
      1. trauma
      2. tumor
      3. myelomeningocele
   G. diabetes mellitus (autonomic neuropathy)
   H. herpes zoster at the level of the sacral dorsal root ganglia[56] (p 967)
   I. incomplete opening of the bladder neck: occurs almost exclusively in young males with longstanding obstructive and irritative symptoms[56] (p 968)
   J. following severe bladder over distention from any of the above
3. postoperative retention: well-recognized but poorly understood. More common after lower urinary tract, perineal, gynecologic and anorectal operations. Anesthesia and analgesia may contribute to a number of factors[56] (p 969)
4. psychogenic

EVALUATION OF BLADDER FUNCTION

URODYNAMICS

Usually combined with x-ray (cystometrogram **(CMG)**) or fluoro (videourodynamics). Measures intravesicular pressures during retrograde bladder filling through a urethral catheter, usually combined with sphincter electromyography. Presence or absence (detrusor areflexia, *see below*) of

detrusor reflex is detected. If present, procedure is repeated, asking patient to suppress the urge to void. Inability to suppress is called an un-inhibited detrusor reflex (AKA detrusor hyperreflexia, *see above*).

SPHINCTER ELECTROMYOGRAPHY ***(EMG)***

Either via needle electrodes, or with externally mounted surface electrodes. Voluntary sphincter contraction tests intactness of supraspinal innervation. When combined with CMG, detects electrical activity in sphincters during associated phases of detrusor contraction.

VOIDING CYSTOURETHROGRAM AND INTRAVENOUS PYELOGRAPHY ***(IVP)***

Voiding cystourethrogram **(VCUG)** detects urethral pathology (diverticula, strictures…), abnormalities of bladder (diverticula, detrusor trabeculations associated with longstanding contractions against high resistance…), and vesical-ureteral reflux.

TREATMENT

Goals are to preserve renal function (which usually involves prevention of UTIs, renal calculi, and ureteral reflux due to high intravesicular pressures) and optimization of urinary continence. Patients with inadequate emptying or increased bladder pressure are often managed by intermittent catheterizations and anticholinergics. Anticholinergics and behavioral therapy are used for patients with maintained voluntary bladder emptying with urinary frequency or urgency incontinence.

NOTES

6. Neuroradiology

6.1. Contrast agents in neuroradiology

Also see *Intraoperative dyes*, page 144 for visible dyes useful in the operating room.

IODINATED CONTRAST AGENTS

✖ Caution: iodinated contrast (IV or intraarterial) may delay excretion of **metformin** (Glucophage®, Avandamet®), an oral hypoglycemic agent used in diabetes type II, and can be associated with lactic acidosis and renal failure. The manufacturer recommends withholding metformin 48 hrs prior to and following contrast administration (or longer if there is evidence of declining renal function following use of contrast). Metformin should also be held ≈ 48 hours before any surgery, and should not be restarted post-op until the patient has fully recovered and is eating and drinking normally.

Maximum dose of iodine with normal renal function is ≈ 86 gm in a 24 hour period.

INTRATHECAL CONTRAST AGENTS

The primary approved agent employed for intrathecal use today is iohexol (Omnipaque®) (*see below*).

Inadvertent intrathecal injection of ionic contrast agents

✖ Caution: serious reactions can occur with inadvertent intrathecal injection (e.g. for myelography, cisternography, ventriculography…) of iodinated contrast media that are not specifically indicated for intrathecal use (including ionic contrast agents as well as some non-ionic agents (e.g. Optiray®, Reno-60…)). This can cause uncontrollable seizures, intracerebral hemorrhage, cerebral edema, coma, paralysis, arachnoiditis, myoclonus (tonic-clonic muscle spasms), rhabdomyolysis with subsequent renal failure, hyperthermia, and respiratory

compromise, with a significant fatality rate[1].

Management suggestions include:

1. immediately remove CSF + contrast if the error is recognized when the opportunity is available (e.g. withdraw fluid through myelography needle)
2. elevate head of bed ≈ 45° (to keep contrast out of head)
3. if there is a question about what may have occurred (i.e. it is not certain if an inappropriate contrast agent was used) send blood and CSF with contrast for high-performance liquid chromatography for identification of agent[2]
4. antihistamines: e.g. diphenhydramine (Benadryl®) 50 mg deep IM
5. respiration: supplemental oxygen, and if needed, intubation
6. control HTN
7. IV hydration
8. IV steroids
9. sedation if patient is agitated
10. treat fever with acetaminophen and if needed with a cooling blanket
11. pharmacologic paralysis if necessary to manage muscle activity
12. anticonvulsant medication: more than one agent may be required (e.g. phenytoin + phenobarbital + a benzodiazepine)
13. consider unenhanced brain CT scan: may help assess if contrast has diffused intracranially, but this requires placing patient flat and may not be advisable
14. insertion of lumbar subarachnoid drain
15. monitor: electrolytes, anticonvulsant levels, creatine kinase **(CK)**
16. repeat EEGs to assess seizure activity while sedated/paralyzed

Iohexol (Omnipaque®)

A non-ionic triiodinated compound. It has replaced metrizamide. Concentrations expressed as follows: e.g. Omnipaque 300 contains the equivalent of 300 mg of organic iodine per ml of media (300 mgI/ml).

Usually reserved for IV contrast CT scan of brain primarily for patients with previous dye reaction, e.g. to Reno-60. Uses and concentrations are shown in *Table 6-1*.

Table 6-1 Iohexol concentrations for adults

Procedure	Concentration (mgI/ml)	Volume (ml)
lumbar myelography via LP	180 240	10-17 7-12.5
thoracic myelography via LP or cervical injection	240 300	6-12.5 6-10
cervical myelography via LP	240 300	6-12.5 6-10
cervical myelography via C1-2 puncture	180 240 300	7-10 6-12.5 4-10
complete myelography via LP	240 300	6-12.5 6-10
cerebral arteriography*	300	≈ 6-12 ml/vessel
IV contrast enhanced CT scan of the brain	240 350	120-250 ml IV drip 70-150 ml bolus†
CT cisternography via LP or C1-2 puncture	300 350	12 12
CT ventriculography via ventricular catheter	180‡	2-3
plain film ventriculography via ventricular catheter	180	2-3
plain film "shunt-o-gram" injected via shunt into ventricles	180	2-3
plain film "shunt-o-gram" injected via shunt <u>distal</u> to valve so as not to enter into ventricles (to check distal shunt function)	300 350	10-12 10-12

* most centers use Optiray®, see text

† follow with 250 ml bolus of 0.45% NS to rehydrate patient

‡ 180 will be very dense on CT, and some use 1-3 ml of 140 or diluted 180%(dilute approximately 2 parts contrast to 1 part preservative-free normal saline)

Intrathecal use: NB: only Omnipaque 180, 210, 240 and 300 are labeled for intrathecal use. 140 and 350 are <u>not</u> FDA approved for intrathecal use, however, some neuroradiologists will use Omnipaque 140 or diluted 180 e.g. for CT ventriculography.

Consider discontinuing neuroleptic drugs (including: phenothiazines, e.g. chlorpromazine, prochlorperazine, and promethazine) at least 48 hours prior to procedure. Elevate HOB ≥ 30° for the first few hours after the procedure. Hydrate orally or IV.

Use with caution in patients with seizure history, severe cardiovascular

disease, chronic alcoholism or multiple sclerosis.

Iohexol undergoes slow diffusion from the intrathecal space to the systemic circulation and is eliminated by renal excretion with no significant metabolism or deiodination.

Maximum dosage: a total dose of 3060 mg iodine should not be exceeded in an adult during a single myelogram (some say up to 4500 mg is OK) (e.g. 15 cc of Omnipaque 300 = 15 ml **x** 300 mgI/ml= 4500 mg of iodine).

Iopamidol (e.g. Isovue 300, Isovue 370®)

Triiodinated, non-ionic, water-soluble. Used for intravascular and intrathecal radiographic contrast. Isovue 300 and 370 contains 300 and 270 mg iodine/ml, respectively.

NON-INTRATHECAL CONTRAST AGENTS

For inadvertent intrathecal injection of contrast agents <u>not</u> intended for intrathecal use, *see above*.

Diatrizoate meglumine (e.g. Reno-60®, Reno-dip®)

✖ Not for intrathecal use (*see above*).

A tri-iodinated benzine derivative similar to Conray. Both have been available for a long time. Due to the fact that it ionizes, it is <u>ionic</u> and <u>hyperosmolar</u>. Widely used IV, in neuroradiology for IV contrast enhanced CT **(CECT)** scan when there is no history of prior reaction to IV contrast agents (use iohexol in patients with previous reaction, *see above*).

- CECT of the brain in adult patient with no history of previous dye reaction:
  - A. 300 ml IV drip of Reno-dip® (30% solution, i.e. 300 mg/ml) over ≈ 15 mins
  - B. 50-150 ml of Reno-60 (60% solution). Typically: 150 ml is used
- body CT: bolus of 150 ml of Reno-60® (3 vials of 50 ml each), followed e.g. by 250 ml of 0.45% NS to help prevent dehydration. Usually given more slowly to diabetics and the elderly where there is increased risk of renal failure

Ioversol (Optiray®)

✖ Not for intrathecal use (*see above*).

Uses and concentrations include:

- arteriography: Optiray 300 (ioversol 64%) or Optiray 320 (ioversol 68%). Total procedural dose should not usually exceed 200 ml
- IV contrast enhanced CT scan of brain:
  A. adult: 50-150 ml of Optiray 300, 320, or 100-250 ml of Optiray 240. Typically: 100 ml of Optiray 320
  B. pediatrics: 1-3 ml/kg of Optiray 320

Iopromide (Ultravist®)

✖ Not for intrathecal use (*see above*). Available in 150, 240, 300 & 370 mg iodine/ml. Osmolality of Ultravist 300 is 607.

Cerebral angiography (300 mg/ml): maximum dose is 150 ml per procedure.

Contrast enhanced CT **(CECT)** (**300 mg/ml**). ***Rx*** Pediatrics (> 2 years age): typical dose in is 1-2 ml/kg IV, maximum dose is 3ml/kg per procedure. Adult: typical dose is 50-200 ml, maximum dose is 200 ml.

Iodixanol (Visipaque®)

✖ Not for intrathecal use (*see above*). Triiodinated, non-ionic, iso-osmolar to blood. For intravascular use. FDA approved for CECT, some angiographers use Visipaque 270 for cerebral angiography (slightly lower opacification, but also slightly lower iodine dose). Available in 270 and 320 mg iodine/ml.

6.1.1. Iodinated contrast preps

6.1.1.1. Allergy prep

Indicated for patients with previous history of reaction to IV iodinated contrast material. Minor previous reactions such as hives and itching should merit preparation with this regimen whenever possible. Patients with anaphylactic shock or severe edema causing compromise of the airway should probably not receive IV iodine even with this prep, unless absolutely necessary. ✖ Caution: the patient may still have serious reaction (modified[3]). This prep has also been used for the rare gadolinium allergy.

1. utilize non-ionic contrast medium (e.g. iohexol) whenever possible
2. have emergency equipment available during study
3. medications:
   A. steroid (*see page 31* for further details of steroid dosing)

1. prednisone 50 mg PO: 20-24 hrs, 8-12 hrs & 2 hrs before study
2. equivalent dose of IV Solumedrol® (methylprednisolone): ≈ 25 mg

B. diphenhydramine (Benadryl®) 50 mg, *EITHER* IM 1 hr before, *OR* IV 5 min before study

C. optional: H_2 antagonist, e.g. cimetidine 300 mg PO or IV 1 hr before study

Medications for an emergency scan when 24 hour prep is not possible:

- hydrocortisone 100 mg IV then scan within 2 hours

6.1.1.2. Prep for renal insufficiency

For patients with DM or mild renal insufficiency (e.g. slight serum creatinine elevation, > 1.2 mg/dL (U.S.) which is > 100 µmol/L), to mitigate against iodine contrast-induced nephropathy:

- N-acetyl cysteine (Mucomyst)[A]: regimens all accompany hydration and include:
  A. 800 mg PO q 8 hrs for 24 hours before the study[4], followed by 600 mg PO BID for 24 hours after the study
  B. 600 mg PO BID X 2 days before the study, 600 mg PO BID for 24 hours after
  C. 600-mg IV bolus before the study, and 600 mg PO BID for 48 hours after[5]
- hydration: 1 L of sterile water with 3 amps of sodium bicarbonate IV at 100 ml/hr, start 1 hour prior to the study, and continue until entire L given

A. the actual efficacy of NAC has not been proven, and may be no better than hydration alone

6.1.2. Reactions to intravascular contrast media

BETA BLOCKERS

Beta blockers can increase the risk of contrast media reactions, and may mask some manifestations of an anaphylactoid reaction.

They also make use of epinephrine inadvisable since the alpha effects of epinephrine will predominate (bronchospasm, vasoconstriction, increased vagal

tone). If treatment is required for hypotension, may try **glucagon** 2-3 mg IV bolus, followed by 5 mg IV drip over 1 hour (glucagon has positive inotropic and chronotropic effect that is not mediated through adrenergic pathways).

IDIOSYNCRATIC REACTIONS AND TREATMENT

For treatment of inadvertent intrathecal injection of ionic contrast agents, *see page 122*.

HYPOTENSION WITH TACHYCARDIA (ANAPHYLACTOID REACTION)

1. mild: Trendelenburg position. IV fluids
2. if no response but remains mild:
   epinephrine (use with caution in patients with coronary artery disease, limited cardiac reserve, hypertension, or unclipped cerebral aneurysm)
   A. 0.3-0.5 ml of 1:1000 SQ (0.3-0.5 mg) q 15-20 mins (peds: 0.01 mg/kg)
   B. or, ASEP recommendations (especially for elderly or patients in shock): 10 ml of 1:100,000 IV over 5 to 10 min (put 0.1 ml of 1:1000 in 10 ml of NS, or dilute 1 amp of 1:10,000 to 10 ml with NS)
3. moderate to severe or worsening (anaphylaxis): add:
   A. IV colloidal fluids, e.g. hetastarch (Hespan®) 6% (colloids are required since there is extravascular shift of fluids due to seepage, these agents also carry a small risk of allergic reaction)
   B. epinephrine (*see above*). May repeat **x** 1
   C. O_2 2-6 L/min per NC. Intubate if necessary
   D. EKG to R/O ischemic changes
4. if shock develops: add dopamine, start at 5 mcg/kg/min (*see page 22*)

HYPOTENSION WITH BRADYCARDIA (VASOVAGAL REACTION)

1. mild:
   A. Trendelenburg position
   B. IV fluids
2. if no response, add:
   A. atropine 0.75 mg IV, may repeat up to 2-3 mg over 15 mins PRN. Use with caution in patients with underlying heart disease
   B. EKG and/or cardiac monitor: especially if atropine or dopamine are used
3. if no response: add dopamine, start at 5 mcg/kg/min (*see page 22*)

Urticaria

1. mild: self limited. No treatment necessary
2. moderate:
   A. **diphenhydramine** (Benadryl®) 50 mg PO or deep IM (avoid IV, can cause anaphylaxis itself)
   B. **cimetidine** (Tagamet®) 300 mg PO or IV diluted to 20 ml and given over 20 mins. H_2 receptors contribute to wheal and flare of reaction
3. severe: treat as above for moderate reaction, and add:
   A. epinephrine (*see above*)
   B. maintain IV line

Facial or laryngeal angioedema

1. epinephrine: *see above*. May repeat up to 1 mg
2. if respiratory distress: O_2 2-6 L/min. Intubate if necessary (orotracheal may be very difficult due to swelling of tongue, nasotracheal intubation or emergency cricothyrotomy may be required)
3. diphenhydramine: *see above*
4. cimetidine: *see above*
5. if angioedema is accessible, add ice pack
6. maintain IV line
7. steroids are usually effective only for <u>chronic</u> angioedema

Bronchospasm

1. mild to moderate:
   A. epinephrine: *see above*. May repeat up to 1 ml
   B. if respiratory distress: O_2 2-6 L/min. Intubate if necessary
   C. maintain IV line
   D. inhalational therapy with a ß-adrenergic agonist, e.g. albuterol (Proven-til®) if respiratory therapy is available, otherwise, metered dose inhaler e.g. pirbuterol (Maxair®) or metaproterenol (Metaprel®), 2 puffs
2. severe: treat as above for moderate reaction, and add:
   A. aminophylline 250-500 mg in 10-20 cc NS slow IV over 15-30 mins. Monitor for hypotension and arrhythmias
   B. intubate
3. prolonged: add the following (will not have immediate effect):

   A. hydrocortisone 250 mg IV
   B. diphenhydramine: *see above*
   C. cimetidine: *see above*

PULMONARY EDEMA

1. O_2 2-6 L/min per NC. Intubate if necessary
2. raise head and body
3. furosemide (Lasix®) 40 mg IV
4. EKG
5. if hypoxia develops (may manifest as agitation or combativeness), add:
   A. morphine 8-15 mg IV. May cause respiratory depression, be prepared to intubate
   B. epinephrine: *see above*. ✖ CAUTION: use only if MI can be R/O as cause of the pulmonary edema. Patients with acute intracranial pathology may be at risk of neurogenic pulmonary edema (*see page 28*)

SEIZURES

If seizure is not self limited, start with lorazepam (Ativan®) 2-4 mg IV for an adult. Take precautions for status epilepticus (*see page 404*) and proceed to other drugs as indicated (*see page 405*).

6.2. Radiation safety for neurosurgeons

Radiation exposure has both a deterministic component (exposure over a certain threshold will cause a specific injury) as well as a stochastic component (any dose increases the chances of an adverse event, and the higher the cumulative dose, the higher the chances).

UNITS[6]

Absorbed dose: the amount of energy absorbed per unit mass. Expressed in Gray or rads.

Gray (Gy): the SI unit. 1 Gy = 100 cGy = 100 rads = an absorbed dose of 1 Joule/kg.

Rad: 1 rad = an absorbed dose of 100 ergs/gram = 0.01 joule/kg = 0.01 Gy =

1 cGy.

The biological effect (dose equivalent) of radiation: can be expressed in rem or Sieverts.

Sievert (Sv): the SI unit. The dose equivalent in sieverts is equal to the absorbed dose in grays multiplied by a "quality factor" **(Q)** which differs for different sources of radiation, e.g. high-energy protons have a Q of 10, x-rays have a Q of 1. 1 Sv=100 rems.

Roentgen-equivalent man (rem): the absorbed dose in rads multiplied by Q. 1 rem is estimated to cause ≈ 300 additional cases of cancer per million persons (one third of which are fatal). 1 rem = 0.01 sievert.

TYPICAL RADIATION EXPOSURE

The average annual exposure to radiation is 360 mrem (about 30 mrem are due to background cosmic radiation). A transcontinental airline flight exposure is ≈ 5 mrem.

CXR: causes about 0.01-0.04 rem of exposure to the chest.

Spine x-ray with obliques: 5 rem.

CAT scan (brain, noncontrast): median effective dose to the head = 0.2 rem, but the range varied 13 fold within and across institutions[7].

Spine CT: 5 rem.

Cerebral arteriogram: ≈ 10-20 rem (including fluoroscopy)[9].

Cerebral embolization: 34 rem.

Bone scan: 4 rem.

C-arm fluoroscopy[8]: exposure is shown in *Table 6-2*.

Doses during a minimally invasive TLIF[10]:

Patient exposure: mean 60 mGy to the skin in the AP plane (range: 8-250 mGy), 79 mGy in the lateral plane.

Surgeon exposure: 76 mrem to dominant hand, 27 mrem at the waist under a lead apron, and 32 mrem to an unprotected thyroid level detector.

Table 6-2 Radiation exposure with fluoroscopy[8]*

Distance from beam		Typical team member	Deep exposure	Superficial exposure
feet	meters		(mrem/min)	
Direct beam		patient	4000	
1	0.3	surgeon	20	29
2	0.6	assistant	6	10
3	0.9	scrub tech	0	≤ 2
5	1.5	anesthesiologist	0†	0†

* in a mock OR set up for maximal scatter

† after 10 minutes of exposure

Occupational exposure

The U.S. Nuclear Regulatory Commission **(NRC)** maximal recommended annual occupational dose limits for radiation are shown in *Table 6-3*.[11]. The 1990 recommendations of the International Commission on Radiological Protection **(ICRP)** was to keep exposure ≤ 2 rem/year averaged over 5 years[12].

ALARA: an acronym for "As Low As Reasonably Achievable" by which the NRC means making every reasonable effort to keep radiation dose as far below the limits as possible consistent with the purpose for which the licensed activity is undertaken[13].

Table 6-3 Annual occupational radiation dose limits

Target organ	Recommended MAXIMAL dose (rem/yr)
whole body	**5**
lens of eye	15
skin, hands, feet	50
other organs (including thyroid)	15

Steps to reduce occupational radiation dose (to staff) during surgery:

1. increase the distance from the radiation source: radiation exposure is proportional to the inverse square of the distance. Conventional wisdom is to try to keep 6 feet away. In a AANS publication, **3 m** (10 ft) was recommended[14]

   Lead aprons/shields may or may not work. Distance ALWAYS works[19] (inverse square law - double the distance and get 1/4 the radiation!).

2. use shielding: shielding is less effective at higher kV (used with larger patients). Portable lead "doors" are more effective than aprons. Wrap-around 2-piece aprons are better than front side aprons. Non-lead aprons may not provide the rated protection at levels > 100 keV[15]
3. don't overuse magnification: most fluoro systems increase the radiation emitted **x** ≈ 4 to compensate for the associated reduction in image brightness
4. "boost" mode can double the radiation output. Use should be kept to a minimum
5. use live fluoro only when absolutely necessary
6. for lateral imaging, stand on the "downstream" (image intensifier **(ImI)**) side of the C-arm: scatter is the most significant cause of exposure here and is higher on the source side[16] (this asymmetry is not as significant for C-spine[17])
7. keep the ImI as close to the patient as possible (reduces patient & staff exposure)
8. on AP images (with the patient prone or supine): position the x-ray tube under the table with the ImI over the patient (lowers scatter exposure to staff)[18]
9. collimate the beam as much as possible: reduces radiation to patient and to staff, and results in less image degradation
10. keep hands, arms, etc. out of the primary beam at all times (consider using leaded gloves if hands need to be within the beam or nearby for an extended time)
11. minimize number of images: plan your shot, avoid frequent "checks" or peeks
12. use image guided navigation when possible and practical
13. leaded glasses are recommended only for personnel with very high fluoro times: cataracts can be induced by single doses of 200 rads (very high), cumulative doses of 750 rads have not been associated with cataracts

6.3. CAT scan or CT scan

Attenuation of the x-ray beam on a CT scan is defined in Hounsfield units. These units are not absolute, and vary between CT scanner models. Some sample values are shown in *Table 6-4*.

If there are no calibration marks on a scan, one can estimate the average adult globe (eyeball) is 25 mm in diameter (through its equator).

Table 6-4 Hounsfield units for a sample CT scanner

DEFINITIONS	Hounsfield units	Comment
no attenuation (air)	–1000	definition
water	0	definition
dense bone	+1000	definition
CRANIAL CT		
brain (grey matter)	30 to 40	
brain (white matter)	20 to 35	
cerebral edema	10 to 14	
CSF	+5	
bone	+600	
blood clot*	75 to 80	acute SDH or EDH, fresh SAH
fat	–35 to –40	
calcium	100 to 300	
enhanced vessels	90-100	
SPINE CT		
disc material	55-70	disc density is ≈ 2 **x** thecal sac
thecal sac	20-30	

* Hct < 23% will cause an acute SDH to be isodense with brain

Differential diagnosis of an intracranial hyperdense (with respect to brain) structure on non-contrast CT:

1. acute blood
2. calcium
3. vessels with low flow
4. melanoma: may be slightly hyperdense to brain due to melanin

Contrast enhanced CT scan (CECT)

Used primarily for imaging neoplasms or vascular malformations.

Typical IV dose of contrast: 60-65 ml of e.g. Isovue 300® (*see page 123*) which delivers 18-19.5 grams of iodine.

6.3.1. CT angiography (CTA)

Employs rapid injection of iodinated contrast at 3-4 cc/sec, typically 65-75 ml of e.g. Isovue 300®.

Accuracy is diminished for vessels that are perpendicular to the axial CT plane. Also in the vicinity of dense clot, CTA has trouble resolving the adjacent vessels.

6.3.2. CT perfusion (CTP)

Requires use of iodinated contrast. Areas of interest are selected from an unenhanced CT scan in the 3 supratentorial vascular territories. Contrast is given at a standard rate (e.g. 40 ml IV at 5 ml/sec). Scans through the regions of interest are repeated at intervals, e.g. every 2 seconds for 1 minute.

Acetazolamide (ACZ) (Diamox®) **challenge**: after the above, a bolus of 1000 mg of IV ACZ is given, and scans are repeated at intervals for approximately 10 minutes, with a final scan usually at 15 minutes. Parameters then calculated from the images: cerebral blood volume **(CBV)**, CBF, meant transit times **(MTT)**, and time to peak **(TTP)**.

Abnormalities that can be demonstrated (also, *see page 1011*):

1. flow significant stenosis: decreased CBV & CBF, increased MTT and TTP
2. steal: after ACZ challenge (*see above*), CBV & CBF decrease, often with increases in the corresponding contralateral territory; MTT increases

In comparison to perfusion weighted MRI **(PWI)** (*see page 132*):

1. PWI acquires multiple slices of the whole brain over and over. CTP is limited to a given slice or several slices (usually 10-20 mm thick), and one has to choose where to place that slice
2. PWI has more artifact than CTP

6.4. Magnetic resonance imaging (MRI)

6.4.1. General information

DEFINITIONS[20]

Abbreviations

TR	time to repetition
TE	time to echo
T_I	time to inversion
T_1	spin-lattice relaxation time ("time to magnetize") (regrowth)
T_2	spin-spin relaxation time ("time to demagnetize") (decay)

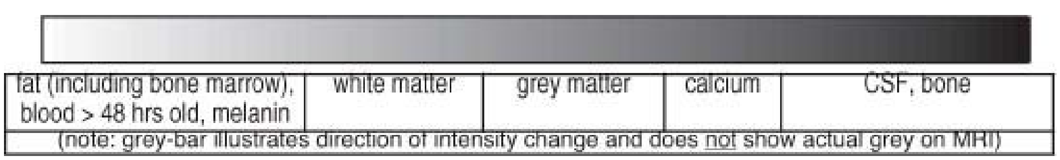
Table 6-5 Range of acquisition data

	short TE (te < 50)	long TE (te > 80)
short TR (TR < 1000)	T1WI	
long TR (TR > 2000)	proton density or spin density	T2WI

T_1 weighted image (T1WI)

Short T_1 → high signal (bright). "Anatomic image", somewhat resembles CT. Shorter acquisition time than T2WI. Proton rich tissue (e.g. H_2O) has long T_1.

Clues to recognizing T1WI: CSF is black, subcutaneous fat is white, TR and TE are short (hundreds and double digits, respectively).



★ The only objects that appear white on T1WI are: fat, melanin, Onyx® (*see page 1102*), and subacute blood (> 48 hrs old). White matter is higher signal than grey matter (myelin has a high fat content). Most pathology is low signal on T1WI.

T_2 weighted image (T2WI)

Long T_2 → high signal (bright). "Pathological image". Most pathology shows up as high signal, including surrounding edema.

Clues to recognizing T2WI: CSF is white, TR & TE are long (thousands and

hundreds, respectively).

Differentiating blood and fat: both fat and 7-14 day-old blood (see *Table 32-4*, page 1125) are high signal on T1WI. On T2WI blood remains high signal but fat "drops out" and becomes black.

Spin density image

AKA balanced image, AKA proton density image. Partway between T1WI and T2WI. CSF = grey, approximately isodense with brain (useful in white matter demyelinating disease).

FLAIR

Acronym: FLuid-Attenuated Inversion Recovery. Long TR and TE. Resembles a T2WI except the CSF is nulled out (appears dark). The grey/white intensity pattern is reversed from T1WI and is more prominent. Most abnormalities including MS plaques, other white matter lesions, tumors, edema, encephalomalacia, gliosis and acute infarcts appear bright. Periventricular lesions such as MS plaques become more conspicuous. Also good for demonstrating abnormalities in CSF.

Differential diagnosis of increased signal in subarachnoid spaces on FLAIR:

1. subarachnoid hemorrhage (SAH): ★ the best sequence for detecting SAH on MRI
2. meningitis: occurs in some cases
3. meningeal carcinomatosis
4. superior sagittal sinus thrombosis
5. stroke
6. adjacent tumor: ? if related to higher protein
7. previous administration of gadolinium
8. high levels of FIO_2 especially at levels nearing 100% as may be used in patients getting MRI under general anesthesia[21]. Shows up in basal cisterns and in sulci over the convexity, but not in ventricles

Echo train (AKA fast spin echo (FSE))

tr is held constant, te is progressively increased utilizing multiple echoes (8-16) rather than 1. Image approaches T2WI but with substantially reduced acquisition time (fat is brighter on FSE, which may be rectified by fat suppression techniques).

Gradient echo

AKA T2* (called T2-star), and some manufacturers have trademarked names for this, e.g. "GRASS" (a GE trademarked acronym for Gradient Recalled Acquisition in a Steady State) or FISP. A "fast" T2WI utilizing a partial flip angle. CSF and flowing vessels appear white. Bone, calcium and heavy metals are dark. Typical acquisition data: TR = 22, TE = 11, angle 8°. Used e.g. in cervical spine to produce a "myelographic" image, improves MRI's ability to delineate bony spurs. Also shows small old cerebral hemorrhages (seen in 60% of patients presenting with hemorrhagic infarction, and in 18% with ischemic infarcts[22]); these patients may be at increased risk of hemorrhage from anticoagulation. ★ Gradient-echo T2WI MRI is the most sensitive test for blood (which appears dark) due to high sensitivity to paramagnetic artifact.

"STIR" image

Acronym for "Short Tau Inversion Recovery". Summates T_1 & T_2 signals. Causes fat to drop out - sometimes also called **fat suppression** or "**fat sat**" (for fat saturation), allows gadolinium enhancement to show up better in areas of fat. Useful primarily in spine and orbit. Very good for showing bone edema (can help in dating spine fractures). The dorsal root ganglion may enhance on fat suppression images.

MRI contrast

Current agents are mostly based on gadolinium (a rare earth metal which is para-magnetic in solutions) include: gadopentatate dimeglumine (Magnevist®), gadodiamide (Omniscan®), gadoversetamide (OptiMARK®), gadobenate dimeglumine (MultiHance®) and gadoteridol (ProHance®). Adverse reactions:

1. anaphylactic reactions: rare (prevalence: 0.03-0.1%)
2. nephrotoxicity: incidence is lower than with iodinated agents used with CT
3. **nephrogenic systemic fibrosis (NSF)**: a rare, but serious illness

characterized by fibrosis of skin, joints and other organs, which is associated with certain gadolinium containing agents given to patients with severe renal failure (most were on dialysis). ✖ Gadolinium is now relatively contraindicated with a GFR of 30-60 ml/min, and is contraindicated with GFR < 30[23]. Safest agents: Dotarem, Gadovist and ProHance[24]. Contrast agents with a linear structure appear to be associated with a higher risk of NSF and include: Omniscan, Multihance, Magnevist and OptiMARK. In patients with end-stage renal disease, the risk is ≈ 2.4% per gadolinium study[25]

4. gadolinium allergy: use the same allergy prep as for iodine allergy (*see page 124*)
5. for issues related to pregnancy, *see below*

CONTRAINDICATIONS TO MRI

An extensive reference[26] details safety issues. Web sites for MRI safety include: www.MRIsafety.com and www.IMRSER.org. Some issues that come up frequently in neurosurgical patients follows.

Pregnancy and MRI: During the first trimester, MRI can cause reabsorption of products of conception (miscarriage). There are no studies to determine the long term effects of MRI on a fetus after the first trimester (the low risk of MRI in this situation is probably preferable to the known dangers of ionizing radiation of x-rays (including CT)[27]). Gadolinium contrast is contraindicated during all of pregnancy, and is not approved for use in age < 2 years. Breast-feeding must be interrupted for 2 days after administration of gadolinium to the mother.

Contraindications to MRI:

1. cardiac pacemakers/defribrillator, implanted neurostimulators, cochlear implants, infusion pumps: may cause temporary or permanent malfunction
2. ferromagnetic aneurysm clips (*see below*): some centers exclude *all* patients with any type of aneurysm clip
3. metallic implants or foreign bodies with large component of iron or cobalt (may move in field, or may heat up)
4. Swann-Ganz catheter (pulmonary artery catheter)
5. metallic fragments within the eye
6. placement of a vascular stent, coil or filter within the past 6 weeks
7. shrapnel: BB’s (some bullets are OK)
8. relative contraindications:

A. claustrophobic patients: may be able to sedate adequately to perform study
B. critically ill patients: ability to monitor and access to patient are impaired. Specially designed non-magnetic ventilator may be required. Cannot use most brands of electronic IV pumps/regulators
C. obese patients: may not physically fit into many closed bore MRI scanners. Open bore scanners may circumvent this but many utilize lower field strength magnets and produce inferior quality images in large patients
D. non-MRI compatible metal implants in the region of interest (or previous surgery with high speed drills which may leave metal filings): may produce susceptibility artifact which can distort the image in that area
E. programmable shunt valve: (*see page 317*) most will tolerate up to a 3 T MRI without permanent damage, however, the pressure setting may be altered and therefore should be rechecked after having an MRI for any reason

Aneurysm clips and MRI

MRI considerations in patients with a cerebral aneurysm clip:

1. the danger of the MRI magnetic field causing the aneurysm clip to be pulled or torqued off of the aneurysm or to tear the neck
2. the artifact produced by the metal of the clip in the magnetic field
3. heat generated in the region of the clip: not clinically significant

Table 6-6 Magnetic remnance of aneurysm clips[28]

Clip	Type of steel	Magnetic remnance (no units)	MRI compatible?
Drake DR 12	martensitic SS	100	no
Heifetz	17-7PH	44	
Mayfield	martensitic SS	74	
Scoville	EN-58J	64	
Olivecrona		0	yes
Sugita	Elgiloy	0	
Sugita with loop	gold plated	1	
McFadden	Vari-Angle	0	
Yasargil	316	0	
Yasargil	Phynox	0	
Yasargil (old)		1	
silver clip		0	

The more ferromagnetic the clip, the larger the force exerted on it by the magnetic field and the greater the image distortion near the clip.

Stainless steel **(SS)** is classified as **martensitic** (ferromagnetic) or **austenitic** (non-ferromagnetic). Cobalt-based superalloys are non-ferromagnetic and include Elgiloy (Sugita clips), Phynox (Yasargil), and Vari-Angle (McFadden).

Table 6-6 shows the magnetic remnance of various clips which is related to their ferromagnetic properties. If in doubt at the time of aneurysm surgery, apply the following simple test: non-ferromagnetic clips cannot be lifted or dragged with a small magnet.

HEMORRHAGE ON MRI

Because its signal characteristics change with time (and location), blood is one of the most complex entities to interpret on MRI. A mnemonic for the changes in appearance of blood on MRI with time is shown in *Table 6-7*. For intracerebral hemorrhage, *see page 1125*. Blood, hemosiderin and calcium are dark on GRASS images. FLAIR is the best sequence for detecting SAH on MRI (*see page 129*).

Table 6-7 Signal characteristics of blood on MRI with time*

Time	T1WI	T2WI
Mnemonic	Acronym: “George Washington Bridge”	The layers of an Oreo® cookie
Acute	G (gray)	B (black)
Subacute	W (white)	W (white)

Chronic	B (black)	B (black)

* note: on T2WI blood is bright only in the sub-acute phase, and in the chronic phase it is dark on both T1WI & T2WI

6.4.2. Magnetic resonance angiography (MRA)

May be done with contrast (gadolinium, usually for extracranial vessels) or, without (usually for intracranial vessels, using flow related enhancement techniques (most commonly, 2D time of flight **(2D TOF)**)). Anything that appears bright on T1WI will also show up on MRA, but doesn't necessarily represent blood flow. This includes fat and fat-laden macrophages in an area of old CVA. Using fat-sat T1WI can mitigate this. Has some utility in screening for aneurysms (*see page 1038*), and for angiographically occult vascular malformations (*see page 1105*). High-flow AVMs are hard to resolve because arterialized veins can appear similar to arteries.

6.4.3. Diffusion-weighted imaging (DWI) and perfusion-imaging (PWI)

DIFFUSION-WEIGHTED IMAGING

Primary uses: early detection of ischemia and differentiating active MS plaques from old ones. DWI is sensitive to random Brownian motion of water molecules. Two images are generated, an apparent diffusion coefficient **(ADC)** map (based on a number of variables (time, slice orientation…)), and a trace image (the actual DWI)[29]. Freely diffusing water (e.g. in CSF) appears dark on DWI. ★ Parenchymal areas of bright signal on DWI may denote regions of restricted diffusion (abnormal).

The DWI is based on a T2WI, and anything that is bright on T2WI can also be bright on DWI ("**shine-through**"). Problem: bright areas on DWI can represent either restricted diffusion or T2 "shine-through". ∴ check the ADC map: if the lesion is black, then this likely represents true restricted diffusion (recent infarct is the most common etiology).

Differential diagnosis of areas of increased signal (bright) on DWI:

1. ischemic brain: acute stroke and areas with hypoperfusion (penumbra). While restricted diffusion usually indicates irreversible cell injury (death), it can some-times indicate tissue that is just near cell death (penumbra).

Acute brain ischemia can light up within minutes[29, 30]. The DWI abnormality will persist for ≈ 1 month. The ADC map usually normalizes after ≈ 1 week

2. cerebral abscess: DWI = bright, ADC = dark (*see page 352*)
3. active MS plaque (old plaques will not be bright)
4. some tumors: most tumors are dark on DWI, but highly cellular tumors (e.g. some meningiomas…) may have decreased diffusion (bright on DWI)

Other possible uses of DWI:

TIAs: some, but not all[31], are associated with DWI abnormalities. However, factors other than focal ischemia (e.g. global ischemia, hypoglycemia, status epilepticus…) can produce ADC decline and the DWI images must therefore be interpreted in relation to the clinical setting[29].

DWI may also be able to distinguish cytotoxic from vasogenic edema[32, 33] (*see page 109*

Perfusion-weighted MRI

Provides information related to the perfusion status of the microcirculation. PWI is the most sensitive study for ischemia of the brain (more sensitive than DWI) (FLAIR shows infarcted tissue). There are several methods currently in use; the bolus-contrast approach is the most widely employed[29]. Ultrafast gradient imaging is used to follow the gradual reduction to normal following administration of contrast (usually gadolinium). A signal wash-out curve is derived and is compared to contrast in an artery. In practical terms, PWI is not widely used because of technical challenges. Time-to-peak and mean-transit-time are 2 common parameters that are displayed (higher signal = longer times beyond normal).

DWI & PWI mismatch

DWI and PWI may be combined to locate areas of **diffusion-perfusion mismatch** (deficit on PWI that exceeds the zone of diffusion deficit on DWI), thus identifying salvageable brain tissue at risk of infarction ("**penumbra**", *see page 1062*) e.g. to screen for potential candidates for thrombolytic therapy[34].

6.4.4. Magnetic resonance spectroscopy (MRS)

This section specifically covers proton (H^+) MRS which can be performed on almost any MRI scanner (especially units ≥ 1.5 T) with the appropriate software. Spectroscopy of other nuclei (e.g. phosphorous) can be evaluated only with specialized equipment.

Table 6-8 Important peaks on proton MRS

Moiety	Resonance(ppm)	Description
lipid	0.5-1.5	slightly overlaps lactate peak at TE ≈ 35
lactate	1.3	a couplet peak. Not present in normal brain. End product of anaerobic glycolysis, ∴ a marker of hypoxia. Present in: ischemia, infection, demyelinating disease, inborn errors of metabolism… At higher TE (e.g. TE = 144), the peak inverts which can help distinguish it from the lipid peak
N-acetyl aspartate **(NAA)**	2	a neuronal marker. Normally the tallest peak (higher than Cr or Cho). ↓ in ≈ all focal and regional brain abnormalities (CVA, tumor, MS, epilepsy, Alzheimer's disease, abscess, brain injury…)
creatine **(Cr)**	3*	useful primarily as a reference for choline. Higher in grey matter than white matter
choline **(Cho)**	3.2	marker of membrane synthesis. ↑ in neoplasms and some rare conditions of increased cell growth & in the developing brain. ★ CVA is low in choline

* Cr has another less important peak

Single voxel MRS

A small area is selected on the "scout" MRI and the spectroscopic peaks for that region are displayed in resonance as a function of parts-permillion **(ppm)**. Since only small regions are selected, may be subject to "sampling" error.

Clinically important characteristic peaks are delineated in *Table 6-8*.

Illustrative patterns

Normal brain: *See Figure 6-1*.

Tumor: *See Figure 6-1*. ↓ NAA, ↑ lactate, ↑ lipid, ↑ choline (rule of thumb: with gliomas, the higher the choline, the higher the grade up to grade 3, thereafter necrosis reduces relative choline levels and the lipid peak may be utilized).

CVA: ↑ lactate peak predominates. Choline is characteristically low.

Abscess[35]: Reduced NAA, Cr & choline peaks, and "atypical peaks" (succinate, acetate…) from bacterial synthesis is pathognomonic for abscess (not always present). Lactate may be elevated.

Multiple sclerosis: Bland pattern. NAA slightly reduced. Lactate and lipid slightly elevated. Choline not elevated.

Possible uses of MRS

1. differentiating abscess from neoplasm
2. post-op enhancement vs. recurrence of tumor
3. distinguishing tumor from MS plaques: occasionally cannot be differentiated
4. in AIDS: may be able to help differentiate toxoplasmosis from lymphoma from PML (PML: ↓ NAA, no significant increase in choline, lactate or lipid)
5. the promise of differentiating tumor infiltration from edema has not materialized
6. some utility in distinguishing tumor from radiation necrosis (*see page 771*)
7. large inositol peak may distinguish hemangiopericytoma from meningioma[36])

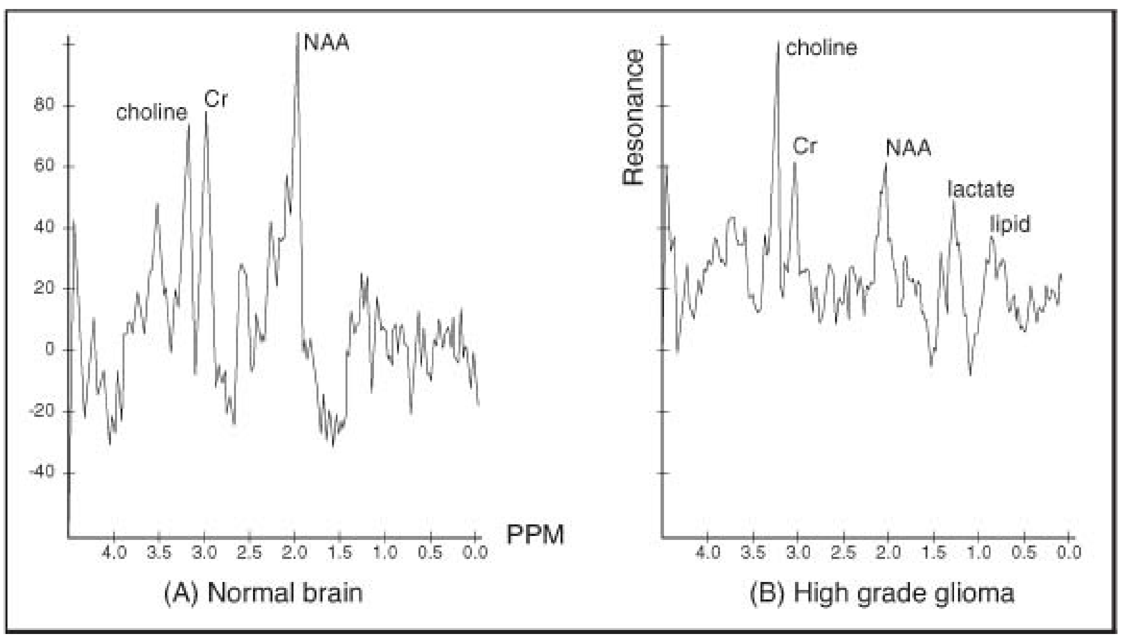


Figure 6-1 Proton MRS of (A) normal brain, and (B) high grade glioma

Multi-voxel MRS

Color coded scan with selected overlay for NAA, choline… one at a time. May reduce risk of sampling error.

6.4.5. Diffusion tensor tractography MRI (DTT)

An MRI technique that demonstrates white matter tracts by exploiting the difference in diffusion parallel to the tracts from diffusion perpendicular to their course.

Available only with specialized software for specific MRI scanners.

Contraindications are same as for MRI in general (*see page 130*).

Probably most useful to permit a surgeon to avoid critical white matter tracts during intraparenchymal brain surgery, especially when a lesion (e.g. tumor, AVM…) may displace these tracts from their expected position.

6.5. Angiography (cerebral)

Risks

Risk varies with the nature of the pathology being investigated and with the experience of the angiography team. Overall risk of a complication resulting in a permanent neurologic deficit[37, 38]: 0.1%. In ACAS, there was a 1.2% complication rate (*see page 1149*).

General information[39]

In general: non-vascular deep lesions cause changes in venous structures, superficial lesions affect arterial structures. The classic feature of a malignant neoplasm (e.g. glioblastoma) on angiography is an early draining vein. Meningiomas “come early, stay late” (appears early in arterial phase, blush persists beyond venous phase) - *see page 617* for other angiographic findings with meningiomas.

Allcock test: evaluates flow through the posterior communicating arteries by vertebral injection with simultaneous common carotid artery compression in the neck.

To help find the middle meningeal artery on lateral ECA angio, follow the anterior sweep of the sphenoid air sinus.

Intraoperative angiography

Typically used in aneurysm surgery to confirm exclusion of the aneurysm from

the circulation and to verify patency of critical adjacent vessels, and during AVM surgery to confirm total elimination of the nidus.

1. using traditional iodinated contrast and fluoroscopy. Requires use of radiolucent headholder. Typically the introducer sheath is placed in the femoral artery at the time of initial pre-op angio, and is left in place for intraoperative use
2. indocyanine green (ICG)[40, 41]: can be visualized under normal light, or sometimes to better advantage when illuminated with near-infrared light. Use is restricted to surface vessels. May be less reliable with giant or wide-neck aneurysms or with thick-walled atherosclerotic vessels[42]. Also used intraoperatively with some spinal AVMs

6.6. Plain films

6.6.1. C-Spine

NORMAL FINDINGS

For radiographic signs of cervical spine trauma, see *Table 28-7*, page 939, and for guidelines for diagnosing clinical instability, see *Table 28-30*, page 970.

CONTOUR LINES

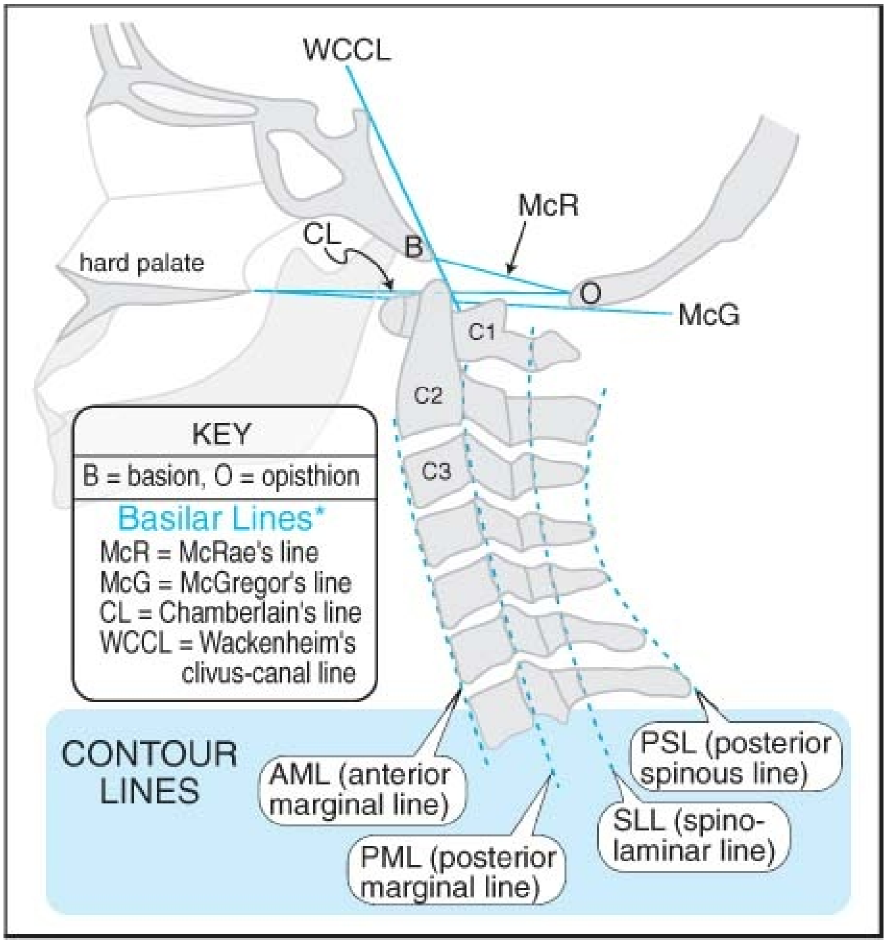

Figure 6-2 Spinal contour lines and lines used to diagnose basilar invagination Lateral view through craniocervical junction. *For a discussion of the basilar lines, see page 139

On a lateral C-spine x-ray, there are 4 contour lines (AKA arcuate lines). Normally each should form a smooth, gentle curve (*see Figure 6-2*):

1. posterior marginal line **(PML)**: along posterior cortical surfaces of vertebral bodies **(VB)**. Marks the anterior margin of spinal canal
2. anterior marginal line **(AML)**: along anterior cortical surfaces of VBs
3. **spinolaminar line (SLL)**: along base of spinous processes. The posterior margin of the spinal canal
4. posterior spinous line **(PSL)**: along tips of spinous processes

Relation of Atlas to Occiput

See *page 952* for criteria for atlantooccipital dislocation (AOD).

Relation of Atlas to Axis

These measurements are useful for atlantoaxial subluxation/dislocation e.g.

in trauma (*see page 957*) or rheumatoid arthritis (*see page 495*).

Rule of Spence

On AP or open-mouth odontoid x-ray, if the sum total overhang of both C1 lateral masses on C2 is **≥ 7 mm** (x + y in *Figure 6-7*), the transverse atlantal **(TAL)** ligament is probably disrupted[43, 44] (when corrected for an 18% magnification factor, it has been suggested that the criteria be increased to ≥ **8.2 mm**[45])

(Anterior) atlantodental interval (ADI)[A]

AKA predental space. The distance between the anterior margin of the dens and the closest point of the anterior arch of C1 (“C1 button”) on a lateral C-spine x-ray (*see Figure 6-3*). The normal maximal ADI is variously given in the range of 2 to 4 mm[46, 47]. Commonly accepted upper limits are shown in *Table 6-9*. An abnormally increased ADI is a surrogate marker for TAL disruption[48]

A. the term ADI usually refers to the *anterior* atlantodental interval (there is also a posterior ADI (*see page 495*) and a lateral ADI which can be seen on AP radiographs)

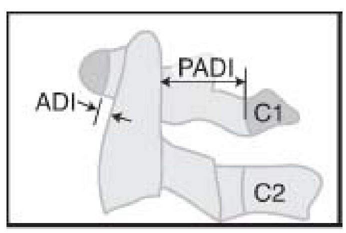

Figure 6-3 The atlantodental interval (ADI) and posterior atlantodental interval (PADI) on a lateral C-spine x-ray

Table 6-9 Normal ADI

Patient	ADI
adults	
males	≤ 3 mm
females	≤ 2.5 mm
pediatrics[49] (≤ 15 yrs)	≤ 4 mm

Posterior atlantodental interval (PADI)

AKA the neural canal width **(NCW)**[50]. The PADI is the AP diameter of the bony canal and is measured from the back of the odontoid to the anterior aspect

of the posterior C1 ring (*see Figure 6-3*). It is more useful than the ADI for some conditions (e.g. AAS in rheumatoid arthritis (*see page 495*) or Down syndrome (*see page 498*)).

Canal diameter

Normal canal diameter on lateral C-spine x-ray (from spinolaminar line **(SLL)** to posterior vertebral body with 6 foot tube to film distance)[51]: **17 ± 5 mm**. In the presence of osteophytic spurs, measure from the back of the spur to the SLL.

Cervical spinal stenosis: various cutoffs for the normal minimum AP diameter have been suggested[52]. On a plain lateral C-spine x-ray this is usually measured from the posterior vertebral body (or the posterior aspect of an osteophyte) to the spinolaminar line. Some use 15 mm. Most agree that stenosis is present when the AP diameter is **< 12 mm** in an adult (*see page 489* for correlation with myelopathy).

Prevertebral soft tissue

Abnormally increased prevertebral soft tissue **(PVST)** may indicate the presence of a vertebral fracture, dislocation, or ligamentous disruption[54]. Normal values for lateral C-spine x-ray and CT scan are shown in *Table 6-10*. Plain films are subject to errors due to magnification and rotation. Multi-detector CT **(MDCT)** eliminates these shortcomings[53].

Increased PVST is more likely with anterior than posterior injuries[55]. NB: the sensitivity of these measurements is only ≈ 60% at C3 and 5% at C6[54]. False positives may occur with basal skull/facial fractures, especially with fracture of the pterygoid plates.

An ET-tube may allow fluid to accumulate in the posterior oropharynx which can obscure this measurement. In this setting, one can look for a thin fat layer between the prevertebral muscles and the posterior pharynx on cervical CT; the prevertebral tissue (posterior to this line) will be thickened (no measurements available at this time). MRI can also demonstrate abnormal signal within the prevertebral tissue.

Table 6-10 Normal prevertebral soft tissue

Space	Level	Maximum normal width (mm)		
		Adults		Peds
		MDCT	Lateral X-Ray	
retro-pharyngeal	C1	8.5	10	unreliable
	C2-4	**6-7** *	**5-7**	
retrotracheal	C5-7	18	22	14

* CT data was deemed unreliable at C4[53]

INTERSPINOUS DISTANCES

C-spine AP: a fracture/dislocation or ligament disruption may be diagnosed if the interspinous distance is 1.5 times that at both adjacent levels (measured from center of spinous precesses)[56]. Also look for a malalignment of spinous processes below a certain level which may be evidence of rotation due to a unilaterally locked facet.

C-spine lateral: look for "**fanning**" or "**flaring**" which is an abnormal spread of one pair of spinous processes that may also indicate ligament disruption.

PEDIATRIC C-SPINE

C1 (ATLAS)

Ossification centers[57]: usually 3 (*see Figure 6-4*)

1. 1 (sometimes 2) for body (not ossified at birth; appears on x-ray during 1st yr)
2. 1 for each neural arch (appear bilaterally ≈ 7th fetal week)

Synchondroses[57]:

- synchondrosis of the spinous process: fuses by ≈ 3 yrs age
- 2 neurocentral synchondroses: fuse by ≈ age 7 yrs

Up to 5% of adults have incomplete closure of ossification centers of C1, most commonly posteriorly. The rare anterior defect is usually associated with a posterior defect.

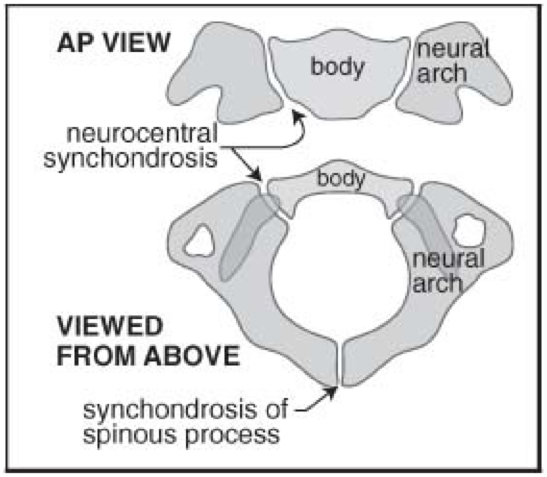

Figure 6-4 Pediatric C1 (atlas)

C2 (AXIS)

4 primary ossification centers (*see Figure 6-5*):

- odontoid process
- vertebral body
- 2 neural arches

Synchondroses: normally fuse between 3-6 years of age.

A secondary ossification center appears at the summit of the dens between 3-6 yrs, and fuses with dens by age 12[57].

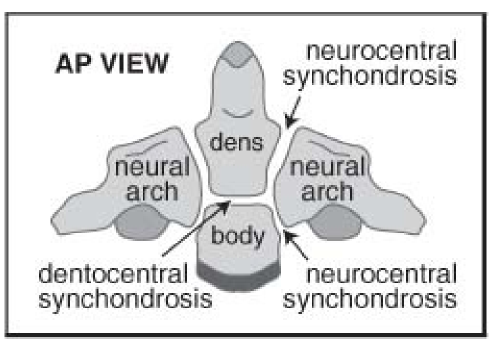

Figure 6-5 Pediatric C2 (axis)

C3-7

Cervical bodies are normally wedge shaped in pediatric population (narrower anteriorly). Wedging decreases with age.

6.6.2. Lumbosacral (LS) spine

L4-5 is normally the lumbar disc space with the greatest vertical height. Also see *Normal LS spine measurements*, page 480.

AP view: look for defect or non visualization of the “owl’s eyes” which is due to pedicle erosion which may occur with lytic tumors (common with metastatic disease).

Oblique views: look for discontinuity in neck of “Scotty dog” for defect in pars inter-articularis.

Butterfly vertebra: An uncommon congenital anomaly thought to arise from failure of fusion of the lateral halves of the VB due to persistent notochord tissue, producing a “butterfly” appearance on AP x-rays or coronal CT scan reconstructions. The involved VB is widened, and adjacent vertebrae may show a compensatory deformity as if to fill in some of the gap. May be associated with other spinal and rib malformations[58]. On lateral views may simulate compression fracture. In severe cases, there may be significant kyphosis and/or scoliosis. Often asymptomatic, requiring no treatment. May be associated with lipomyelomeningocele (*see page 251*).

6.6.3. Skull films

Water’s view: x-ray tube angled up 45° (perpendicular to clivus), AKA submental vertex view. **Towne’s view**: x-ray tube angled down 45°, to view occiput.

SELLA TURCICA

NORMAL ADULT DIMENSIONS ON SKULL X-RAY

Technique: true lateral, 91 cm target to film distance, central ray 2.5 cm anterior and 1.9 cm superior to EAM. *Table 6-11* shows normal values (*Figure 6-6* shows how measurements are made).

Depth **(D)**: defined as the greatest measurement from floor to diaphragma sellae.

Length **(L)**: defined as the greatest AP diameter.

Table 6-11 Normal sella turcica dimensions (*see Figure 6-6*)

Dimension	Max	Min	Ave
D (depth) (mm)	12	4	8.1
L (length) (mm)	16	5	10.6

ABNORMAL FINDINGS

Pituitary adenomas tend to enlarge the sella, in contrast to craniopharyngiomas which erode the posterior clinoids. Empty sella syndrome tends to balloon the sella symmetrically, and also does not erode the clinoids. Tuberculum meningiomas usually do not enlarge the sella, and may be associated with enlargement of the sphenoid sinus (sphenoid pneumosinus dilatans - *see page 1216*).

"J" shaped sella suggests optic nerve glioma. It can also occur congenitally in Hurler syndrome (a mucopolysaccharidosis).

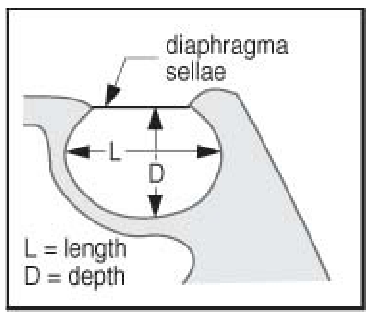

Figure 6-6 Measurements of the sella turcica (lateral view)

BASILAR INVAGINATION & BASILAR IMPRESSION (BI)

Terminology

The terms **basilar impression** and **basilar invagination** are often used interchangeably in the literature, and making a distinction seems pointless[A] (the abbreviation **(BI)** will be used for either). Common feature: upward displacement of the upper cervical spine (including odontoid process, AKA cranial migration of the odontoid) through the foramen magnum into the p-fossa.

A. historically, basilar invagination (AKA **cranial settling**) denoted upward indentation of skull base usually due to acquired softening of bone (*see below*), often associated with atlanto-occipital fusion, while basilar impression implied normal bone

Platybasia: flattening of the skull base. Originally assessed on plain x-rays (which are subject to error due to skull rotation or difficulty identifying landmarks), now more commonly evaluated on CT or MRI. May or may not be associated with BI, and may occur in association with craniofacial abnormalities, Chiari malformation, Paget's disease…

Quantitated by measuring the **basal angle**, which on plain x-rays, measured the angle between lines drawn from the nasion to center of sella and then to the anterior foramen magnum[59], but on MRI was felt to be better represented by the angle between a line drawn along the floor of the anterior fossa to the dorsum sellae and a second line drawn along the posterior clivus[60]. Normal mean basal angle: **130°**. Platybasia: **> 145°** (abnormally obtuse basal angle).

Measurements used in BI

(refer to *Figure 6-2*, page 135, and *Figure 6-7* below):

1. **McRae's line** ("McR" in *Figure 6-2*): drawn across foramen magnum (tip of clivus (basion) to opisthion)[61]. No part of odontoid should be above this line (the most accurate for BI). On CT[62] and MRI[63] the normal odontoid tip is 5 mm (± 1.8 mm) <u>above</u> the line
2. **Chamberlain's line** ("CL" in *Figure 6-2*)[64]: posterior hard palate to posterior margin of foramen magnum (opisthion). Less than 3 mm or half of dens should be above this line, with 6 mm being definitely pathologic. Seldom used because opisthion is often hard to see on plain film and may also be invaginated. On CT[62] and MRI[63] the normal odontoid tip is 1.4 mm (± 2.4) below the line
3. **McGregor's baseline** ("McG" in *Figure 6-2*)[65]: posterior margin of hard palate to most caudal point of occiput. No more than 4.5 mm of dens should be above this. On CT[62] and MRI[63] the normal odontoid tip is 0.8 mm (± 2.4) above the line
4. **Wackenheim's clivus-canal line** ("WCCL" in *Figure 6-2*): the odontoid should be tangential to or below the line that extends the course of the clivus (the clivus baseline). If the clivus is concave or convex, this baseline is drawn to connect the basion to the base of the posterior clinoids on the clivus[66]
5. **(Fischgold's) digastric line** ("FDGL" in *Figure 6-7*): joins digastric notches. The normal distance from this line to the middle of the atlanto-occipital joint is 10 mm (decreased in BI)[67]. No part of odontoid should be

above this line. More accurate than the bimastoid line (FBML)

6. **Fischgold's bimastoid line** ("FBML" in *Figure 6-7*): joins tips of mastoid processes. The odontoid tip averages 2 mm above this line (range: 3 mm below to 10 mm above) and this line should cross the atlanto-occipital joint

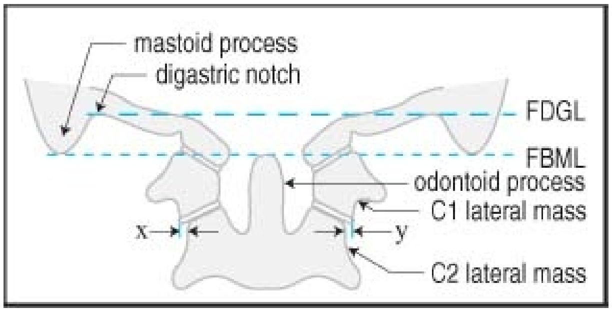

Figure 6-7 AP view through craniocervical junction*

* FDGL = Fischgold's digastric line, FBML = Fischgold's bimastoid line, x + y = total overhang of C1 on C2 (see Rule of Spence page 957)

Conditions associated with BI

1. congenital conditions (BI is the most common congenital anomaly of the craniocervical junction, it is often accompanied by other anomalies[68 (p 148-9)])
   A. Down syndrome
   B. Klippel-Feil syndrome: *see page 253*
   C. Chiari malformation: *see page 233* (in a series of 100 patients, 92 had BI[69])
   D. syringomyelia
2. acquired conditions
   A. rheumatoid arthritis (in part due do incompetence of transverse ligament, see *Basilar impression in rheumatoid arthritis*, page 497)
   B. post-traumatic
3. conditions with BI associated with softening of bone include[70]:
   A. Paget's disease
   B. osteogenesis imperfecta
   C. osteomalacia
   D. rickets
   E. hyperparathyroidism

Two subtypes of BI[71]

Type I: BI without Chiari malformation. Tip of odontoid tends to be above CL, McR, and WCCL in *Figure 6-7*. Brainstem compression is due to odontoid process invagination. 85% can be reduced with traction. Transoral surgery is recommended, usually accompanied by posterior fusion

Type II: BI + Chiari malformation. Odontoid tip tends to be above CL, but not McR or WCCL. Brainstem compression is due to reduced p-fossa volume. Only 15% can be reduced with traction. Foramen magnum decompression is appropriate

6.7. Myelography

Contraindications:

1. anticoagulation
2. allergy to iodinated contrast: requires iodine allergy prep (*see page 124*). NB: risk of adverse reaction still persists

Lumbar myelogram

Using iohexol (Omnipaque® 140 or 180) as shown in *Table 6-1*.

Cervical myelogram with water soluble contrast via LP

Use iohexol (Omnipaque® 300 or 240) as shown in *Table 6-1*. Insert spinal needle into lumbar subarachnoid space, tilt the head of the myelogram table down with the patient's neck extended and then inject dye. If a complete cervical block is seen, have patient flex neck. If the block cannot be traversed, patient may need C1-2 puncture or MRI (first obtain a CT which may show dye above the block that cannot be appreciated on myelography alone).

Post myelographic CT

Increases sensitivity and specificity of myelography (*see page 435*). In cases of complete block on myelogram, CT will often show dye distal to the apparent

site of the block.

6.8. Radionuclide scanning

Three phase bone scan

Technetium-99 (99mTc) pertechnetate is a radioisotope that may be attached to various substrates for use in bone scanning. It may be used to label polyphosphate (rarely used today), diphosphonate[72] **(MDP)**, or phosphorous (HDP) (the most widely agent used currently). Accumulates in areas of osteoblastic activity.

With technetium 99m-HDP, images are obtained immediately after injection (flow phase), at 15 min (blood pooling) and in 4 hours (bone imaging). Cellulitis shows up as increased activity in the first 2 phases, and there is little or diffuse increased activity in the 3rd. Osteomyelitis causes increased uptake in all 3 phases.

Used in evaluation of acute osteomyelitis with sensitivity and specificity of ≈ 95% each, and is usually positive within 2-3 days. False positives can occur in conditions involving increased bone turnover, e.g. fracture, septic arthritis, tumors. False negative can occur in cases with associated bone infarction.

Applications for bone scans include:

1. infection
    A. osteomyelitis of the spine (vertebral osteomyelitis, *see page 382*) or skull
    B. discitis: *see page 385*
2. tumor
    A. spine metastases: *see page 746*
    B. primary bone tumors of the spine: *see page 737*
    C. skull tumors: *see page 698*
3. diseases involving abnormal bone metabolism
    A. Paget's disease: of the skull (*see page 499*) or spine (*see page 499*)
    B. hyperostosis frontalis interna: *see page 701*
4. craniosynostosis: *see page 229*
5. fractures: spine (*see page 940*) or skull
6. "low back problems": to help identify some of the above conditions (*see page 432*)

Gallium scan

Nuclear medicine scan with 67Ga citrate which accumulates in areas of inflammation and some malignancies. Utility in neurosurgery for: sarcoidosis (*see* page 72), *chronic* vertebral osteomyelitis (for comparison to bone scan, *see* page 382).

NOTES

7. Operations and procedures

This section provides information useful in the O.R. that apply to a number of different topics. Some items that are pertinent to only one topic will be found in that section instead (e.g. *transsphenoidal tumor removal* is found in the section on *pituitary tumors*).

REMEMBER: before performing any invasive procedure, know the patient's coagulation status (history, and if indicated: PT, PTT, bleeding time, platelets, FDP…).

7.1. Intraoperative dyes

This section covers visible dyes that may be useful in the operating room. For radioopaque dyes, see *Contrast agents in neuroradiology*, page 122. There is little information available in the literature regarding the intrathecal **(IT)** use of the following agents.

Indigo carmine: a blue dye which has been used intrathecally to locate CSF leaks. There are few published reports, and no accounts of adverse effects. In 1933 a report[1] of IT injection of 5 ml of 0.6% indigo carmine solution produced blue-green discoloration of the CSF draining through a fistula into the nose within 15 minutes, lasting for 5 hours, with no indication of toxicity. It is excreted in the urine (and not in mucous membranes). The consensus is that it should be relatively safe for IT use, but the manufacturer did not recommend this application.

✖ **Methylene blue**: methylene blue is probably <u>cytotoxic</u> and appears to become fixed to neural tissue. It should therefore <u>not</u> be used as a stain in neurosurgical operations or diagnostic tests. CNS damage (some permanent) occurred in 14 patients given an IT injection of a 1% solution. Symptoms included: paraparesis, quadriplegia, multiple cranial nerve involvement (including anosmia and optic atrophy), dementia and hydrocephalus[2].

Fluorescein: although intrathecal injection (e.g. to look for CSF leak) has been used by ENT surgeons with apparently acceptable results, there is a risk of

seizures. 2.5% fluorescein is diluted 1:10 with CSF or saline and ≈ 6 ml is injected into the spinal subarachnoid space (or 0.5 ml of 5% fluorescein mixed with 5-10 ml of CSF[3]).

Fluorescein has also been used IV (adult dose: 1 amp IV) to help mark areas where there is breakdown of the blood brain barrier (e.g. in tumors, *see page 109*), however, fluorescein is eventually excreted in mucus, urine, etc., and just about everything turns orange. It has also been used to perform intraoperative "visible angiograms" during the removal of AVMs.

Indigocyanine green (ICG): used for intraoperative angiography (*see page 135*).

7.2. Operating room equipment

OPERATING MICROSCOPE

Observer's eyepiece

For spine cases, the ideal location of the observer eyepiece is usually directly opposite the surgeon. For intracranial work, the observer's (assistant's) eyepiece is placed to right of operator's except in the following:

1. transsphenoidal surgery (when the surgeon stands to the patient's right)
2. right posterior fossa craniotomy in the lateral oblique (suboccipital) position

HEAD FIXATION

Indications for pin head-fixation:

1. ✖ not recommended for use in age < 3 years[A], use with care in age < 10 years
2. craniotomies:
   A. most intracranial vascular operations: radiolucent head-holder should be used if intraoperative angiogram is to be performed
   B. often for tumor operations
   C. when intraoperative image-guidance (IG) systems are used
3. cervical spine: often used for posterior cervical operations (laminectomies, instrumentation, fusions…)

A. this age cutoff is not based on scientific evidence, most reported complications occur in age > 3 years

Pin fixation devices include the Mayfield head-holder. Application:

1. "**skull block**" (blockade of scalp innervation) may be administered prior to pin placement. Critical for awake craniotomies (for the wake-up), and for vascular cases and cases with increased ICP where the block blunts the precipitous increase in blood pressure[4, 5] that may otherwise accompany pinning which may also increase ICP. For technique, *see page 151*
2. plan pin placement
   A. the manufacturer recommends that the pins be placed within a band-like area similar to a "sweatband" worn just above the orbits and the pinna
   B. avoid placing pins on the thin temporal squamosa, and use with caution over the frontal sinus[6]
   C. the single pin is typically placed anteriorly when the patient is in the supine position (see *Figure 7-7*, page 159), for a posterior fossa approach in the prone position, if the craniotomy is on one side the single pin is placed on that side
   D. the pins in the dual pin "rocker" should be equidistant from the centerline for maximal stability
3. appropriately sized sterile pins are placed in the head-holder:
   A. ✖ children < 3 yrs age[A]: increased risk of calvarial penetration or depressed skull fractures. A padded cerebellar head rest should be used instead[6, 7]
   B. children ≥ 3 yrs age and < 10 yrs age: special pediatric pins should be employed (with a "shoulder" to insure shorter depth of penetration)
4. the pins are often coated with appropriate antibiotic ointment
5. the clamp is squeezed together, allowing the ratchet gears to slide, until the pins are initially seated in the skull
6. the knob housing the tension spring and gauge is tightened (each ring = 20 lbs)
   A. adults: tighten until the **third ring (60 lbs)** is visible; up to 80 lbs has been described
   B. pediatrics: 30-40 lbs has been suggested[6]. ✖ Even with pediatric pins & decreased pressure, complications may occur, consider horseshoe

headrest

Complications of pin head-fixation:

1. malposition of pins:
   A. through unintended anatomic structures: pinna, orbit, superficial temporal artery, shunt hardware, prior craniotomy defect
   B. poor fixation by not properly placing pins close to "equator" resulting in movement during surgery (with risk of cervical spine injury, injury to structures being operated on due to the sudden movement, loss of image guided registration) and possible skin laceration
2. skin penetration by pins: can cause injury to intracranial structures, infection including delayed abscess, epidural hematoma[6]…
   A. overtightening of pins
   B. incorrect pin selection: *see above*
   C. soft skull: in elderly patients, poorly calcified skulls, pediatric patients[6]
3. skin necrosis: especially with pediatric pins due to the "shoulder" of the pins
4. skull fracture: including "ping-pong ball" fractures in young children
5. slippage of any of the joints or connections to the O.R. table
6. clamp breakage[8, 9]: inspect the head-holder for cracks prior to each application, store properly and maintain per the manufacturer's specifications
7. bleeding from pin site: usually when the head-holder is removed. If bleeding does not stop after a minute or so of pressure, a suture or surgical staple may be used

For rapid access or where stabilization is not critical, the head may be placed on a "doughnut" fashioned out of a rolled stockinette covered in plastic. Note: it actually only takes a few moments to apply pin fixation, and if there is any question about the possibility of e.g. a vascular lesion (AVM, etc.) it is worthwhile to have firm pin fixation, especially since many self-retaining retractors attach to the Mayfield head-holder.

7.3. Surgical hemostasis

Methods include:

1. thermocoagulation
   A. electrical coagulation:
      1. monopolar (Bovie) cautery: electric current passes through the patient to a grounding pad. Because of possible transmission through electrically and thermally sensitive neural structures, this modality is not used directly on the brain or in proximity to named nerves (including cranial nerves) & nerve roots
      2. bipolar cautery: current passes only between the tips of the cautery device. Used for precise coagulation. When used directly on or near to the brain or nerves, the current setting is typically reduced from that employed for general use
   B. thermal units: e.g. AccuTemp® disposable eye cautery units (particularly useful to coagulate dura when inserting a ventriculostomy in the ICU)
   C. laser: especially neodymium:yttrium-aluminum-garnet (Nd:YAG) laser
2. mechanical
   A. bone wax: originated by Sir Victor Horsely. Inhibits bone formation
   B. ligature: less commonly used in neurosurgery than other specialties
   C. "silver clips" (e.g. HemoClips®)
3. chemical hemostasis: *see below*

CHEMICAL HEMOSTASIS

See review[10] for more information. Some key points:

1. gelatin sponge (Gelfoam®): no intrinsic coagulating effect. Absorbs 45 times its weight in blood which causes it to expand and tamponade bleeding. Absorbable. May be combined with thrombin as patties or as powder (e.g. FLOSEAL®)
2. oxidized cellulose (Oxycel®) and oxidized regenerated cellulose (Surgicel®): absorbable. Acidic material that reacts with blood to form a reddish brown "pseudoclot". Bactericidal to over 20 different organisms. May retard bone growth. Oxycel® interferes with epithelialization more than Surgicel®
3. microfibrillar collagen (Avitene®): promotes adhesion and aggregation of platelets. Loses effectiveness in severe thrombocytopenia (< 10,000/ml). May be used on bone bleeding. Remove excess material to reduce risk of

infection

4. thrombin (Thrombostat®): does not depend on any intermediate physiological agent. Caution: although thrombin may cause significant edema when placed on brain where the pia has been disrupted, practical experience indicates this is uncommon

7.4. Craniotomies

7.4.1. Intraparenchymal cyst aspiration

When a cystic tumor or intracerebral hemorrhage is being operated on, an attempt should be made to insert a ventricular needle into the lesion and aspirate some but not all of the cyst contents. This often produces significant decompression. Avoid evacuating all of the contents otherwise the lesion might be difficult to find. The needle may then be left in place to allow localization of the lesion (or the needle track can be followed, which may occasionally be difficult).

7.4.2. Intra-operative brain swelling

Under certain circumstances during surgery, the brain may start to severely swell out of the craniotomy wound. Etiologies of this emergency situation include:

1. extraparenchymal bleeding: from a vessel or intraoperative aneurysm rupture, remotely situated epidural/subdural hematoma
2. intracerebral hemorrhage
3. venous outflow obstruction
4. vasodilatation induced by hypercarbia
5. severe diffuse cerebral edema following stroke or traumatic brain injury (TBI)

Management: First efforts should be aimed at ruling out and correcting the aforementioned causes as well as some adjunctive measures. Most maneuvers are similar to those used in controlling an ICP crisis. During the process, it is critical to try to avoid having the brain compress itself against the craniotomy bone edges which can lacerate the cortex and can also further compromise

cortical veins which impairs venous outflow causing more brain edema and swelling which accelerates the vicious cycle.

1. elevate the head of the patient (e.g. with reverse Trendelenburg of the O.R. table)
2. make sure the jugular veins are not kinked: this may require rotating the head by loosening the pivot that connects the table adapter to the Mayfield head holder and rotating the head to a more neutral position
3. rule-out hypercarbia: make sure the endotracheal tube is not kinked, check the patient's end-tidal pCO_2
4. measures to lower ICP and protect the brain
    A. give Mannitol 1 gm/kg IV bolus
    B. drain CSF if an option: from adjacent cistern or lumbar drain
    C. have anesthesiologist hyperventilate to a PCO_2 of 30-35 mm Hg
    D. have anesthesiologist induce burst suppression
5. emergently intubate patients who are undergoing awake craniotomy
6. consider intraoperative ultrasound if rapidly available to rule-out hematoma (intracerebral, EDH, SDH) which could potentially be immediately evacuated
7. during the above steps, place a moist sponge on the surface of the brain and gently but firmly apply evenly distributed pressure to push the brain back into the wound
8. if all else is failing, the craniotomy flap can be enlarged as much as possible to create a decompressive craniotomy. Enlarging the skin incision to do so is preferable to having too small a bony opening which risks brain compression/laceration against the edges. The skin is closed without the bone flap and without dural closure as in a decompressive craniectomy (*see page 165*)
9. a last ditch life-saving measure for continued uncontrollable swelling which is to be taken under advisement with eloquent cortex: use a gloved hand to sweep the herniating brain out of the wound (i.e. remove it from the patient)

7.4.3. Craniotomy pre- & post-op management

RISKS

Many risks cannot be generalized for all craniotomies and are specific to

various tumors, aneurysms, etc. General information:

1. post-operative hemorrhage
   A. overall risk of post-operative hemorrhage[11, 12]: 0.8-1.1%. 43-60% of the hematomas were intraparenchymal, 28-33% epidural, 5-7% subdural, 5% intrasellar, 8% mixed, 11% confined to superficial wound. Overall mortality was 32%
   B. hematoma may occur at the surgical site or in remote locations, e.g. intracerebellar hemorrhage after pterional[13] and temporal[14] craniotomies (*see page 1121*)
2. in craniotomy for brain tumor[15]:
   A. risk of anesthetic complications: 0.2%
   B. increased neurologic deficit in 1st 24 hours post-op: ≈ 10%
   C. wound infection: 2%
3. postoperative headache (*see page 149*)

PRE-OP ORDERS

1. for tumor: if patient on steroids, give ≈ 50% higher dose 6 hrs before and on-call to O.R. (stress doses); if not on steroids give dexamethasone 10 mg PO 6 hrs before and on call to O.R. (in A.M., give with sip water)
2. antiepileptic medication
   A. if there is a history of seizures:
      1. if already on antiepileptic drugs **(AEDs)** continue same doses
      2. if not on AEDs, load with Keppra 500 mg or oral PHT (may give 300 mg PO q 4 hrs **x** 3 doses (total 900 mg) to load orally)
   B. if no history of seizures
      1. if surgery does not require a cortical incision (e.g. aneurysm) then AEDs are generally not used
      2. if a cortical incision is anticipated, option to load with AEDs as above
3. prophylactic antibiotics: (*optional*) ideally 30-60 minutes before incision. For most antibiotics, it is given in the O.r.R before the skin incision. For antibiotics that take a long time to infuse (e.g. vancomycin) it may help to order it to be given "on call to O.R. "
4. DVT prophylaxis: pneumatic compression boots or knee-high TED® hose

POST-OP ORDERS

<u>Guidelines</u> (individualize as appropriate) for patient to be extubated

1. admit PACU, transfer to ICU (neuro unit if available) when stable
2. VS: q 15 min x 4 hrs, then q 1 hr. Temperature q 4 hrs x 3 d, then q 8 hrs. Neuro check q 1 hr
3. activity: bed rest (BR) with HOB elevated 20-30°
4. knee high TED hose or pneumatic compression boots
5. I & O q 1 hr (if no Foley: straight cath q 4 hrs PRN bladder distension)
6. incentive spirometry q 2 hrs while awake (<u>do not use following transsphenoidal surgery</u>)
7. diet: NPO except minimal ice chips and meds as ordered
8. IVF: NS + 20 mEq KCl/L @ 90 ml/hr
9. O_2: 2 L per NC
10. meds:
    A. dexamethasone (Decadron®): if not on chronic steroids, give 4 mg IV q 6 hrs. Otherwise give stress doses based on patients current dose and length of treatment (*see page 32*)
    B. H_2 antagonist, e.g. ranitidine 50 mg IVPB q 8 hrs
    C. Keppra® (levetiracetam): 500 mg PO or IV q 12 hours. Maintain therapeutic AED levels for 2-3 months post-op for most supratentorial craniotomies
    D. Cardene® drip: titrate to keep SBP < 160 mm Hg and/or DBP < 100 mm Hg (use cuff pressures, may use A-line pressures if they correlate with cuff pressures)
    E. codeine 30-60 mg IM q 3-4 hrs PRN H/A
    F. acetaminophen (Tylenol®) 650 mg PO/PR q 4 hrs PRN temperature > 100.5° F (38 C)
    G. *continue prophylactic antibiotics if used:* (e.g. cefazolin (Kefzol®) 500-1000 mg IVPB q 6 hrs x 24 hrs, then D/C)
11. labs:
    A. CBC once stabilized in ICU and q d thereafter
    B. renal profile once stabilized in ICU and q 12 hrs thereafter
    C. ABG once stabilized in ICU and q 12 hrs x 2 days, then D/C (also check ABG after any ventilator change if patient on ventilator)
12. call M.D. if any deterioration in crani checks, for T > 101° (38.5 C), sudden increase in SBP, SBP < 120, U.O. < 60 ml/2-hrs

POST-OP COMPLICATIONS

POSTOPERATIVE DETERIORATION

When the postoperative neurologic status is worse than pre-op, especially in a patient who deteriorates after initially doing well, emergency evaluation and treatment is indicated.

Possible etiologies:

1. hematoma (see *Risks*, page 147)
   A. intracerebral hemorrhage **(ICH)**
   B. epidural hematoma: at or remote from surgical site
   C. subdural hematoma
2. cerebral infarction
   A. arterial
   B. venous infarction: especially with surgery on or around the venous sinuses (e.g. *see page 171*)
3. postoperative seizure: may be due to inadequate anticonvulsant levels, and may be exacerbated by any of the above (*see below for management*)
4. acute hydrocephalus
5. pneumocephalus (also see *Pneumocephalus*, page 890):
   A. tension pneumocephalus: see *Tension pneumocephalus*, page 891
   B. simple pneumocephalus: the simple presence of air in the cranium can cause neurologic symptoms even if not under tension. Symptoms include: lethargy, confusion, severe headache, nausea & vomiting, seizures. Air may be located over the cerebral convexities, in the p-fossa, and/or in the ventricles and usually resorbs with symptomatic improvement in 1-3 days
6. edema: may improve with steroids
   A. worsening of cerebral edema: moderate post-op worsening of cortical function of immediately adjacent brain is not unexpected in many operations, and is usually transient. However, reversible etiologies (such as subdural hematoma) must be ruled out
   B. traction or manipulation of cranial nerves may cause dysfunction that may be temporary. Division of cranial nerves can cause permanent dysfunction
7. persistent anesthetic effect (including paralytics): unlikely in a patient who

deteriorates after initially doing well post-op. Consider reversing medication given during surgery (caution re hypertension and agitation), e.g. naloxone, flumazenil (*see page 281*), or reversal of pharmacologic muscle block (*see page 27*)

8. vasospasm: following SAH or may be due to manipulation of blood vessels

POSTOPERATIVE SEIZURES

Management:

1. intubate if patient does not rapidly regain consciousness, is not protecting airway, or has labored respirations
2. CT scan: rule out hematoma (intracerebral or extra-axial) or hydrocephalus
3. anticonvulsants:
   A. draw blood for appropriate anticonvulsant level
   B. bolus with additional anticonvulsants: do not wait for levels

POSTOPERATIVE HEADACHE

Persistent headache **(H/A)** is well described following posterior fossa craniectomy (incidence range: 0-83%[16]). The time course in one series[17] was: 23% at 3 mos, 16% at 1 yr, and 9% at 2 yrs.

Persistent H/A may also be observed following supratentorial craniotomy[18] (prevalence 1 year after anterior temporal lobectomy for seizures: 12%[18]). The "**syndrome of the trephined**": headache and sometimes pulsatile pain (usually localized to the area of the skull defect), amnesia, inability to concentrate, insomnia… similar in some ways to postconcussive syndrome (*see page 910*).

These H/A have been attributed to: traction on the dura when the bone is not replaced, tension on the dura due to tight dural closure, temporalis or nuchal muscle dissection, nerve entrapment in the closing sutures or in the healing scar, intradural blood and/or bone dust, CSF leak[18].

Prevention

No single method or group of methods has been successful in completely eliminating the complaint of post-op H/A[19, 20]. Until further research can further advance the understanding of the cause and prevention of these H/A, it seems reasonable to employ the following measures as much as possible in an attempt to minimize these debilitating symptoms: restoring function of the temporalis or

suboccipital musculature, rigid fixation of bone flaps, cranioplasty for large craniectomies, meticulous tension-free dural closure (using duraplasty when necessary), and keeping intradural blood clot and bone dust to the minimum possible[21]. Cranioplasty following posterior fossa surgery for vestibular schwannoma reduced the incidence of post-op H/A from 17% to 4%[22].

Treatment

Initially, symptomatic treatment is indicated. Referral to a H/A specialist may be appropriate when it becomes apparent that the H/A are not resolving spontaneously after ≈ 3 months[21].

7.4.4. Intraoperative cortical mapping (brain mapping)

Indications: typically used to locate motor strip, sensory cortex, or speech centers intraoperatively for surgery in and around these eloquent areas. Localization of these areas based on visible anatomy alone is unreliable. These techniques are typically employed in seizure surgery as well as in treating lesions in areas of eloquent brain.

Some techniques require an awake patient, with the surgery being done under local anesthesia with sedation. Motor and sensory cortex can also be localized in anesthetized patients using SSEPs (*see below*).

PHASE REVERSAL METHOD FOR LOCALIZING PRIMARY SENSORY AND MOTOR CORTEX

Utilizes intraoperative SSEPs to localize primary sensory and motor cortex in patients under general anesthesia (as opposed to using brain mapping techniques in awake patients)[23, 24].

Technique: For anesthesia requirements for intraoperative EP monitoring, *see page 4*. A strip grid is placed on the surface of the brain perpendicular to the anticipated orientation of the central sulcus. SSEP stimulation is performed while recording through the strip grid. Phase reversal of the N20/P20 peak between a pair of electrodes in the strip grid indicates that those electrodes straddle the central sulcus (*see Figure 7-1*) with primary motor cortex located anteriorly, and sensory cortex posteriorly. The grid is then repositioned and the test is run again to verify the findings.

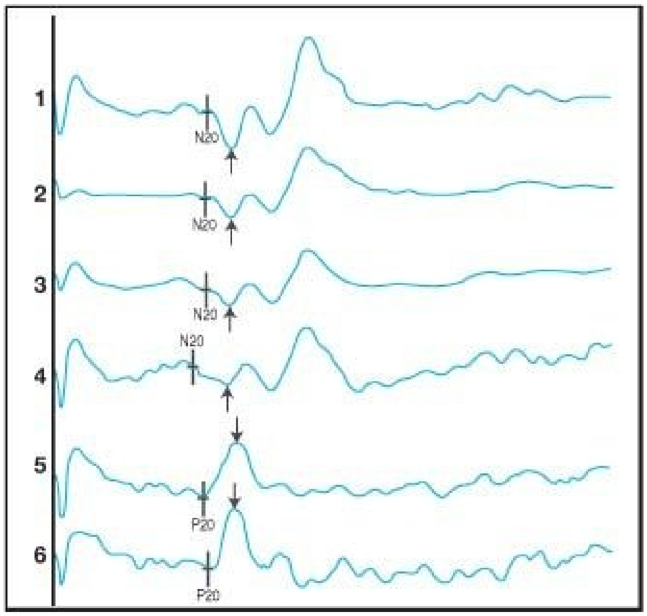

Figure 7-1 Phase reversal Intra-op 6-electrode recording strip placed on the brain during SSEP recording. Phase reversal of the negative N20 peak (arrows) to a positive P20 peak between electrodes #4 & $5 indicates that electrodes #4 & 5 straddle the central sulcus.

AWAKE CRANIOTOMY

Usually employed for brain mapping, especially for speech areas. Numerous techniques and protocols have been described. Typically, the patient is temporarily anesthetized with short acting agents (inhalational and/or injectable). This is supplemented with local anesthetic. The craniotomy is then performed and the patient is allowed to wake up while the brain is exposed to permit neurophysiologic testing during surgery. If (short-acting) paralytics are used, it is critical to reverse these agents 15-30 minutes prior to applying the electrical stimulation and that a train-of-four muscle twitch can be elicited.

Indications

1. surgery in eloquent brain (near motor strip (Brodmann's area 4 in *Figure 5-1*, page 84) or speech/language centers (Wernicke's & Broca's areas)) or thalamus, including tumors and epileptic foci
2. removal of brainstem tumors
3. some seizure surgery to look for seizure focus

Contraindications to awake craniotomy

1. patient unlikely to be able to cooperate: very young or very elderly

patients, confused patients, those with significant speech deficits already present or language barrier

Booking the case - awake craniotomy

Also see defaults & disclaimers (*page v*) and pre-op counselling (*see below*).

1. position: depends on lesion location, with pin headholder (for image guided navigation if used)
2. equipment:
   A. microscope if needed e.g. for tumor dissection
   B. image guided navigation system (if used)
   C. ultrasonic aspirator (for tumors)
3. anesthesia: pre-op consult for "awake craniotomy" & skull block
4. consult neurology or neuropsychology to be available during surgery for intra-op neurologic testing for "awake craniotomy"
5. EEG techs to perform intra-op EEG and provide brain stimulator
6. post op: ICU
7. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery on the brain to be performed with periods where the patient will be woken up for testing, (plus whatever else is planned, e.g. removal of tumor, removal of seizure source…)
   B. alternatives: the same surgery under general anesthesia, nonsurgical management, (for some diagnoses, e.g. tumor, radiation therapy)
   C. complications: (usual craniotomy complications: stroke, bleeding, coma, death, infection, seizures), difficulty accurately mapping the desired areas of the brain

Patient counselling pre-op

Patients need to be aware of what the sequence of events will be and what will be expected of them. It may be helpful to have them practice reading some typical material that will be used in the O.R. Patients over age ≈ 40 usually need reading glasses to see written material, and they should have their own available in the O.R., although the temples (earpieces) usually can't be accommodated. The patient should be advised that there may be some pain involved.

Patient positioning for surgery

Significantly more time must be spent on patient positioning to ensure that they will be as comfortable as possible without moving. Extra padding is employed. Access to the patient's face is necessary for the anesthesiologist and the neurophysiologist.

Typical sequence for anesthesia[204]

1. in the pre-op holding area, load with Precedex® (dexmedetomidine) 0.5 mcg/kg IV over 20 minutes followed by intra-op infusion at 0.4-1.0 mcg/kg/hr
2. induction of anesthesia utilizes propofol 3 mg/kg IV followed by laryngeal mask airway **(LMA)** placement
3. **skull block** 4: injection of local anesthetic (e.g. 30 ml of 0.5% bipuvicaine) to permit the skin incision and also rigid head fixation with pins (as required for image navigation devices, and situations where no head movement can be tolerated during surgery) without pain at the time of the wake-up. Injection at 4 regions on each side as shown in *Figure 7-2*:
   - ❶ supraorbital & supratrochlear nerves: 2 ml injected 1.5 cm above the supraorbital foramen above the medial third of the orbit
   - ❷ auriculotemporal nerve: 5 ml injected 1.5 cm anterior to the tragus. ✖ Caution: to avoid anesthetizing the facial nerve, inject just deep to the subcutaneous tissue

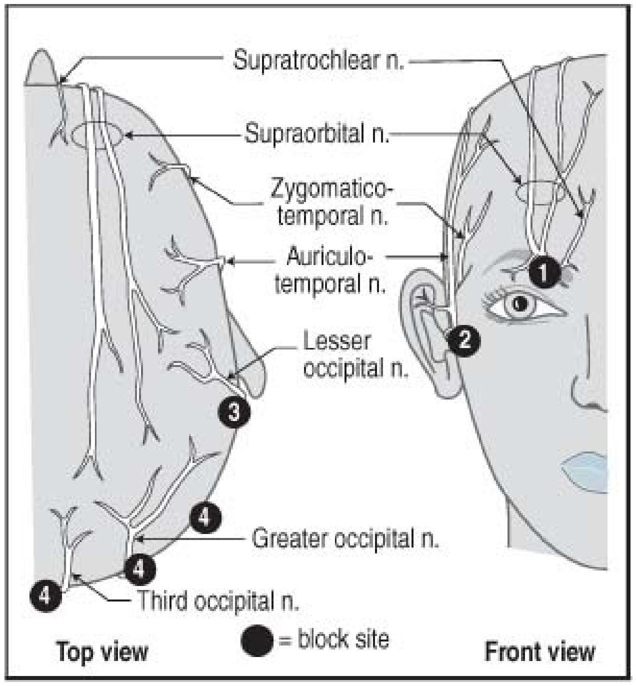

Figure 7-2 Infiltration sites for skull block

- ❸ postauricular branches of the greater auricular nerve: 2 ml 1.5 cm posterior to the antitragus
- ❹ greater, lesser & third occipital nerves: inject 5 ml with a 22 gauge spinal needle at the mastoid process and proceed along the nuchal ridge until the midline is reached

4. start inhalational anesthesia with 0.5 MAC desflurane with the patient breathing spontaneously while the scalp incision, craniotomy, and dural opening are performed (the dura is pain sensitive, the brain is not)
5. as the dural opening is begun, the desflurane is turned off and a remifentanyl infusion of 0.1-0.2 mcg/kg/min IV is started
6. by the time the dural opening is completed, the desflurane has usually worn off and the LMA can be removed
7. remifentanyl is then titrated for pain control
8. neurophysiologic testing can usually be performed at this time (e.g. see *Speech mapping* below)
9. the operation may often be carried to completion with the patient awake, although once the intracranial part of the operation is completed, more pain relief may be desired and general anesthesia may be needed for pain control or agitation (LMA may suffice here)

SPEECH MAPPING

Typical settings for a constant current generator using a bipolar electrode are shown in *Table 7-1*. If a voltage based unit is used, start at 1 volt and increase.

Speech mapping

There are numerous methodologies. One protocol:

1. requires awake craniotomy
2. once temporal lobe is exposed, a recording electrode strip is place on the brain surface
3. using a bipolar stimulator, start with a low current (e.g. 2 mA) and begin stimulate an area of cortex for 3-5 seconds, and observe for afterdischarges (akin to a focal seizure) on the recording strip. If no afterdischarges, in crease the current in 2 mA increments up to a maximum of ≈ 10 mA. If afterdischarges occur, back off by 1-2 mA and then test that area for speech changes as follows
4. stimulate cortex while patient names objects shown on picture cards (automatic verbalization, such as counting, is robust and may persist). Observe for effects ranging from total speech arrest to paraphasic errors
5. repeat the above steps at the next area (first finding threshold for afterdischarges and then stimulating while testing)

Table 7-1 Settings for constant current generator

Control	Setting*
frequency	50-60 Hz
waveform	biphasic square wave
duration	2-4 mS peak-to-peak
mode	repeat
polarity	normal
current	varies between 2-16 mA

* not all settings are present on all models

7.4.5. Posterior fossa (suboccipital) craniectomy

INDICATIONS

To gain access to the cerebellum, cerebellopontine angle **(CPA)**, to one vertebral artery, posterior brainstem, fourth ventricle, pineal region, or, using extreme lateral posterior fossa approach to the anterolateral brain stem. See paramedian (*page 154*) and midline (*page 156*) suboccipital craniectomies for details.

TECHNIQUE

POSITION

Position options include:

1. sitting position: *see below*
2. lateral oblique: patient three-quarters oblique (almost prone), *see page 154*
3. semi-sitting
4. supine with shoulder roll, head almost horizontal
5. prone
6. Concorde position: prone, thorax elevated, neck flexed and tilted away from the side on which the surgeon will be standing

SITTING POSITION

Used less frequently than in the past because of associated complications and acceptable alternative positions (except for some specific circumstances). However, some experts feel that the risks of the sitting position have been greatly overstated[25].

Advantages

1. improved drainage of blood and CSF out of surgical site
2. enhanced venous drainage which helps reduce venous bleeding and also ICP
3. easy ventilation due to unencumbered chest
4. patient's head may be kept exactly midline, aiding operator orientation, and reducing risk of kinking of vertebral arteries

Disadvantages/risks

1. possible air embolism (*see below*)
2. fatigue of operators hands
3. increased surgical risks from placement of CVP catheter (required to treat

possible AE): e.g. pneumothorax with subclavian vein catheterization, thrombosis

4. risk of post-op hematoma at the operative site may be increased since potential venous bleeders may remain occult while the patient is sitting, but may manifest when patient returns to a horizontal position post-op. However, one study found no such increased incidence[11]
5. risk of post-op subdural hematoma: 1.3% of p-fossa cases[26]
6. possible brachial plexus injury: prevent this by not allowing patient's arms to hang at the side. Instead, fold them across abdomen
7. midcervical quadriplegia[27, 28]: presumably due to flexion myelopathy[29-31]. The combination of the sitting position with hypotension[32] or neck flexion with possible compression of the anterior spinal artery, ± cervical bar, and elevation of the head thus reducing the arterial pressure may all contribute
8. sciatic nerve injury (**piriformis syndrome**)[33]: prevent this by flexing patient's knees (reduces tension on sciatic nerve)
9. extent of post-op pneumocephalus is more pronounced, and may increase the risk of tension pneumocephalus[34] (see *Pneumocephalus*, page 890)
10. venous pooling of blood in the LEs under anesthesia may cause relative hypovolemia and should be counteracted by binding the LEs prior to positioning
11. decreased cerebral blood flow due to lower hemodynamic arterial pressure[35]

Air embolism (AE): A potentially fatal complication of any operation when an opening to air occurs in a non-collapsible vein (e.g. diploic vein or a dural sinus) when there is a negative pressure in the vein (e.g. when the head is elevated above the heart)[36]. Air is entrained in the vein and can become trapped in the right atrium which may impair venous return causing hypotension. May also produce cardiac arrhythmias. **Paradoxical air embolism** can occur in the presence of a patent foramen ovale[37] or pulmonary AV fistula, and may produce ischemic cerebral infarction.

Greater negative pressures occur in the sitting position due to the extreme elevation of the head, but AE can occur in any operation with the head elevated higher than the heart. Incidence: a wide range has been quoted in the literature, and depends on the monitoring method used: ≈ 7-25% incidence with the sitting position using Doppler monitoring is an estimate[26].

Operations with significant risk of AE[A] require the use of a right atrial CVP

line (to aspirate air), and monitoring for air embolism; options include: transesophageal echo (the most sensitive), precordial Doppler monitoring.

A. although technically the risk of air embolism includes any case where the head is higher than the right cardiac atrium, practically it is limited to cases where the head of the bed is ≈ > 30° which is mostly limited to the sitting position for posterior fossa tumors

Table 7-2 Treatment for air embolism

1. find and occlude site of air entry, or else rapidly pack wound with sopping wet sponges/laps and wax bone edges
2. lower patient's head if at all possible (30° or less from horizontal)
3. jugular venous compression (bilateral best; second choice: right only)
4. rotate patient <u>LEFT</u> side down (attempt to trap air in right atrium)
5. aspirate air from right atrium via CVP catheter
6. ventilate patient with 100% O_2
7. discontinue nitrous oxide if used (may expand AE)[38]
8. use pressors and volume expanders to maintain BP
9. PEEP is <u>ineffective</u> in preventing or treating AE; may increase the risk of paradoxical AE[36]

Diagnosis and treatment:

The earliest clue to the occurrence of AE may be a fall in the end tidal pCO_2. On TE an air bubble will be visualized. Machinery sounds in the precordial Doppler also suggest AE. Hypotension may develop. Measures shown in *Table 7-2* should be immediately instituted.

Lateral oblique position

AKA "**park bench**" position. Axillary roll for the down side arm (*see Figure 7-3*) (or, position the patient so that the down side arm extends over the edge of the table and is held in place by a sling formed by the Mayfield table attachment with copious padding). Upper arm supported on pillows or towels (avoid using a Mayo stand which restricts the ability to laterally tilt the OR table during surgery). Elevate thorax 10-15°. Tilt the vertex of the head towards the floor (*see below*). Optional spinal drainage (usually for large tumors). Pillow between the legs.

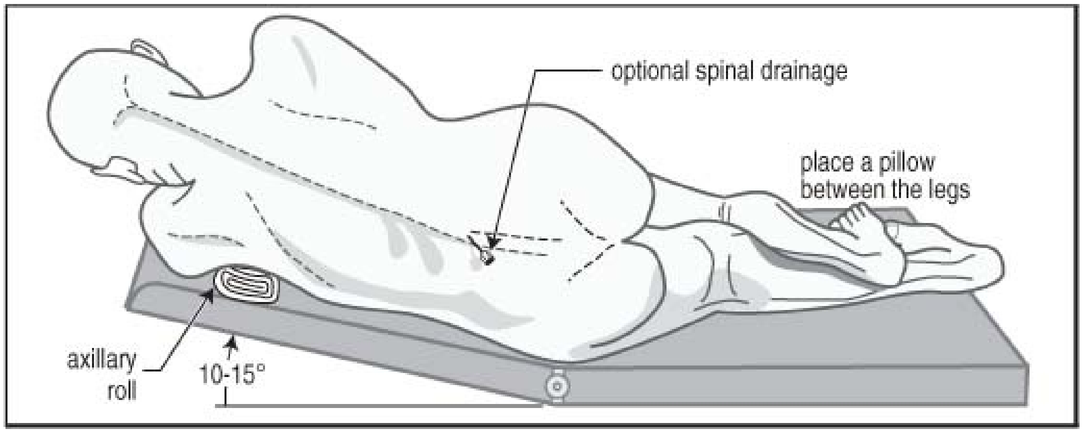

Figure 7-3 Lateral oblique ("park bench") position

For access to the porus acusticus or more caudally

(e.g. for vestibular schwannomas; not necessary for microvascular decompression for trigeminal neuralgia).

Get the shoulders out of the way by flexing the neck as much as possible while maintaining patent airway (aided by use of non-kinking wire-reinforced ET tube, so-called "**armored tube**"). The upper shoulder is retracted caudally by adhesive tape (avoid excess traction which may injure brachial plexus).

Head positioning

A Mayfield head-clamp is placed with the single pin on the side of the lesion, slightly anterior to a true-lateral on the skull, *see Figure 7-4*). The head is then rotated 20-30° face-down from the horizontal.

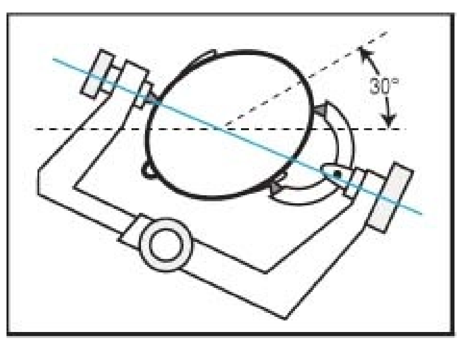

Figure 7-4 Position of head and head-holder for right suboccipital craniectomy (looking down on top of patient's head)

PARAMEDIAN SUBOCCIPITAL CRANIECTOMY

Indications:

1. access to the cerebellopontine angle **(CPA)**
   A. CPA tumors, including:
      1. vestibular schwannoma
      2. CPA meningioma
      3. epidermoid
   B. microvascular decompression
      1. trigeminal neuralgia
      2. hemifacial spasm
      3. miscellaneous: geniculate neuralgia, glossopharyngeal neuralgia
2. lesions of one cerebellar hemisphere:
   A. tumors: metastases, hemangioblastomas…
   B. hemorrhage within cerebellar hemisphere
3. access to vertebral artery
   A. aneurysms: PICA, vertebrobasilar junction
   B. vertebral endarterectomy
4. access to anterolateral brainstem tumors (extreme lateral p-fossa approach)
   A. foramen magnum tumors, including: chordomas, meningiomas

POSITION

Alternatives are listed on page 152. See page 154 for lateral oblique position.

SKIN INCISION

Linear (paramedian) incisions

Access to CPA. For microvascular decompressions and small CPA tumors, a linear incision provides adequate exposure and involves less trauma to overlying muscles, and may be easier to get watertight closure than with midline incision. For all of the following, the linear skin incision is located 5 mm medial to the mastoid notch (a palpable land-mark), (*see Figure 7-5*):

1. "5-6-4" incision (incision placed 5 mm medial to mastoid notch, extending from 6 cm above notch to 4 cm below). High enough to expose transverse sinus:
   • for approach to fifth nerve: microvascular decompression for trigeminal neuralgia
2. "5-5-5" incision (5 mm medial, extending 5 cm up to 5 cm down), used for approach to seventh/eighth nerve complex:

• microvascular decompression for hemifacial spasm
• small vestibular schwannoma

3. "5-4-6" incision (5 mm medial, extending 4 cm up to 6 cm down): used for approach to lower cranial nerves:
   • glossopharyngeal neuralgia

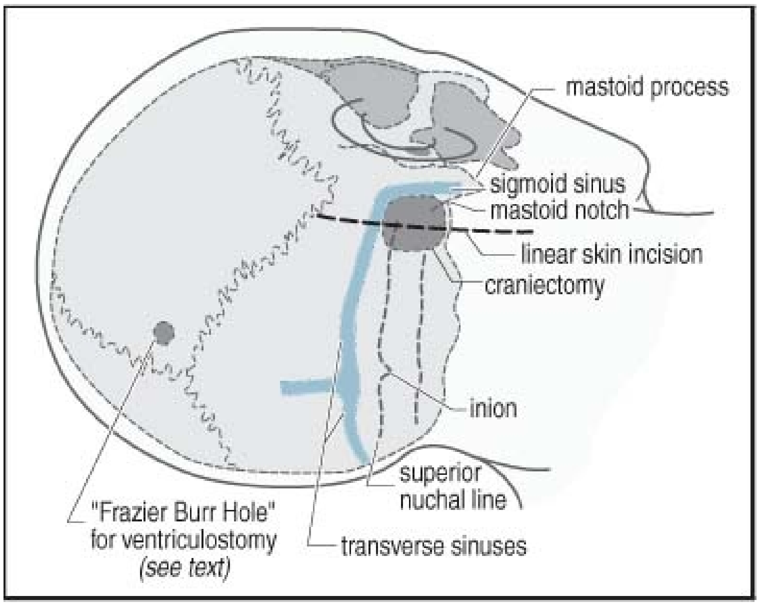

Figure 7-5 Paramedian suboccipital craniectomy

"Hockey-stick" incision

Useful for cerebellar hemispheric lesions as well as for larger CPA lesions where getting the muscles out of the way will facilitate maneuvering instruments about the posterior fossa.

Incision is made in the mid-line starting at ≈ C2 spinous process, proceeding superiorly to just above the inion, and then laterally to just beyond the mastoid tip (*see Figure 7-6*). A short optional caudal curve may be made laterally to further remove the muscle from the operative field.

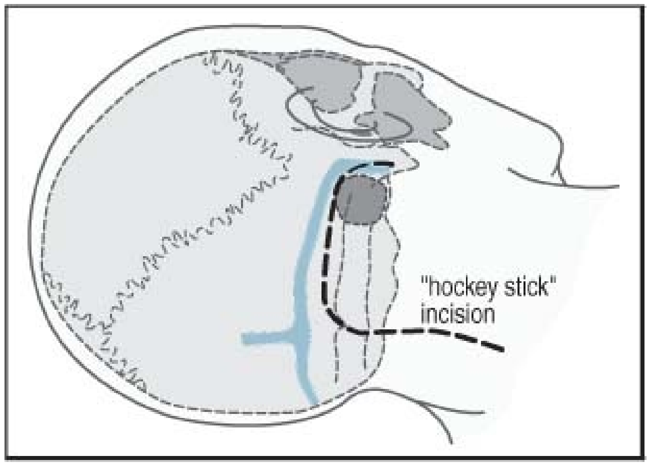

Figure 7-6 "Hockey-stick" skin incision

Craniectomy

Landmarks

The location of the inferior margin of the transverse sinus is quite accurately estimated at two finger-breadths above the upper limit of the mastoid notch (usually just above the superior nuchal line). This should be the upper limit of the skull opening.

For <u>small</u> tumors (< 2.5 cm)

May be done through craniectomy of ≈ 4 cm diameter placed in the angle between transverse and sigmoid sinuses.

For <u>large</u> tumors

A larger craniectomy may be needed, the size of which is limited by:

- transverse sinus superiorly
- foramen magnum inferiorly (which may be opened as prophylaxis against tonsillar herniation in the event of p-fossa edema post-op)
- sigmoid sinus laterally (opening mastoid air cells is acceptable, but to prevent CSF leak, these must be packed with bone wax and muscle (or bone dust from craniectomy[39]), and may be covered with reflected dura or fascia)
- midline medially (unless the tumor extends across the midline)

For approach to lower cranial nerves

(e.g. for glossopharyngeal neuralgia).

Craniectomy is extended inferiorly to ≈ 1/2 cm above foramen magnum.

Burr hole for emergency ventriculostomy

Optionally placed prophylactic occipital burr hole (**Frazier burr hole**) usually for intraparenchymal cerebellar tumors or any situation where post-op swelling or hydrocephalus is likely (not commonly used for microvascular decompression or small vestibular schwannomas).

Location: 3-4 cm from midline. In adults, 6-7 cm above the inion[40]; in pediatrics, 2-3 cm above the transverse sinus[41] (p 429) (i.e. ≈ 3-4 cm above the inion).

See *Post-op management* below for use.

Approach to the CPA

The angle of approach determines which portion of the posterior fossa is visualized.

- retracting the cerebellum <u>inferiorly</u> (working in the junction of the tentorium and petrous bone) gives access to the region of the trigeminal nerve, e.g. for microvascular decompression for trigeminal neuralgia
- <u>medial</u> retraction gains access to the region of the porus acusticus, e.g. for vestibular schwannomas
- <u>superior</u> retraction gains access to the lower cranial nerves, e.g. for geniculate neuralgia

MIDLINE SUBOCCIPITAL CRANIECTOMY

Indications: access to the midline or both sides of the posterior fossa

1. midline posterior fossa lesions
   A. cerebellar vermian and paravermian lesions, including: vermian AVM, cerebellar astrocytoma near the midline
   B. tumors of the fourth ventricle: ependymoma, medulloblastoma
   C. pineal region tumors
   D. brainstem lesions: brainstem vascular lesions (e.g. cavernous angioma)
2. decompressive craniectomies
   A. for Chiari malformation

3. cerebellar tumors: metastases, hemangioblastoma, pilocytic astrocytoma…

Position

For positioning, *see page 154*.

Skin/fascia incision

Midline incision from ≈ 6 cm above inion to ≈ C2 spinous process. Take the incision a little higher if a Frazier burr hole is to be done (can then utilize the same skin incision). The skin incision should leave the muscles and fascia intact. It is often difficult to place Raney clips on the skin in this region. To facilitate water-tight closure, the fascia is "T'd" at the top, leaving a cuff of tissue on the occiput just above the superior nuchal line.

Craniectomy

Craniectomy implies removal of bone (often piecemeal) with no intention of replacing it. Although craniotomy with replacement of bone flap at end of procedure has been used successfully, there is some concern that if there is post-op swelling, the inelastic bone flap may cause more pressure to be transmitted to the brain stem.

Usually taken down to foramen magnum. For cerebellar hemisphere tumors, many remove the posterior arch of C1 (caution re vertebral arteries on superior aspect of C1).

Approach

A "Y" shaped durotomy is often used. If the lesion has a cystic component, aspiration through a ventricular needle is used to partially decompress it.

Extreme lateral posterior fossa approach

Allows access to anterolateral region of brain stem. Differs from above in that the skin incision is designed to get the bulk of the skin and muscle flap out of the way.

Key: remove the lip of the foramen magnum as far laterally as possible, best done with a diamond drill.

Cranioplasty for suboccipital craniectomy

Methylmethacrylate cranioplasty as part of the closure following suboccipital crani for vestibular schwannoma reduced the incidence of post-op H/A from 17% to 4%[22].

POST-OP CONSIDERATIONS FOR P-FOSSA CRANI'S

POST-OP CHECK

In addition to routine, the following should be checked:

❑ 1. respirations: rate, pattern (see *Intubation* below)

❑ 2. follow closely for hypertension (*see below*)

❑ 3. evidence of CSF leak through wound

POST-OP MANAGEMENT

Intubation

Post-op intubation for 24-48 hours is sometimes maintained on a precautionary basis: many complications often have respiratory arrest as the initial manifestation (*see below*), and the patient may deteriorate precipitously from this point. There is a trade-off as the stimulus of the endotracheal tube may exacerbate hypertension and patient agitation, and so sedation is often required, which may obscure the neuro exam and depress respirations. If the patient wakes up extremely well from an uncomplicated p-fossa crani and it is not late at night, most surgeons will extubate.

Hypertension

Hypertension should be avoided at all costs to prevent bleeding from tenuous vessels (e.g. nitroprusside should be prepared prior to termination of the operation, and should be hanging and ready to titrate to keep SBP $\leq$ 160 mm Hg during the reversal of anesthesia and post-op).

Physician should be called for any sudden changes in BP post-op (may indicate elevated pressure in posterior fossa, *see below*).

POST-OP COMPLICATIONS

Posterior fossa edema and/or hematoma

In the posterior fossa, a small amount of mass effect can be rapidly fatal due to the paucity of room and the immediate transmission of pressure directly to the brain stem. It can also occlude CSF circulation through the aqueduct and cause acute hydrocephalus with the attendant risk of tonsillar herniation. Increased pressure in the p-fossa is usually heralded by sudden increases in BP or changes

in respiratory pattern (pupillary reflexes, level of consciousness and ICP are not affected until late). See *Table 7-3* for emergency treatment measures.

To expedite ventricular taps, a prophylactic occipital burr hole (**Frazier burr hole**) is often placed during posterior fossa surgery to permit drainage of CSF from the lateral ventricles in the event of acute hydrocephalus from blockage of the 4th ventricle or aqueduct. If acute hydrocephalus develops (e.g. from a hematoma), an emergent percutaneous ventricular tap with ventricular needle (or, if not available, spinal needle) is performed, passing the needle through the burr hole aiming for the middle of the forehead. In the presence of acute hydrocephalus, CSF should be encountered at a depth of 3-5 cm. NB: this maneuver may provide a few more minutes while preparing for the definitive treatment of reopening the wound; however, hydrocephalus may not initially be present since it takes some time to develop.

Table 7-3 Emergency treatment for p-fossa swelling

★ Rapid intubation, ventricular tap (through previously placed burr hole, if possible, *see below*), and reoperation is indicated. The wound should be opened immediately wherever patient is (recovery room, ICU, floor…). CT scanning may cost valuable minutes; it is rarely appropriate to delay treatment for this (must be judged on an individual basis).

CSF fistula

Occurs in 5-17% of cases. A potential source of meningitis, thus CSF leak must be treated immediately.

Etiologies: controversial. May include:

1. abnormal CSF hydrodynamics (i.e. hydrocephalus). Maneuvers to stem the leak will likely fail until the CSF is shunted or hydrodynamics normalize
2. poor wound closure: probably blamed more often than it is the actual cause
3. subarachnoid scarring

May be associated with meningitis (aseptic or infectious), multiple operations. Formation may be facilitated by coughing/sneezing, postural changes, one-way ball-valve mechanism due to a tissue flap.

An external CSF leak may occur through:

1. the skin incision
2. via the eustachian tube (*see* *page 630* for possible routes of egress

following sub-occipital vestibular schwannoma removal):
   A. through the nose (CSF rhinorrhea)
   B. down the back of the throat
3. the ear (CSF otorrhea) in cases with perforated TM

Treatment:

Initial treatment measures to temporize in the hope that CSF hydrodynamics will normalize and/or that the leak site will scar closed within a few days:

1. elevate the HOB
2. lumbar subarachnoid drainage
3. if the leak occurs through the skin incision:
   A. reinforce the incision with sutures, e.g. running locked 3-0 nylon after preparation of the skin with antimicrobial and local anesthetic
   B. alternatively, the incision may be painted with several coats of collodion

If persistent, a CSF fistula requires surgical correction, see *CSF fistula (cranial)*, page 300 for general information, *see page 631* for CSF fistula following suboccipital removal of vestibular schwannoma.

Suboccipital pseudomeningocele: An "internal" CSF fistula. Incidence following suboccipital craniectomy: 842-28%[43].

May be asymptomatic, but also may be associated with H/A, nausea/vomiting, local pain/tenderness. Some are soft and compressible, others may be tense.

Treatment options (up to 67% require permanent CSF drainage[44]):

1. noninvasive measures: expectant management, fluid restriction, head wrapping, keeping HOB elevated, acetazolamide. Steroids may be used if aseptic meningitis is suspected
2. percutaneous aspiration: "tap and wrap"[41 p 436, 45]. Risks introducing bacteria, causing infection
3. direct surgical exploration with multilayer re-closure[41 p 436]
4. lumbar drain: effective only if pseudomeningocele communicates with the subarachnoid space. ✖ May produce acute posterior fossa syndrome (H/A, nausea, vomiting, ataxia…)[42] especially if the pseudomeningocele doesn't communicate. Symptoms usually resolve with prompt discontinuation of lumbar drainage[42, 43]. Other potential complications: vagal nerve palsy, tonsillar herniation, subdural hematoma, kinking of PCA → stroke.

Drainage options:

A. external drain (temporary)

B. lumboperitoneal shunt (permanent)

5. ventricular drainage

   A. EVD (temporary)

   B. shunt (permanent)

Fifth or seventh nerve injuries

Causes diminished corneal reflex with potential corneal ulceration; initially managed with isotonic eye drops (e.g. Natural Tears®) q 2-4 hrs & PRN, or with a moisturizing insert (e.g. Lacricert®) q day, and at night with an eye patch or taping eyelid shut.

Miscellaneous

Supratentorial intracerebral hemorrhage has been described, and may result from transient hypertension[46].

7.4.6. Pterional craniotomy

INDICATIONS

1. aneurysms
   A. all aneurysms of anterior circulation
   B. basilar tip aneurysms
2. direct surgical approach to cavernous sinus
3. suprasellar tumors
   A. pituitary adenoma (when there is a large suprasellar component)
   B. craniopharyngioma

TECHNIQUE

POSITION

- supine, ipsilateral shoulder roll if head turned > 30° (*see below*)
- elevate thorax 10-15°: reduces venous distension
- flex knees

• Mayfield 3 pin head-holder: applied between true AP and true lateral (so that it is ≈ horizontal when head is rotated to the necessary position, *see Figure 7-7*)
• neck extended 15°: allows gravity to retract frontal lobe away from skull base
• head rotated from vertical as shown in *Figure 7-7*:

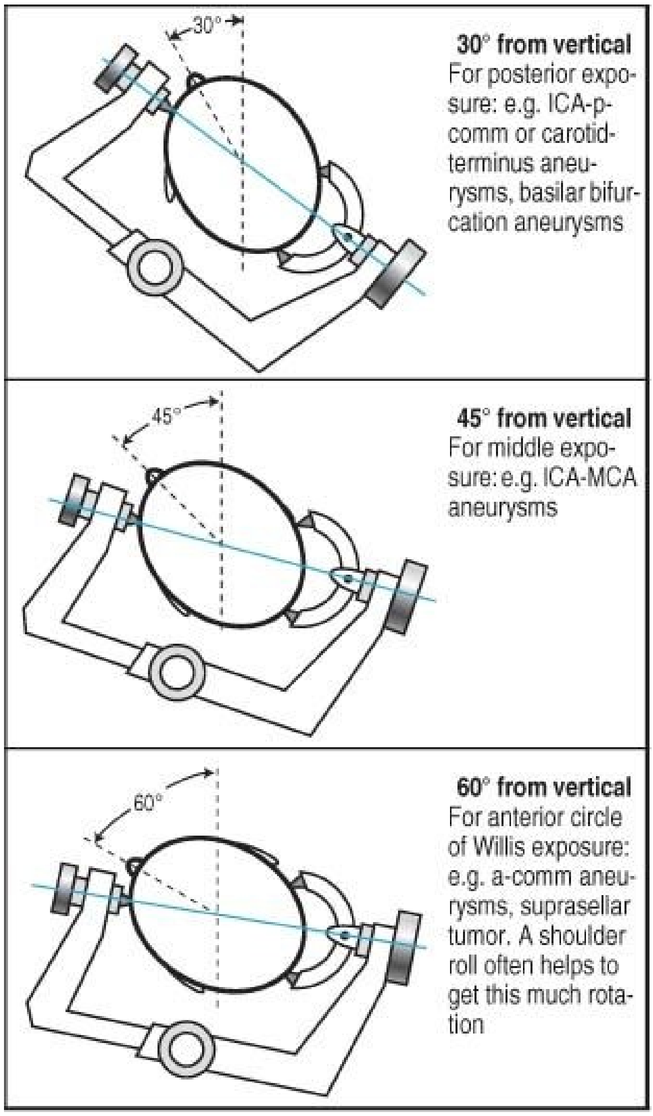

Figure 7-7 Head position for pterional craniotomy depending on exposure required. The blue line indicates the approximate centerline

ROOM ARRANGEMENT

1. microscope: observer tube to operator's right for either right or left pterional crani

SKIN INCISION

See Figure 7-8. From zygomatic arch 1 cm in front of tragus (to avoid frontalis branch of facial nerve and frontal branch of superficial temporal artery), curving slightly anteriorly, staying behind hairline to widow's peak, optional additional curve beyond midline to aid in skin retraction. Over temporalis muscle, incise skin down to but not through temporalis fascia.

The temporalis muscle may be incised caudal to the skin incision (i.e. closer to zygomatic arch): this minimizes the muscle mass that needs to be retracted inferiorly and yet keeps the scar behind hairline (note: there is an increased risk of frontalis weakness with this technique than if the temporalis muscle is incised inline with the skin incision).

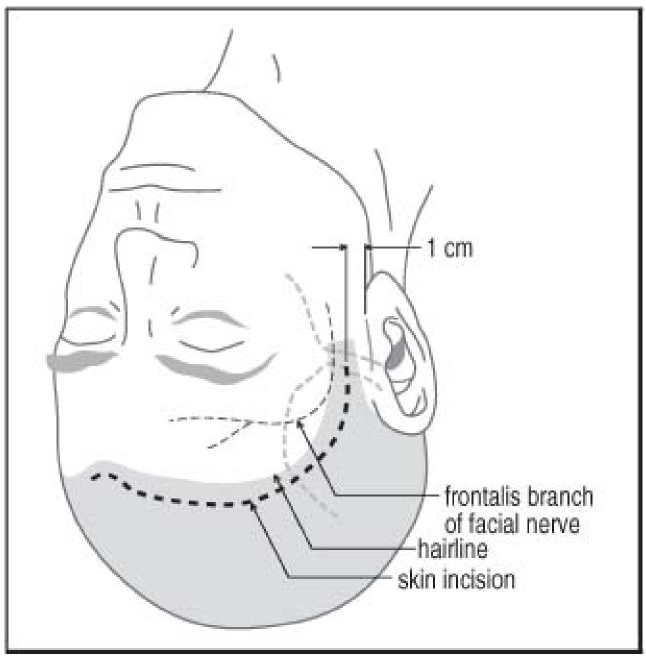

Figure 7-8 Skin incision for pterional craniotomy

CRANIOTOMY

There are numerous ways to cross the pterion (the lesser wing of the sphenoid makes this difficult). One method is outlined here, *see Figure 7-9*.

Burr holes

Two burr holes are sufficient; made as far caudally as possible to minimize the amount of bone to be rongeured off to gain access to the floor of the middle cranial fossa. One burr hole is made at the posterior insertion of the zygomatic arch ("**A**" in *Figure 7-9*); this burr hole may be placed slightly forward when

exposure is centered over structures around the ACoA (e.g. suprasellar tumor). The second burr hole ("**Z**") is made at the intersection of the zygomatic bone (near the frontozygomatic suture), the superior temporal line and the supraorbital ridge. The hole should be as low as possible on the orbit (Yasargil facetiously said "If you don't see intraorbital fat, you're not low enough."), aim the drill slightly superiorly to avoid actually entering the orbit. The dura is dissected off the inner table with a Penfield #3 dissector.

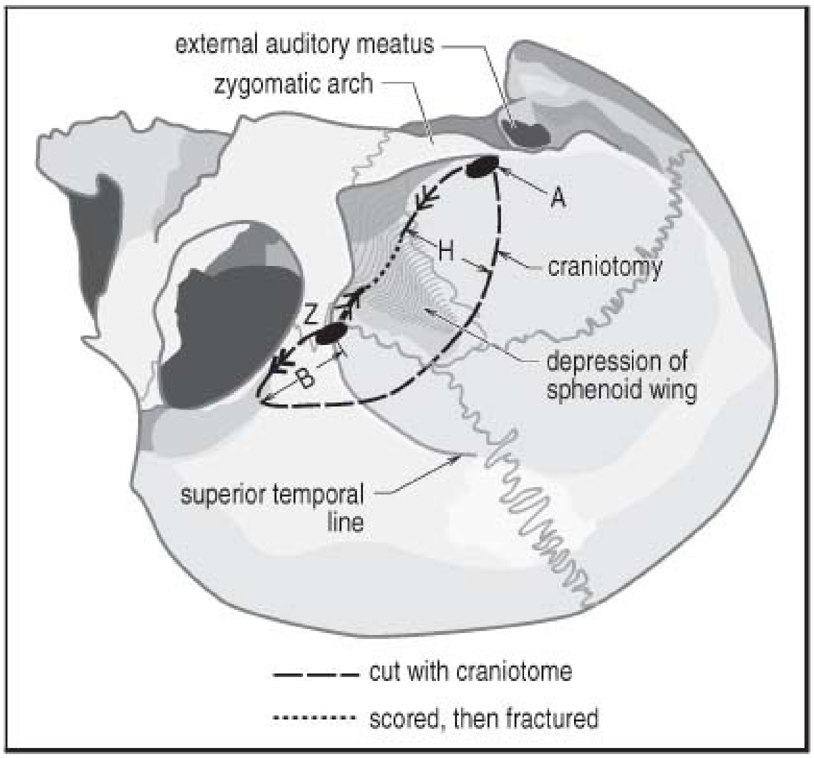

Figure 7-9 Skull landmarks for right pterional craniotomy

Craniotomy

The resulting bone flap is centered over the depression of the sphenoid ridge. Approximately 33% of the craniotomy is anterior to the anterior margin of temporalis muscle insertion, ≈ 66% is posterior.

With the craniotome, starting at the frontal burr hole the craniotomy is taken anteriorly across the anterior margin of the superior temporal line staying as low as possible on the orbit (to obviate having to rongeur bone, which is unsightly on the forehead). The distance "**B**" from the medial extent of the craniotomy to the frontal burr hole is 3 cm for anterior circulation aneurysms. For the approaches to skull base (e.g. Dolenc approach), distance "B" is larger and takes the opening to ≈ the mid orbit. Then from point "B", a sharp superior turn is made and the

opening is taken back to point “A”. The height (“**H**”) of the craniotomy needs to be only ≈ 3 cm for aneurysms of the Circle of Willis, and slightly larger (≈ 5 cm) for middle cerebral artery aneurysms. Minimal exposure of temporal cortex is necessary for aneurysms of the skull base region. For large flaps (e.g. for tumors), “H” is made larger to expose more temporal lobe.

From the frontal burr hole, the craniotomy is then taken posteriorly towards the depression corresponding to the sphenoid wing until the drill hangs up.

The craniotomy from the posterior burr hole is taken forward towards the depression corresponding to the sphenoid wing until the drill hangs up.

The bone between the two points where the drill hangs up is scored with the craniotome, and then the bone is fractured at this point. A rongeur is used to remove as much sphenoid wing as possible.

Dural flap

Curvilinear, centered over sphenoid wing, retracted inferiorly with dural stitch.

Dissection

For some anterior circulation aneurysms (e.g. MCA aneurysms) and for the Yasargil approach to basilar tip aneurysms, the sylvian fissure needs to be split. This can be accomplished by working from the lateral aspect of the fissure medially, or, by starting at the point where the carotid artery penetrates the fissure and working laterally. The latter method may be easier when prolific veins overly the junction of the frontal and temporal lobe. There are no arteries that cross the sylvian fissure, and so if the correct plane is maintained, no arteries need to be sacrificed.

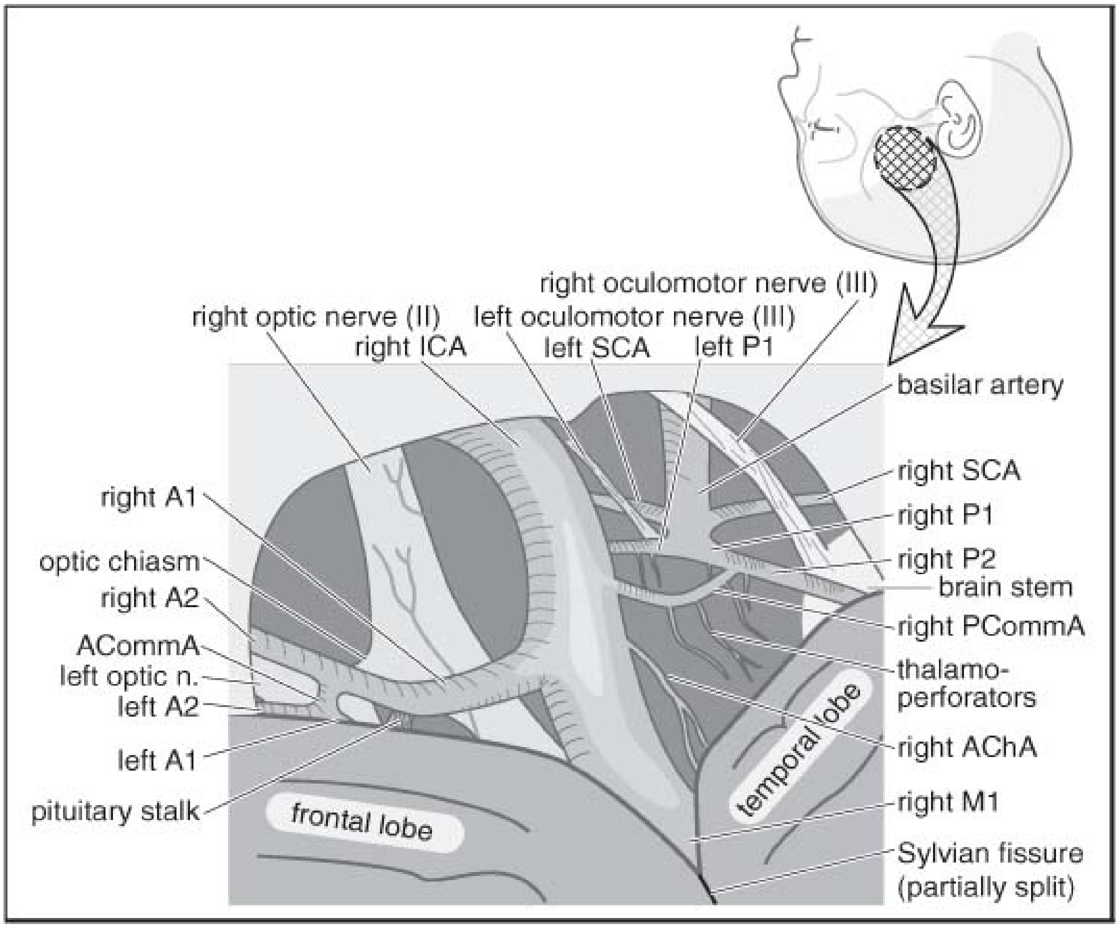

Figure 7-10 Right sided sylvian fissure dissection, surgical view

Figure 7-10 shows a theoretical exposure of the circle of Willis possible through a pterional craniotomy. This diagram is semi-schematic, and in reality dissection would be directed either anteriorly (e.g. to expose ACoA) or posteriorly (e.g. for basilar tip aneurysms) but not both.

7.4.7. Temporal craniotomy

INDICATIONS

1. temporal lobe biopsy: herpes simplex encephalitis
2. temporal lobectomy: for resection of seizure focus, decompression post-trauma…
3. hematoma (epidural or subdural) overlying temporal lobe
4. tumors of the temporal lobe
5. small, laterally located vestibular schwannomas[47]

6. access to the floor of the middle cranial fossa (including foramen ovale/Meckel's cave, the labyrinthine and upper tympanic portion of the facial nerve)
7. access to **medial temporal lobe** e.g. for amygdalo-hippocampectomy (*see page 423*) or for mesial temporal sclerosis (*see page 395*)

TECHNIQUE

Two basic methods for temporal craniotomy:

1. small craniotomy or craniectomy through a linear skin incision: good for cortical biopsy or draining chronic subdural hematoma. Also permits access to floor of middle fossa. Simple quick closure
2. question-mark skin incision with standard craniotomy flap: useful for temporal lobe exposure for tumor or acute hematoma

POSITION

- patient supine with shoulder roll (to assist in rotating neck to get head almost horizontal)
- elevate thorax 10-15°: reduces venous distension
- flex knees slightly
- Mayfield 3 pin head-holder: true AP with single pin anteriorly
- head rotated almost horizontal to floor: avoid over-extending to prevent kinking neck veins

SMALL CRANIECTOMY

Linear skin incision completely within the extent of the temporalis muscle. To access the temporal tip: place the incision midway between the lateral canthus and external auditory canal **(EAC)**; extend it from the zygomatic arch upward for ≈ 6 cm. For small, laterally located vestibular schwannomas, the incision is made 0.5 cm anterior to the EAC extending ≈ 7-8 cm above the zygomatic arch[47]. To drain a subdural, place the incision just anterior to the tragus and start it 1-2 cm above the zygomatic arch for ≈ 6 cm (modified based on the location of the epicenter of the subdural). Take the incision down to temporalis fascia with the knife, and incise the fascia and muscle with Bovie cautery. Spread with self-retaining retractors, and make a burr hole. Enlarge with rongeurs and/or Kerrison punches.

STANDARD CRANIOTOMY

Question-mark skin incision

See *Figure 7-11*. Used for access to the temporal lobe including tip (a *reverse* question mark incision may be used to gain access to the middle and posterior temporal lobe).

- the pinna is either sutured inferiorly out of the way before draping, or it can be folded under the drapes which may be stapled to the skin
- the lower limb extends from the zygomatic arch just anterior to the tragus (to avoid the superficial temporal artery)
- at the level of the top of the pinna it curves as far posteriorly as ≈ 6-7 cm on the non-dominant side, or ≈ 8-9 cm on the dominant side (these dimensions allow access to the "safe" area of temporal tip for lobectomy)
- then superiorly to the level of the superior temporal line
- then anteriorly towards the forehead, stopping at the hair line

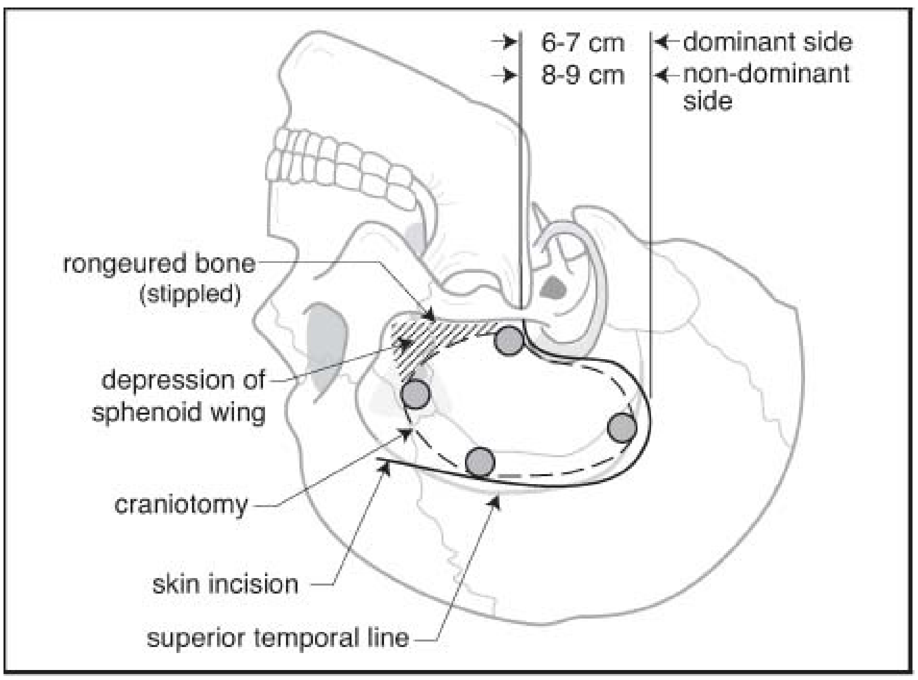

Figure 7-11 Temporal craniotomy (exposing entire temporal lobe)

Burr hole placement

1. at the posterior insertion of the zygomatic arch
2. at upper anterior junction of zygomatic arch
3. one or two burr holes along posterior and superior aspect of the skin incision

Craniotomy

Connect the burr holes with the craniotome, keeping as low as possible in the middle fossa to minimize the amount of bone that must be rongeured. The remaining bone is rongeured down to the floor of the middle fossa (cross-hatched area in *Figure 7-11*).

Temporal lobectomy

✖ Danger points:

1. dominant hemisphere: Wernicke's speech area. Although variable (see *Temporal lobectomy*, page 423), one can usually safely resect up to 4-5 cm from temporal tip
2. non-dominant hemisphere: one can resect up to 6-7 cm before running the risk of injuring the optic radiation
3. sylvian fissure (middle cerebral artery): it is best to amputate the temporal lobe backward from the tip for the extent of the desired resection, and then work deep
4. medially, the incisura should be identified to avoid injury to the brain stem which lies just medial to this

---

7.4.8. Frontal craniotomy

INDICATIONS

1. access to frontal lobe: e.g. for infiltrating tumor
2. approach to third ventricle or to sellar region tumors in some situations, including craniopharyngiomas, planum sphenoidale meningiomas
3. repair of ethmoidal CSF fistula

✖ **Danger points:**

1. anterior cerebral arteries in the midline (deep)
2. superior sagittal sinus **(SSS)** in the midline (note: the SSS may be sacrificed in its anterior third without engendering venous infarction in most cases, whereas venous infarction will almost always occur with division of the SSS posterior to that)
3. avoid inadvertently crossing the midline into the contralateral hemisphere through the corpus callosum
4. dominant hemisphere: Broca's (motor speech) area is located in the

inferior frontal gyrus

TECHNIQUE

Two basic choices for craniotomy:

1. unilateral craniotomy through a curved skin incision taken anteriorly up to the hairline: used when one does not need to be low in the frontal fossa in the midline (otherwise the skin incision would have to be taken far into forehead) and when there is no need to cross the midline
2. large bifrontal skin incision from "ear-to-ear" (souttar skin incision[48]) allowing low approach to one or both frontal fossa

UNILATERAL FRONTAL CRANIOTOMY

See Figure 7-12. Skin incision starts < 1 cm anterior to the tragus, and does not need to go all the way down to the zygomatic arch. It curves superiorly and slightly posteriorly before being taken to the midline frontally.

Burr holes

1. at the junction of the superior temporal line and the orbital rim
2. just posterior to the depression of the sphenoid wing (behind the pterion)
3. anteriorly just behind the hairline to avoid having a burr hole under the forehead (which causes an unsightly depression)
4. superiorly

BILATERAL FRONTAL CRANIOTOMY

1. "ear-to-ear" or souttar skin incision
   A. just behind hairline with a slight widow's peak at the front
   B. does not need to go all the way to the zygomatic arch, it just needs to be ≈ as low as the orbital roof
   C. unlike pterional craniotomy, usually do not need to incise the temporalis muscle and fascia. Dissect the flap off the muscle/fascia
   D. if a periosteal flap is likely to be needed, it sometimes helps not to incise the periosteum at the same time as the skin incision. Then, the periosteum can be incised *behind* the skin incision to yield a longer periosteal graft than would have otherwise been obtained
2. burr holes: to avoid burr hole defects on the forehead, the bone flap can be created with two burr holes straddling the superior sagittal sinus **(SSS)**

close to the skin incision, and two burr holes laterally

3. the SSS may be divided low, near the orbital roof, with little risk
4. if the frontal sinus is entered, it is dealt with as outlined under *Frontal sinus fractures*, *page 889*

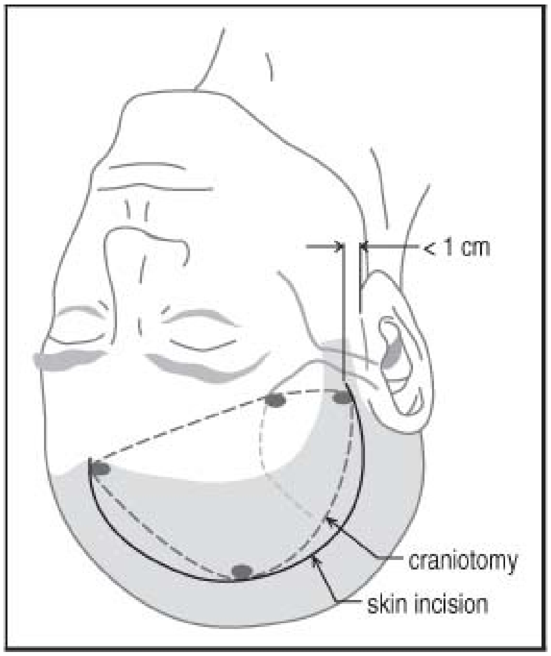

Figure 7-12 Unilateral frontal craniotomy

7.4.9. Occipital craniotomy

INDICATIONS

Occipital lobe tumors including posterior falx meningiomas or tentorial meningiomas with only supratentorial component. Occipital lobe intracerebral hemorrhages.

POSITIONS

Supine

Shoulder roll on affected side; elevate thorax 15°. Mayfield 3 pin headholder with single pin in forehead off to the side of the crani, double pin just over midline on opposite side.

Lateral oblique

- affected side up, can operate either
  - A. from behind patient similar to p-fossa crani for CPA lesion
  - OR
  - B. from top of table
- alternative approach: affected side down. Useful in lesions adjacent to the falx (see *Interhemispheric approach* above)

7.4.10. Decompressive craniectomy

Indications: controversial. Include:

1. malignant middle cerebral artery occlusion syndrome (*see page 1022*) primarily for nondominant hemisphere. Use on dominant side is more controversial
2. traumatic intracranial hypertension
   - A. as an adjunct for persistent intracranial hypertension when other ICP control measures fail[61] (*see page 892*)
   - B. early in the management: may be considered for patients undergoing emergent surgery (for fracture, EDH, SDH…)[62]
3. uncontrollable brain swelling during craniotomy (*see page 147*)
4. reported in children with refractory nontraumatic intracranial hypertension[63] (e.g. infection, infarction, Reye's syndrome…)

Potential complications:

1. bleeding
2. herniation of the brain through the opening, compressing and lacerating the brain on the bone edges (risk may be reduced by making generous craniectomy)
3. post-op injury to the brain from inadvertent external pressure applied to the now relatively less protected brain
4. post-op fluid collections: hygromas or hematomas at the operative site, on the contralateral side, or interhemispheric

TECHNIQUES

General considerations

1. it is necessary to open the dura
2. options for the removed bone flap
   A. discard it: this may be the best option when the bone flap has been contaminated as a result of an open traumatic scalp laceration
   B. place it in a separate subcutaneous pouch in the patient's abdomen for later retrieval and reimplantation into the skull. This is especially helpful if the patient's own skull is preferred and the patient does not live in the area where he/she is having the surgery
   C. store it for future implantation: saturate with sterile solution (e.g. RPMI medium 1640 www.invitrogen.com/GIBCO) and then place within sterile storage (e.g. intestinal bags which are then placed in a sterile plastic container) and store in a bone freezer at -80° C
   D. for non-contaminated situations (e.g. stroke): reimplantation can be considered after 6-12 weeks
3. bone openings need to be large (e.g. > 12 cm diameter[64], often > 15 cm)

POSTERIOR FOSSA DECOMPRESSIVE CRANIECTOMY

1. skin incision: midline skin incision from above inion to ≈ C2 spinous process
2. bone opening: laterally to sigmoid sinuses, superiorly to transverse sinus. C1 laminectomy is typically performed as well[63]
3. dural opening: "Y" shaped incision

HEMICRANIECTOMY

1. some prefer use of a Mayfield headholder placed low (*see Figure 7-13*) to give greater access[62] (not feasible with severe comminuted skull fractures)
2. AP axis of head is placed horizontal to floor (unless C-spine not cleared or if neck too immobile - one may compensate for this by rotating table)
3. skin incision: two options
   A. (*Figure 7-14-A*) starts at widow's peak, similar to trauma flap (*see page 865*), but with increased exposure by taking it posteriorly close to the inion then turning sharply anteriorly and hugging the ear to preserve blood supply
   B. (*Figure 7-14-B*) "T" incision. Less risk of flap ischemia. The "T" joins the midline incision behind the coronal suture to preserve the STA[62]

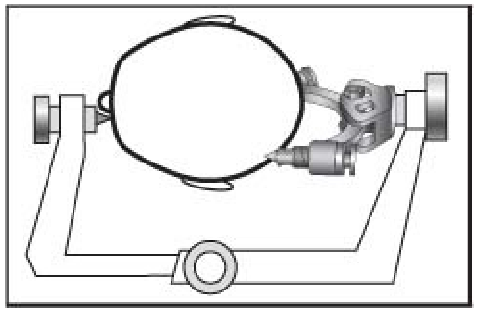

Figure 7-13 Position of head and head-holder for right hemicraniectomy (looking down on top of patient's head)

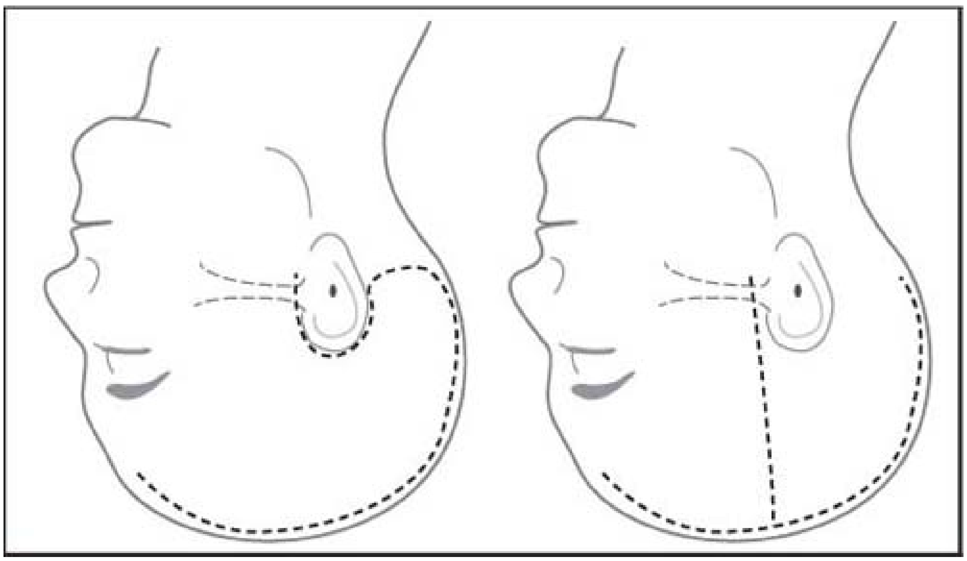

Figure 7-14 Two options for skin incision for hemicraniectomy (see text)

C. burr holes (*see Figure 7-15*): a burr hole is made just above the posterior root of the zygomatic arch, a second one may be made just behind the frontal insertion of the zygomatic arch, inferior to the superior temporal line

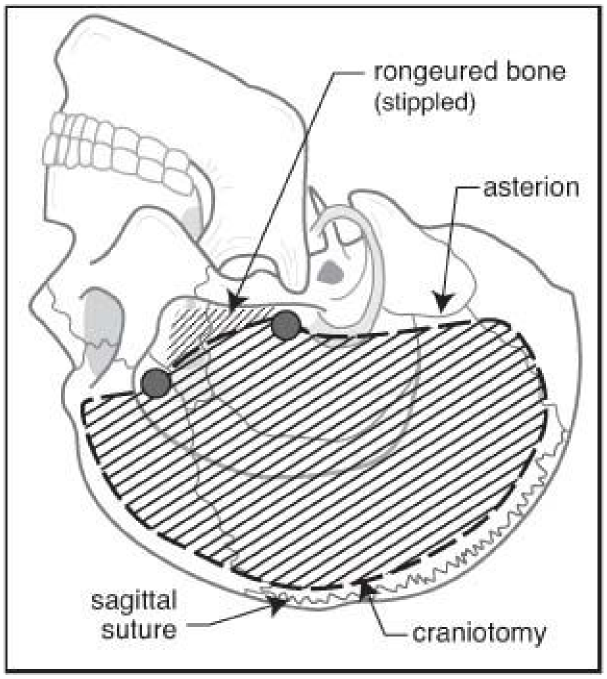

Figure 7-15 Hemicraniectomy bone flap

D. bone flap: proceed posteriorly from the posterior zygomatic arch using the footplated craniotome. Posteriorly, stay ≈ 1 cm superior to asterion to avoid the transverse sinus. The flap is taken 1 cm beyond the lambdoid suture, and then up towards the sagittal suture, crossing the lambdoid suture again (this leaves a small amount of bone posteriorly on which the head can rest post-op). An anterior turn is made 1 cm short of the sagittal suture to avoid the superior sagittal sinus, and the sagittal suture is paralleled. The coronal suture is crossed and the drill is taken as low as possible in the frontal fossa near the midline. Staying as low as possible, the orbital roof is followed posteriorly towards the second burr hole. The burr holes are then connected

E. some bone may need to be rongeured to expose the floor of the middle fossa (stippled area in *Figure 7-15*)

F. dural opening: based inferiorly, taken to 1 cm short of the craniotomy edge. Dural releasing incisions may be made at intervals up to the bone margin to avoid strangulation of the brain on the dural edge

G. duroplasy
   1. onlay: 2 cm wide strips of dural substitute can then be placed partway under the dural edge around the periphery to isolate the brain from the undersurface of the skin flap where there will be a

gap in the dura

2. some authors suture a dural draft in place

H. the dural flap is then replaced on top of the brain and dural substitute strips, and is not sutured

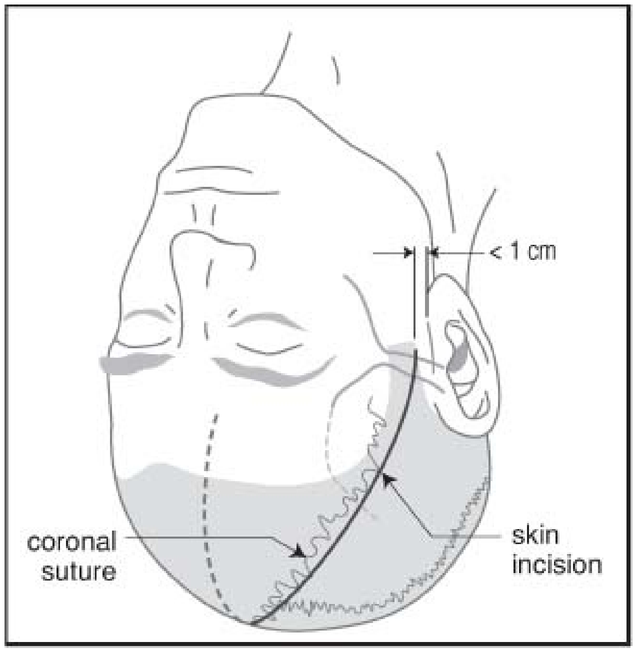

Figure 7-16 Bilateral craniectomy skin incision

Bilateral craniectomy

The above procedure can be performed bilaterally, however, it is difficult to position the head to do this. Alternatively, a bifrontal craniectomy can be performed.

1. skin incision: bicoronal, posterior to the coronal suture (*see Figure 7-16*)
2. burr holes: may use the same ones as for hemicraniectomy (*see above*) bilaterally. Addition burr holes to straddle the superior sagittal sinus may be made if a large single bone flap is planned
3. bone flap: two options, both are taken back to the coronal suture
   A. a single large bone flap[65] extending back to the coronal sutures, or
   B. two frontal flaps leaving a thin strip of bone in the midline overlying the superior sagittal sinus (if this strip is too wide, it can damage the brain)

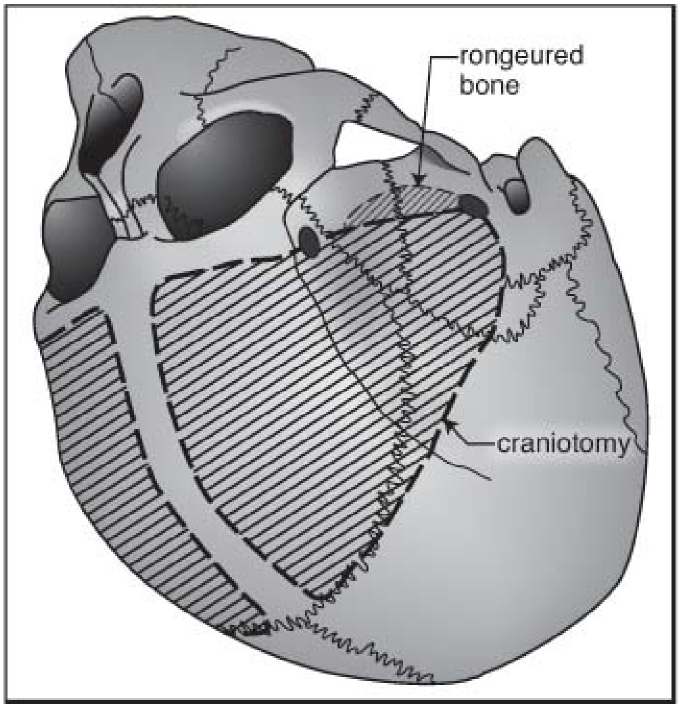

Figure 7-17 Bilateral craniectomy skull flap Shown with 2 separate frontal flaps (the preserved midline bone strip over the superior sagittal sinus is optional)

4. dural opening: bilateral, based against the midline (superior sagittal sinus)

7.4.11. Approaches to the lateral ventricle

Classic review[40] (p 561-74) summarized:

1. atrium (AKA trigone)[50]; numerous approaches include:
   A. middle temporal gyrus: through the dilated temporal horn
   B. lateral temporal parietal
   C. superior parietal occipital
   D. transcallosal (*see below*)
   E. transtemporal horn: access to temporal horn is via lobectomy of the temporal tip
   F. occipital lobe incision or occipital lobectomy: recommended only if patient has homonymous hemianopsia pre-op
2. frontal horn
   A. middle frontal gyrus
3. midventricular body
   A. transcallosal

B. middle frontal gyrus: usually prevents access to vascular supply until most of the tumor is removed (especially for tumors supplied primarily by posterior choroidal artery)
4. temporal horn
A. middle temporal gyrus
B. transtemporal horn

7.4.12. Approaches to the third ventricle

Classic references review the microsurgical anatomy[51] and surgical approaches[52], and are briefly summarized below.

Alternative approaches for lesions of the anterior third ventricle[53]:

1. transcortical: approach is through the lateral ventricle and is feasible only in the presence of hydrocephalus; especially useful if the tumor extends from the third ventricle into one of the lateral ventricles. Risk of seizures is 5% (higher then with transcallosal). *See page 172*
2. transcallosal: may be preferable in the absence of hydrocephalus (*see below*)
   A. anterior transcallosal: good visualization of both walls of third ventricle; risk of bilateral forniceal damage
   B. posterior transcallosal: allows approach to quadrigeminal plate or pineal region; risk of damage to deep veins
3. subfrontal: allows four different approaches
   A. subchiasmatic: between optic nerve and optic chiasm
   B. optico-carotid: through the triangular space bordered by optic nerve medially, carotid artery laterally, and ACA posteriorly
   C. lamina terminalis: above the optic chiasm[54]
   D. transsphenoidal: requires removal of tuberculum sellae, planum sphenoi-dale, and anterior wall of the sella turcica
4. transsphenoidal
5. subtemporal
6. stereotactic: may be useful for aspiration of colloid cysts (see *Stereotactic drainage of colloid cysts*, page 666)

GENERAL PRINCIPLES OF TUMOR REMOVAL

Summarized[52]. During the approach, deep veins should be preserved at all

costs, even if it means stretching them to the point that they may rupture.

It is helpful to place a suture through the tumor capsule to act as a tether.

The tumor should first be removed from within the capsule; techniques include aspiration, and then opening the capsule and debulking from within. The capsule may then be collapsed and dissected from adherent structures. If the capsule adhesions seem unyielding, the most likely cause is incomplete intracapsular evacuation.

Vessels on the surface of the tumor should be presumed to be supplying normal brain, and should be dissected off the capsule once it is completely emptied.

TRANSCALLOSAL APPROACH TO LATERAL OR THIRD VENTRICLE

Performed through an interhemispheric approach to the corpus callosum **(CC)** via a parietal craniotomy, usually right sided in a left-hemisphere dominant patient.

INDICATIONS

Primarily for tumors or lesions of the lateral or third ventricle, including:

1. colloid cysts
2. craniopharyngiomas
3. cysticercosis cysts
4. thalamic glioma
5. AVM

BOOKING THE CASE - TRANSCALLOSAL SURGERY

Also see defaults & disclaimers (*page v*).

1. position: supine with pin headholder
2. equipment:
    A. microscope
    B. image guided navigation system
3. post op: ICU
4. consent (in lay terms for the patient - not all-inclusive):
    A. procedure: operation between the two halves of the brain to remove

lesion

B. alternatives: non-surgical management, surgery through the surface of the brain (transcortical), radiation therapy for some diagnoses

C. complications: stroke, "disconnection syndrome" (uncommon - *see page 423*), hydrocephalus with possible need for a shunt, memory deficits

TECHNIQUE[51, 52, 55]

See Figure 7-18. Image-guided navigation is very helpful in ascertaining the correct trajectory which permits minimizing the size of the callosotomy, and helps distinguish the corpus callosum from the cingulate gyri.

POSITION

Supine with neck flexed. Thorax elevated 20°. Spinal drain not used. Keep the head perfectly vertical to minimize disorientation that can easily occur with this approach. Alternatively, gravity retraction may be employed either by tilting the head slightly to the right (causing the right hemisphere to fall away) or by using the lateral position.

SKIN INCISION

Either of the following may be used:

1. inverted "U" with the top just left of midline, extending from **6 cm anterior** to the coronal suture to **2 cm behind** the coronal suture, taking the sides for 7-8 cm
2. souttar skin incision

CRANIOTOMY

Pre-op angiography is recommended to plan the position of the flap to avoid sacrificing large cortical veins. MRI may also suffice for this[56]. The bone flap is either trapezoidal or triangular in shape, for adequate exposure it is critical to go all the way to the superior sagittal sinus **(SSS)**. Several techniques may be used (NB: the SSS is often to the right of the sagittal suture - *see page 87*):

1. to expose the SSS, straddle the SSS with paired burr holes anteriorly and posteriorly, dissect the dura from the inner table between pairs, and make the longitudinal cut on the left of midline. Disadvantage: removing the midline bone puts the SSS at greater risk of injury and makes it more difficult to control lacerations

2. one can make the long cut well to the right of midline, and then under direct vision rongeur off the bone to the SSS. Safe, but leaves a large bone gap that may need to be filled (e.g. with methyl methacrylate) and is time consuming
3. most risky for causing a sagittal sinus laceration is to make the long cut just right of the midline (over the edge of the SSS, which may lacerate it)

To stay away from the motor strip and to keep the sagittal sinus exposure as anterior as possible, 2/3 of the opening should lie anterior to coronal suture, 1/3 posterior (generally: 6 cm total with 4 cm anterior and 2 cm posterior). The craniotomy extends laterally to 3-4 cm to right of mid-line. The last cut with the craniotome should connect the burr holes along the sinus (mid-line); leaving this cut for last permits rapid access to the sinus in case it is torn. The dural flap is based to-wards the sagittal sinus.

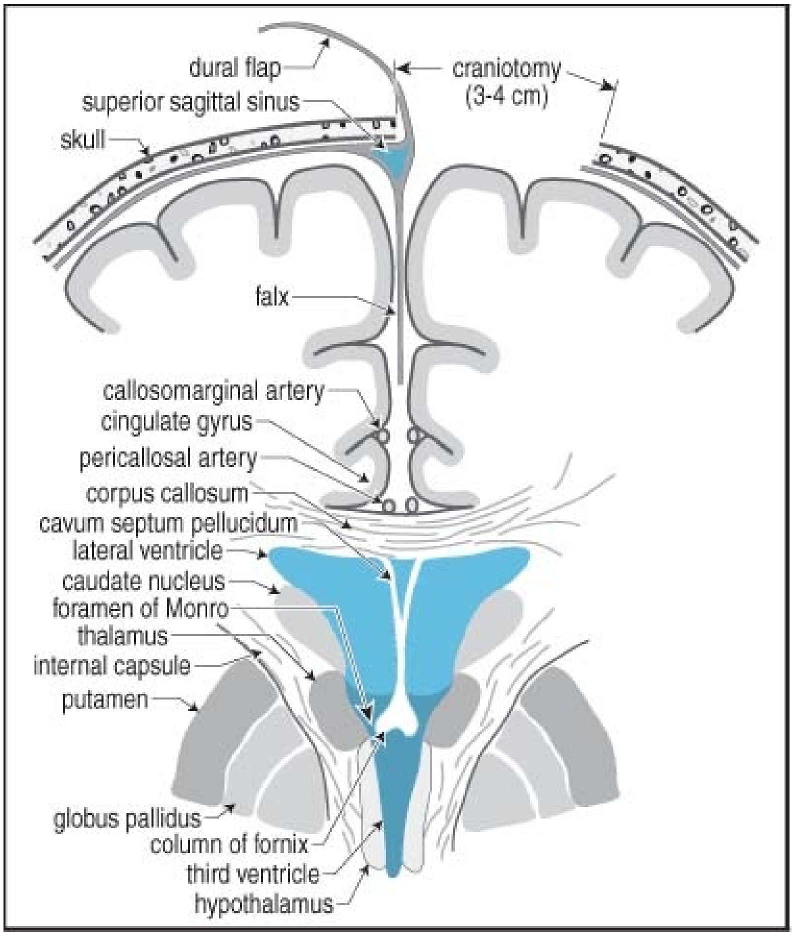

Figure 7-18 Transcallosal approach to the third ventricle: frontal view

APPROACH TO CORPUS CALLOSUM

None, or at most, only one bridging vein from the cortex to the sagittal sinus may be sacrificed (and then, only if it is not a large draining vein). Gently retract the right hemisphere. Avoid retractors on the sagittal sinus to prevent injury to

the SSS which may lead to sinus thrombosis (once CSF is released (with the callosotomy) retraction will be easier). Enter the interhemispheric fissure and follow the falx deep. Open the arachnoid membrane beyond the deep edge of the falx.

The two cingulate gyri may be adherent in the midline, and can easily be mistaken for the corpus callosum **(CC)**. This error may be compounded by mistaking the calloso-marginal arteries for the pericallosal arteries. Erroneously entering the cingulate gyrus disorients the surgeon and could cause injury to the pericallosal arteries. To differentiate: the CC is a pure white structure, is usually deeper than one anticipates, and is appreciated beneath the paired pericallosal arteries. Image guided surgery or measuring the depth to the CC on the pre-op MRI may help.

Callosotomy

The callosotomy is usually performed between the two pericallosal arteries. Some arterial branches may cross the midline, occasionally it is necessary to sacrifice some. **Trajectory**: a line drawn from the coronal suture (in the midline) to the external auditory canal (the foramen of Monro lies along this line); this helps avoid the tendency to tunnel posteriorly through the CC. Either the bipolar cautery, suction and sharp knife, or the laser is used to make the callosotomy. In hydrocephalus, the callosum will be thin. Entering the lateral ventricle releases CSF which aids retraction. When the foramen of Monro is occluded (e.g. with colloid cyst), it helps to fenestrate the septum pellucidum to prevent it from bulging into the ventricle in which one is operating (otherwise, as CSF is aspirated from the ipsilateral lateral ventricle, it cannot escape from the other).

Disconnection syndrome (*see page 423*): more common with posterior callosotomy (near the splenium) where more visual information crosses. The risk is reduced by creating a callosotomy **< 2.5 cm** in length extending posteriorly from a point 1-2 cm behind the tip of the genu[57]. For an interfornicial approach, the callosotomy must be perfectly midline.

Approach to third ventricle

Usually, the callosotomy will not be exactly midline, and one of the lateral ventricles will be entered. Great care must be taken to correctly identify which lateral ventricle has been entered, another potentially disorienting pitfall. For orientation (*see Figure 7-19*), the choroid plexus passes forward in the choroidal fissure to the foramen of Monro (which is medial) where it converges with the thalamostriate vein approaching from a more lateral position in the groove

between the thalamus and caudate. The septal and caudate veins approach the foramen from anterior. With colloid cysts, the foramen of Monro may be hard to recognize initially as it will be plugged with the cyst which can resemble the ependymal lining of the ventricle, but on close inspection is usually slightly grayer (the choroid plexus enters the posterior aspect of the foramen).

Another possible pitfall upon incising the CC is entering a **cavum septum pellucidum** (*see page 1218*). The give-away here is that no landmarks will be visible.

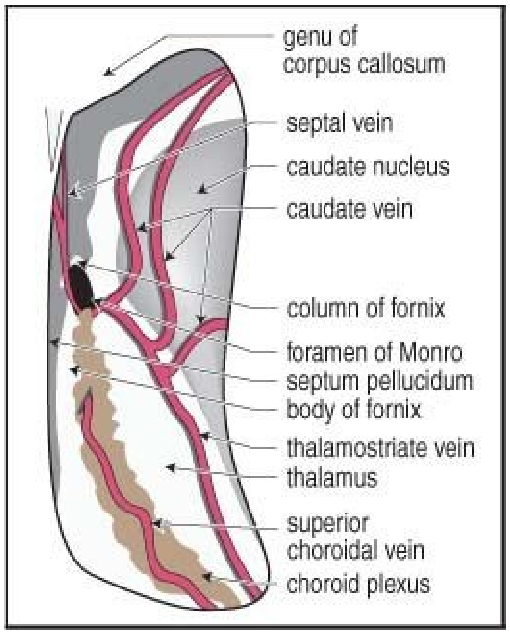

Figure 7-19 Right foramen of Monro viewed from above through right lateral ventricle (adapted[51])

Alternative approaches to third ventricle

1. interfornicial[57]: go above body of fornix, approaches roof of third ventricle. Well suited for lesions of the mid and posterior third ventricle. Callosotomy should be as close to midline as possible
2. from lateral ventricle through the foramen of Monro: with hydrocephalus, the foramen of Monro is usually dilated. If the foramen is too small for adequate access to the third ventricle, one can:
   A. return to the interfornicial approach (*see above*) or
   B. enlarge the foramen of Monro only if absolutely necessary. Either by:
      1. opening the foramen laterally
      2. the "subchoroidal" approach, making the incision posteriorly (sacrificing the thalamostriate vein) which is reportedly well

tolerated[52, 58]

3. last resort: incising the antero-superior margin of the foramen through the column of one fornix[57]. Caution: if the other fornix is non-functional for any reason, this would produce a bilateral forniceal lesion and may (but not definitely[57]) result in loss of short term memory and ability for new learning

Colloid cyst removal

It is critical to debulk and empty a cystic lesion, such as a colloid cyst, before delivering it from the third ventricle through the foramen of Monro. This will minimize the retraction and manipulation of the fornix. Inserting a needle and aspirating may work. The partially emptied cyst is grasped with a micro-pituitary and is delivered into the lateral ventricle through the foramen of Monro. One should only attempt to deliver the empty capsule through the foramen of Monro (see *General principles of tumor removal*, page 168). There is usually a stalk attaching the lesion to the roof of the third ventricle, this is coagulated with bipolar cautery and divided.

For other tumors, if the tumor is too large to fit through the foramen of Monro, it should be gutted from within.

Complications

1. venous infarction, may be due to:
   A. sacrifice of critical cortical draining veins: plan the flap to avoid this with preoperative angiography, or with sagittal T2WI MRI images[59]
   B. superior sagittal sinus **(SSS)** thrombosis[60]. Factors that may contribute to sinus injury include[56]:
      1. injury from retractor: avoid placing retractor on sinus (deformation of midline should not exceed 5 mm)
      2. over-retraction of the dural sinus flap or on SSS itself (lateral deformation should be < 2 cm)
      3. injury during the opening of the bone in the region of the sinus
      4. over-use of bipolar coagulation in the region of the SSS
      5. hypercoagulable state of the patient, including dehydration
2. transient mutism as a result of bilateral cingulate gyrus retraction or thalamic injury in conjunction with section of the midportion of the callosum[59]

TRANSCORTICAL APPROACH TO LATERAL OR THIRD VENTRICLE

INDICATIONS

In the absence of hydrocephalus, it is difficult to navigate through the ventricular system. Thus, with normal sized ventricles, the third ventricle and region of the foramen of Monro are better approached transcallosally (*see page 169*).

1. tumors of the atrium of the lateral ventricle
2. tumors of the roof of the third ventricle
3. third ventricular tumors with significant extension into one lateral ventricle

APPROACHES

1. posterior parietal
2. middle temporal gyrus: useful when temporal horn of lateral ventricle is dilated due to hydrocephalus caused by the tumor; access is through the temporal horn
3. **middle frontal gyrus approach**: a 4 cm incision is made parallel to the axis of the middle frontal gyrus, above and anterior to the expressive speech center (Broca's area) and anterior to the motor strip[52] (about the same point as used for frontal ventriculostomy, see *Kocher's point*,page 207)

7.4.13. Interhemispheric approach

INDICATIONS

For lesions abutting on midline, deep to surface, but superficial to corpus callosum (lesions that can "fall away" from midline). Similar to transcallosal approach above, except that the pathology can be placed on the down side, which allows gravity to retract the hemisphere and thus minimizes pressure necrosis injury from mechanical retractors.

TECHNIQUE

POSITION

True lateral (prevents getting lost from unusual angles). Head tilted slightly up.

Approach

Similar to transcallosal see *Position*, page 169. Need to be sure that lateral portion of craniotomy extends at least 4 cm from midline to minimize the necessity of retraction of brain against bone.

7.5. Cranioplasty

Indications

1. cosmetic restoration of external skull symmetry
2. relief of symptoms due to craniotomy defect (*see page 149*)
3. protection from trauma (blunt or penetrating) in area of post-craniotomy or post-traumatic skull defect

Timing

In certain cases, no consensus is possible. To avoid the risk of infection, authors recommend delaying cranioplasty with a “foreign body” at least 6 months after an open (i.e. contaminated) wound or one that traverses the nasal sinuses (*see page 887*). Others perform primary closure at the time of repair of the skull fracture. In “clean” cases (e.g. repair of defect after removing hemangioma of the skull) there is little argument against immediate cranioplasty.

Material

Options for material include:

1. the patients own bone if it was previously removed in a sterile fashion and saved either in a sterile manner under refrigeration, or in an abdominal pocket at the time of craniectomy
2. materials that can be formed by the surgeon
    A. methylmethacrylate: mixed in the O.R., molded to desired shape, and allowed to set before being attached to the skull usually with plates (alternatively, sutures or wire may be used). Setting is an exothermic reaction and ample irrigation and preferably removal from the operative site during the process avoids undesirable transmission of

heat to the brain

B. mesh: may be made of titanium or tantalum.

3. pre-fabricated custom flaps may be made by a number of commercial vendors using thin-cut CT scans to generate computer models of the defect and, if available, to use the contralateral side as a “mirror image” model for the desired shape

   A. methylmethacrylate

   B. PEEK (poly-ether-ether-ketone)

   C. titanium

4. split thickness calvaria

When foreign material is used, some recommend perforating the flap with a dozen or so drill holes to prevent the accumulation of fluid (either underneath the flap, or between the flap and the skull). This cannot be done with titanium plates.

7.6. Localizing levels in spine surgery

Identifying the correct level in spine surgery may be extremely challenging in certain situations. With the proliferation of minimally invasive spine techniques and the associated reduction in the structures that are directly visualized, the reliance on intraoperative imaging to determine the spinal level has increased. Gone are the days of “palpate the sacrum with your finger” through an open laminectomy wound.

Potential **pitfalls** which increase the chances of error, including:

1. pre-op, pathology is usually identified on MRI, and there are problems in translating MRI images to imaging available in the O.R.

   A. thoracic lesions: pre-op MRI usually counts from the top (C2) down, and in surgery it is often necessary to count from the bottom up, the count could be off if there are not 5 lumbar vertebra and 12 pairs of ribs

   B. lumbar spine: a well developed S1-2 disc (so-called lumbralized S1) or an L5 vertebra fused to the sacrum (sacralized L5) can confuse the count

2. not all patients have 12 ribs, or 5 “lumbar” vertebrae. In the modal (most common) human spine, there are 24 presacral vertebrae, however some

individuals have 23 and others have 25[A]. A HLD at the ultimate disc space (usually L5-S1) most often impinges on the 25th nerve root (however, in the variant cases, it may actually impinge on the 24th or 26th root)[66]

3. patients may have variant or ambiguous anatomy (e.g. a well-developed S1-2 disc space, an enlarged L1 transverse process which mimics a rib)
4. some "landmarks" used for localizing levels are unreliable or changeable
5. plain radiographs (and fluoroscopy) has difficult imaging the upper thoracic and sometimes the lower cervical spine
   A. on lateral imaging, the shoulder often obscure lower cervical/upper thoracic levels
   B. on AP imaging, the pronounced kyphosis of this region requires cranio-caudal angulation of the x-ray beam, which throws off imaging at other levels
6. spinous processes of lumbar and especially thoracic levels are below the corresponding VB
7. changes may occur between the time of the pre-op imaging and the surgery

---

A. variations include: 11 or 13 rib bearing vertebrae, or a lumbosacral transitional vertebrae; the terminology of a "lumbralized S1 vertebrae" or a "sacralized L5 vertebrae" is imprecise and confusing

---

Aids in determining spinal levels

1. image guided systems, when available
2. some O.R. suites have intra-op MRI or CT (or CT-like modalities, e.g. O-arm™ by Medtronic or ARCADIS® C-arm by Siemens) or image guided spine technology
3. ★ pre-op plain x-rays: lumbar (for lumbar pathology) and lumbar + thoracic (for thoracic pathology) to verify there are 12 thoracic vertebrae and 5 lumbar
4. on lateral lumbar spine x-rays, the top of the iliac crests are even with the L4 spinous process or the L4-5 interspinous space
5. on sagittal MRI there are generally no numbering cues, but on axial MRI, the sacral ala are reliably identifiable and this can be used to identify L5-S1 disc space
6. counting methods (if possible, using more than 1 method is highly recommended)

A. counting up from T12 or L5 on fluoro: be sure there are 12 ribs. You can "bridge" from lumbar or lower thoracic spine to higher thoracic levels using an instrument on the patient as a marker, or you can count up to one level (e.g. T9) and then while a hemostat is placed at this level on the fluoro screen, under real-time fluoro the machine is slowly moved up the spine and the hemostat is moved along with T9 (to count up from L5, verify there are 5 lumbar (i.e. non-rib bearing) presacral vertebrae). Radiation safety: avoid live fluoro as much as possible
B. AP view: starting at T12 (lowest rib) or from L5
C. lateral view: starting at the L5 and counting up
D. counting down from T1 (first rib) on AP fluoro: the fluoro machine may need to be angled caudally from the anterior position because of the thoracic kyphosis. Sometimes counting pedicles helps
E. by palpation: with thoracotomy, in the upper T-spine you can palpate the ribs from the inside from T1 and count down. The rib inserts at the upper end of the thoracic vertebra near the junction with the VB above (e.g. the T5 rib joins T5 close to the T4-5 disc space)

7.7. Anterior approaches to the spine

The following may be altered to take into account the possibility of overlap (e.g. a tumor of C7 which requires access down to at least T1 to permit stabilization).

Approaches

1. cervical spine
   A. anterior odontoid screw: *see page 181*
   B. C1-3 (upper cervical spine):
      1. transoral approach: including odontoidectomy (*see page 176*)
      2. extrapharyngeal approaches: use nasotracheal intubation (so that the mandible can be completely closed) through the contralateral nares. The head is slightly extended and is rotated 15° to the contralateral side. Avoid any oral tubes
         a. medial extrapharyngeal approach: medial to carotid sheath. Provides a more anterior position than the lateral retropharyn geal approach. Structures encountered: branches of external carotid artery, upper laryngeal nerves, hypoglossal nerve

b. lateral retropharyngeal approach: only the spinal accessory nerve is encountered

C. C3-C7: standard anterior cervical discectomy approach

2. thoracic spine
   A. T1 and below: extracavitary posterolateral approach. Bilateral costotransversectomies allows access to VB for resection of tumor, infection or fracture. Anterior cage placement can then be performed via this approach[67-71]
   B. T1-3: sternal splitting anterior approach (*see page 178*)
   C. T4-11:
      1. thoracotomy: in lateral decubitus position
         a. the patient needs to be able to tolerate deflation of the upper lung (sometimes partial deflation is adequate and is better tolerated)
         b. approach often by cardiovascular or thoracic surgeon. Left side is preferred by some (mobilizing the aorta is not difficult), others prefer right
         c. T3-4: often involves mobilizing some of the shoulder muscles which adds to complexity of exposure
         d. intubation: double-lumen tube permits unilateral lung deflation
      2. endoscopic approaches
   D. intra-op localization (determining level): especially challenging in the upper thoracic spine due to difficulty with lateral imaging through the shoulders. For pitfalls and compensatory measures *see page 173*
3. lumbar spine
   A. L1-5
      1. indications: tumor, fracture
      2. practical points
         a. aortic bifurcation located at the mid body of L3: a true anterior approach is therefore not practical. Therefore a <u>retroperitoneal approach</u> is used
         b. iliac crests may prevent a pure lateral approach to L4 and especially L5, which limits the placement of screws for the compression plate
         c. if a 360° fusion with pedicle screws is to be employed: potential problem with screws from compression plate hitting pedicle screws. There is some leeway in angulation of the pedicle screws to compensate for this
         d. complications to avoid:

i. injury to great vessels, especially the left iliac vein
ii. unnecessary sacrifice of intercoastal nerve which can cause atrophy of the abdominal muscles and eventration of the abdominal wall (not a true incisional hernia)
iii. do not enter the peritoneum
iv. injury to the kidney and ureter
v. ✖ anterior instrumentation must be avoided to prevent delayed vascular injury from repeated pulsations

3. position
   a. left sided approach is preferred (i.e. right lateral decubitus position). Exceptions where a left sided approach is used:
      i. primarily right-sided pathology
      ii. CT or MRI shows there is not enough room because of the location of the aorta
   b. level of pathology is positioned over the break in table (to get the iliac crest out of the way during initial approach - remember to unbreak table before final instrumentation!). Key: shoulders and pelvis true vertical for x-ray localization
   c. axillary roll
   d. flex the upper thigh (to relax psoas muscle) & knee
   e. stabilized with bean bag (keep patient exposed from midline anterior to posterior) and wide adhesive tape over pads at shoulder and thigh (keep iliac crest exposed for donor bone)
   f. use a fluoro compatible table, or place patient on table reversed to permit access by C-arm
4. incision[72]
   a. to access L2 and below: oblique incision starting anteroinferiorly at the edge of the rectus muscle extending cephalad and posteriorly through the bed of the 12th rib, ending posteriorly at the vertebral musculature
   b. exposure of L1: e.g. for instrumentation, requires extending the incision cephalad through the bed of the 10th rib, and may require radical takedown of the diaphragm for full exposure
5. approach[72]
   a. the 12th rib can be divided or disarticulated posteriorly, and may be used as a source of bone for fusion
   b. the kidney and ureter are retracted anteriorly, the psoas muscle is retracted laterally

c. segmental vessels are ligated or coagulated at the midportion of the VB
d. Bookwalter retractor is useful
6. surgical aspects
   a. to get the lateral compression plate true lateral, place it as "posterior" as possible (also keeps it away from the great vessels)
7. post op
   a. TLSO for 3 months
   b. increase activity slowly in brace
   c. some bulging of the flank muscles is normally associated with this approach

---

7.7.1. Transoral approach to anterior craniocervical junction

Primarily useful for midline extradural lesions (approach to intradural lesions has been described[73], but the use has been extremely limited because of difficulties obtaining watertight closure and increased risk of meningitis). Refinements in techniques and equipment (e.g. flexible reinforced oral endotracheal tube, McGarver or Crockard retractor, operating microscope, and suturing transnasal red-rubber catheters to the uvula to aid in retraction) allows access from as high as the inferior third of the clivus to as low as C3 (and sometimes C4[74]) vertebral body without need for tracheostomy or splitting of the tongue. Additional access can be achieved with use of extended techniques including splitting of the hard & soft palate, tongue splitting, and transmandibular approach.

TRANSORAL ODONTOIDECTOMY

75% of patients undergoing transoral removal of the odontoid process required posterior fusion afterwards[75] due to ligamentous instability[76, 77].

Indications

Anterior extradural compression of the cervicomedullary junction as with pannus from rheumatoid arthritis, irreducible basilar invagination, tumors of C2, infection.

Stabilization

Most patients require surgical stabilization as a result of transoral odontoidectomy. While the stabilization intuitively seems like it should be done first, it is often done following the decompression at the same sitting or at a soon to follow date. Some reasons for decompressing before stabilization:

1. positioning the patient for fusion may cause neurologic compromise if there is cord compression
2. one can do a post-odontoidectomy MRI to determine if there is enough decompression. If not, a laminectomy can be done at the same time as the posterior stabilization
3. the amount of destabilization may not be known until after the odontoidectomy - in some cases a C1-2 fusion may suffice

Stabilization usually entails posterior occipitocervical fusion. Occasionally fusion may be limited to C1-2 or C1-3 without the occiput. It is also possible to place an anterior strut between the body of C2 and the clivus, or between C2 and C1. Fibula is recommended. Metal instrumentation should be avoided.

Pre-op preparation

1. make sure that the patient can open the mouth at least 25 mm. If not, then other approaches such as translabiomandibular should be considered
2. for conditions resulting in malalignment or basilar invagination, cervical traction for 1 or more days is sometimes required
3. radiographic evaluation
   A. cervical MRI without and with contrast to define the soft tissue pathology
   B. CT of the craniocervical junction with sagittal and coronal reconstruction
   C. CTA to assess the position and involvement of the vertebral arteries. Measuring the distance between the VAs provides useful information

Booking the case - transoral approach

Also see defaults & disclaimers (*page v*).

1. position: supine with pin headholder
2. equipment

   A. microscope
   B. high-speed drill with long bits
   C. C-arm
   D. image guided navigation system (if used)
3. instruments
   A. transoral set (usually includes oral retractor such as Crockard, Dingman, Dickman-Sonntag…)
   B. long instruments: microdiscectomy instruments often work
4. anesthesia: awake, fiberoptic endotracheal intubation
5. some surgeons use ENT to perform the approach and closure and for follow-up
6. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: transoral resection of odontoid, placement of halo-vest immobilization, MEP monitoring (MEP should be consented specifically due to risk of seizures). Need for posterior stabilization at the same setting or in the immediate future
   B. alternatives: nonsurgical management, radiation therapy for some diagnoses
   C. complications: CSF leak with possible meningitis, spinal cord injury, wound breakdown, swallowing difficulties (may require PEG tube), breathing problems (may require tracheostomy), seizures with MEP

Technical considerations

The surgical procedure is beyond the scope of this book. For details, see references[74, 75, 78]. Some key points:

Awake fiberoptic orotracheal intubation is employed. Nasotracheal **(NT)** is used by some, but at the narrow upper part of the exposure the NT tube tends to get in the way.

SSEP and MEP monitoring is used in appropriate cases.

Positioning: 3-point fixation with a Mayfield headholder is typically used. The patient is supine with no neck rotation (distorts the anatomical relationships and may bring one VA closer to the midline). Tilt the whole patient or the table towards the surgeon. 10-15° neck extension improves the exposure. Alternatively, the surgeon can stand above the patient who is kept perfectly supine.

A specialized retractor (e.g. Crockard transoral retractor) or a conventional Dingman retractor is placed. Check that the tongue is not being compressed

against the teeth.

Landmark: the tubercle of the atlas can be palpated through the posterior pharynx to locate the midline and for craniocaudal orientation.

The mucosa of the posterior pharynx is infiltrated with 1% lidocaine with epinephrine. Some authors culture the oropharynx to obtain drug sensitivities of organisms for use in the event of infection. Some advocate liberal topical use of 1% hydrocortisone ointment to the mucosa of the oropharynx and posterior tongue at the beginning and also during the operation to reduce intra-op and post-op swelling. Others feel it has no effect, and IV Decadron is used by some.

A 3 cm long vertical midline incision is made.

To reduce the risk of C1 spreading and allowing basilar invagination, C1 ring-sparing surgery may be attempted by removing only the inferior half to two-thirds of the anterior C1. When C1 ring-sparing is not done, the central 3 cm of the atlas is removed with a high-speed drill.

There is ≈ about 20-25 mm working distance between the two vertebral arteries at their point of closest approximation where they enter the foramen transversarium at the inferior aspect of the lateral mass of C2.

Closure: a two layer closure is preferred by some. Others recommend a single layer closure incorporating deep muscle, superficial muscle, and mucosa[74]. If the dura has been violated, a fascial patch is secured with tissue adhesive and a lumbar subarachnoid drain is placed in the O.R. and maintained at low pressure for 3-4 days. An NG tube is placed under direct visualization to avoid injury or penetration of the mucosal closure.

Possible complications

1. dural tear with CSF leak and risk of meningitis
2. vertebral artery injury
3. spinal cord injury

Post-op care

1. NG feeding or IV hyperalimentation is used initially (in anticipation of oropharyngeal swelling (lasts 2-3 days) and to avoid disruption of the mucosal closure)
2. intubation is maintained until the swelling subsides. Initial removal of the endotracheal tube over a tube changer facilitates reintubation if needed; the tube changer can be removed if no problem develops after 1 hour[78]
3. if the NG tube comes out, it should only be replaced under direct vision

(usually be ENT physician) to avoid injury/penetration of the mucosal incision
4. halo-vest immobilization is maintained until the posterior fusion is performed
5. for staged procedures when the fusion is being done at a later date, a post-op MRI should be done to assess the degree of decompression. If further decompression is needed, then a laminectomy can be added to the posterior fusion

Posterior stabilization

Transoral odontoidectomy produces instability in most cases (sometimes delayed)[76, 77].

For basilar invagination or occipitocervical instability, an occipitocervical fusion is recommended[78] (*see page 179*).

For C1-2 instability alone, a posterior C1-2 arthrodesis may be performed[78] (*see page 183*).

7.7.2. Anterior access to the cervico-thoracic junction/upper thoracic spine

Sternal splitting procedure

Permits access down to T3 (occasionally as far as T5) from an anterior midline approach (access to this region with a lateral (transthoracic) approach is poor due to small amount of room in pulmonary apices).

The neck and thorax are prepped down to the umbilicus. A hockey stick incision may be used, the horizontal portion is the usual for an ACF. The vertical limb is centered over the sternum. A CV surgeon splits the sternum and divides the sternocleidomastoid. This approach does not violate the pericardium or pleura, and a chest tube is not required (but is often used as a large bore drain to prevent hemomediastinum, and also as a precaution in case the parietal pleura is cut during the exposure). Because of the depth of the approach, longer instruments than the routine 7 inch length instruments used for an ACDF are required.

The exposed sternal edges may also be used to obtain cancellous bone for the graft.

7.7.3. Anterior access to mid & lower thoracic spine

Transthoracic approach

Position the patient on the O.R. on a bean-bag table with the break in the table under the level of pathology (remember to unbreak the table prior to instrumenting). Stabilize the patient using adhesive tape over surgical towels. An axillary roll is placed. A double-lumen endotracheal tube is used to permit dropping the lung on the side of the thoracotomy. If the patient does not tolerate completely deflating one lung, it is often adequate to just partially deflate the lung.

To increase the exposure, a rib may be resected. Generally, the level opened and the rib removed are one or two levels above the level of pathology (e.g. for T7 VB tumor, the T6 or T5 rib are removed).

If a compression plate is going to be used, the goal is to be lateral on the VB, to achieve this try to position it as far posterior as possible (rongeur off a little bit of the rib heads to facilitate this).

ANTERIOR ACCESS TO MID THORACIC SPINE

Laterality of approach: if the pathology does not dictate use of one side over another:

1. advantages of right-sided thoracotomy: the heart, mediastinum and brachiocephalic vein do not impede access
2. advantages of left-sided thoracotomy: aorta is easier to mobilize and retract

Determining the level in the upper T-spine can be quite difficult intraoperatively. Counting up from the sacrum on an AP view using live fluoro sometimes will work when lateral spine x-rays cannot penetrate the lower c-spine due to the shoulders.

ANTERIOR ACCESS TO LOWER THORACIC SPINE

Unless pathology is predominantly right-sided, a left-sided thoracotomy is preferred (easier to mobilize aorta than vena cava).

At about T10 and below, the attachment of the diaphragm increases the difficulty of the approach.

7.7.4. Anterior access to thoracolumbar junction

Retroperitoneal approach

Unless pathology is predominantly left-sided, a right-sided retroperitoneal approach is preferred (eliminates liver from impeding access).

7.7.5. Anterior access to the lumbar spine

Trans-abdominal approach

Through a Pfannenstiel's incision.

The location of the bifurcation of the inferior vena cava generally ranges from just above to just below the L4-5 disc space. When the bifurcation is at or below the disc space, procedures such as L4-5 ALIF van be very difficult if the veins cannot be mobilized off the vertebrae.

At L5-S1, the anterior sacral artery runs down the middle and has to be sacrificed to do an ALIF.

7.8. Surgical fusion of the cervical spine

Posterior cervical rigid fixation (lateral mass screws & rods, transarticular screws…) have largely supplanted non-rigid methods (wires/cables).

7.8.1. Occipitocervical fusion

The patient will lose about 30% of neck flexion mobility with this fusion.

Indications for occipitocervical fusion[79]:

1. traumatic occipitoatlantal dislocation
2. absence of a complete arch of C1
   A. congenital
   B. post-decompression[A]
   C. posttraumatic: "bursting" C1 fracture (bilateral or multiple C1 ring fractures)[A]. NB: some feel that this may be satisfactorily treated with

halo immobilization until the atlas fracture heals (as they almost all do) followed by C1 to C2 wiring/fusion[80]

3. congenital anomalies of the occipitocervical joints
4. upward migration of the odontoid into the foramen magnum
5. marked irreducible shifts of C1 or C2

A. alternatively, C1-2 lateral mass fusion (with or without lateral mass screws, *see page 184*) may be used in these cases if only the posterior arch of C1 is compromised

Disadvantages of occipitocervical fusion:

1. loss of movement at the occipitoatlantal junction further reduces the range of motion as follows[81]:
   A. flexion/extension: reduced by ≈ **30%** (13° occurs at occiput-C1 junction)
   B. lateral rotation: 10° is lost
   C. lateral bending: 8° is lost
2. non-union rate is higher than with C1-2 fusion alone[82]

Options

1. keel plate (placed centrally over the thickest portion of the occipital bone) connected via rods to cervical screws (C2 pedicle screws and C3 lateral mass screws): reduced range of motion (ROM) to 17% of normal in a cadaver study[83] (for technique, *see below*)
2. occipital condyle **(OC)**-C1 polyaxial screws[84]: *see below*
3. occipital-C1 (AKA atlantooccipital) transarticular screws (*see below*)
4. looped rod wired to the occiput via wire cables placed through holes drilled in the occiput. Reduced ROM only to 31% of normal[83]

KEEL PLATE OCCIPITAL-CERVICAL FUSION

Pre-op planning:

1. CT scan through C2
   A. to rule-out aberrant position of foramen transversarium
   B. to measure diameter of pedicles (may be best done on coronal sections due to the fact that the axial images are not usually oriented along path

of pedicle) and estimate length of screws to be used

C. to verify trajectory of screws

2. measure thickness of occipital bone to determine screw-length for occipital screws

Technique:

1. occipital keel screws/plate
   A. a drill, tap and screwdriver with flexible shafts or universal joints are usually needed because of interference from patient's skin
   B. midline holes are preferred since occipital bone is thickest here
   C. drill with drill guide to 8 mm, check depth with probe, if the inner cortex has not been breached, drill to 10 mm, check depth again, keep drilling 2 mm at a time until the inner cortex is breached, use that screw length
   D. SCREWS 4.5 diameter <u>blunt</u> screws, 8-12 mm length
2. C2 pedicle screws: see *C2 screws*, page 187
3. C3 lateral mass screws (if used): see *C3-6 fixation*, page 188

OCCIPITAL CONDYLE TO C1 POLYAXIAL SCREW FUSION[84, 85]

Utilizes polyaxial screws placed in the occipital condyles that are then connected to screws placed at lower levels (*see below*) via connecting rods.

1. PROS compared to occipital plate/keel instrumentation:
   A. circumvents problem of poor occipital bone purchase which may occur with keel plates
   B. can be used even following posterior fossa craniectomy
   C. greater surface area for fusion
   D. avoids risk of intracranial injury from occipital screws
2. CONS: due to condylar variability, not all patients are candidates
3. biomechanics: compared to occipital plate, similar stiffness in flexion-extension and axial rotation, increased stiffness to lateral bending[86]
4. clinical: 1 patient, 2 years F/U with solid OC fusion[87]

Pre-op planning: CT scan occiput through C2.

Technique:

Structures to avoid include: hypoglossal nerve in hypoglossal canal (just above the occipital condyles **(OC)**), carotid and vertebral arteries, jugular bulb. IG may be helpful

1. occipital condyle screws
    A. ENTRY 4-5 mm lateral to the foramen magnum, 1-2 mm rostral to the atlanto-occipital joint (do not need to or want to expose the entire condyle - there is an emissary vein laterally which is best left alone)
    B. TRAJ 12-22° medial (mean: 17°), 5° maximal superior angulation
    C. SCREWS 3.5 mm diameter polyaxial screws; bicortical purchase obtained using 20-24 mm length (mean: 22 mm)
2. condyle screws are connected with 3mm diameter rods to either:
    A. screws in C1 lateral mass and C2 pedicles (*see page 187*), or
    B. C1-2 transarticular screws (*see page 184*)

Occipital-C1 (AKA atlantooccipital) transarticular screws[88, 89]

Reduced ROM to 3% of normal[83]

1. PROS: no compromise of C1-2 joint
2. CONS: steep trajectory requires additional incision at level of C-T junction
3. ENTRY midpoint of posterior C1 lateral mass
4. TRAJ 10-20° medially, aiming cranially to TARGET middle of occipital condyle
5. SCREWS 28-32 mm cannulated lag screws
6. biomechanics: ≈ equal to occipital plate-C1 lateral mass fusion[90]
7. clinical data: 2 cases reported, 2 year F/U, co complication

Post-op

1. for severe C1 fractures, or those with impaired bone healing capacity (elderly or unreliable patients, smokers…) a halo-vest is recommended **x** 8-12 weeks
2. otherwise, if C1 is not badly damaged, a collar that limits flexion (e.g. Miami-J collar) suffices **x** 8-12 weeks

7.8.2. Anterior odontoid screw fixation

Introduction

50% of axial rotation of the head occurs at the C1-C2 complex. Treatment of

odontoid fractures by C1-2 fusion significantly reduces this mobility (although subaxial articulations will compensate to some degree over time). Odontoid screw fixation **(OSF)** attempts to treat odontoid fractures by restoring the structural integrity of the odontoid process (osteosynthesis) without sacrificing the normal mobility.

Stability of the C1-2 joint depends primarily on the integrity of the odontoid process and the atlantal transverse ligament (which is the most important structure holding the odontoid process in position against the anterior arch of C1 - *see page 92*).

Evaluation

A full set of C-spine x-rays is needed, including an open-mouth odontoid view. MRI is recommended to rule-out disruption of atlantal transverse ligament. Cervical axial CT with coronal and sagittal reconstructions are also recommended to demonstrate the orientation of the fracture path and to verify the integrity of the posterior elements.

Indications

Reducible odontoid Type II fracture (and Type III fractures where the fracture line is in the cephalad portion of the body of C2 in an elderly patient who may not fuse as well with immobilization as a younger patient[91]). The transverse ligament must be intact.

Contraindications

1. fractures of the C2 vertebral body (except cephalad Type III fracture)
2. disruption of atlantal transverse ligament: see *Transverse atlantal ligament i (TAL) injuries*, page 957. May be directly demonstrated on MRI. Indirect evidence: if the sum of the overhang of the lateral masses of C1 on C2 exceeds 7 mm (rule of Spence, *see page 957*)
3. large odontoid fracture gap
4. irreducible fracture
5. age of fracture: controversial. Fusion rates in fracture > 18 months old was 25%[92]. Fracture < 6 months old have ≈ 90% fusion rate[92]
6. patients with short, thick necks and/or barrel chest: makes it difficult to achieve the proper angle. May be circumvented by the instrumentation distributed by Richard-Nephew which utilize a cannulated flexible drill,

tap and screwdriver
7. pathologic odontoid fracture
8. fracture line in oblique orientation to frontal plane (shearing forces can cause malalignment during screw tightening)

Booking the case - odontoid screw fixation

See defaults & disclaimers (*page v*).

1. position: supine head on horseshoe headrest, halter traction
2. anesthesia: awake fiberoptic or nasotracheal intubation. Do NOT use a wire reinforced endotracheal tube
3. equipment: **2** C-arms for biplane fluoro, or O-arm image guidance
4. instrumentation:
   A. ACDF surgical set
   B. tube retractor (e.g. METRx® by Medtronic)
   C. some surgeons use specialized instrumentation (e.g. Apfelbaum set)
5. implants: cannulated screw set
6. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery to place screw(s) from the front of the neck across the fractured odontoid bone. Possible posterior approach in case the anterior approach cannot be completed
   B. alternatives: nonsurgical management in a collar, fusion
   C. complications: screw breakage/pullout, failure to fuse which might require addition surgery (which will reduce neck motion)

Technique summary

Various instrumentation systems have been developed to facilitate the procedure. The following describes some of the basic elements that are not specific to any one instrumentation (see reference by Apfelbaum[93] for details of his instrumentation distributed by Aesculap Instrument Corporation, South San Francisco, CA).

Two C-arm fluoroscopy machines are mandatory for biplane imaging (simultaneous AP and lateral views). Some surgeons prefer placing 2 screws if there is enough bone to accommodate them, however, this may also reduce the amount of bone surface that can heal and the fusion rate appears to be the

same[94].

Anesthetic considerations: The anesthesiologist is positioned at the foot of the table. Awake fiberoptic or nasotracheal intubation is recommended, especially for easily dislocatable fractures. Do NOT use a wire reinforced endotracheal tube since the wire interferes with the AP imaging.

Position: Supine. The neck is placed in extension (critical to performing the procedure) either with Holter traction and a small shoulder roll with the head on a doughnut (a strip of tape across the forehead stabilizes the head), or a radiolucent head holder may be used. Place the lateral fluoro unit first, then the AP unit slides into the "C" of the lateral unit. Lateral fluoroscopy is used to assess reduction of the fracture fragment, and the head is repositioned to try and achieve reduction. If there is retrolisthesis of the odontoid, the neck may need to be slightly less extended. A radiolucent mouth gag is placed to hold the mouth open for AP transoral imaging (a gauze roll works well). Abort the procedure if AP and lateral fluoroscopic views do not adequately image the odontoid.

Approach: A Cloward-type of horizontal skin incision at ≈ C5-6 (the entry site can be verified by placing a guidewire adjacent to the patients neck and taking a lateral fluoro) and approach identical to anterior cervical discectomy is used (all the way to exposing the longus coli muscles - *see page 463*). A Kittner is used to dissect superiorly anterior to the longus coli muscles in the loose areolar tissue up to C2. A self-retaining retractor (e.g. Caspar retractor - not *distractor*) with a superior retractor blade is attached (or a hand-held retractor, preferably radiolucent, may be used). Alternatively, a retractor tube system[95] (e.g. METRx® by Medtronic) may be used. The bovie is used to remove the soft tissue over the inferior front of C2.

Procedure: Localization: lateral fluoro is used to place the tip of an awl as far anteriorly as possible on the inferior endplate of C2 (*see Figure 7-20*) (a common error is to go too far back along the inferior margin of C2, then the guidewire end up towards the back of the dens). AP fluoro is used place the awl in the exact center of the C2 body in the lateral dimension. The awl is used to make a pilot hole at this location.

Guidewire placement, drilling, tapping and ultimately screw placement are performed while monitoring the progress on frequent fluoro images, aiming for the exact middle of the dens on AP fluoro, and aiming towards the apex of the odontoid fracture fragment (skimming just within the anterior part of the C2 vertebral body) on lateral fluoro.

Drilling is performed under fluoro all the way through the apical cortex of the dens to avoid cracking the dens with the screw (the area just distal to the apex of the dens is safe).

A titanium partially threaded (lag) screw is placed. If an appropriately sized lag screw is not available, one can overdrill the part of the path through the body of C2 up to the fracture. In this way, a fully threaded screws can be used which will slip through the overdrilled hole and still have a lag effect on the fracture fragment. If a second screw is used, it may be fully threaded. In chronic nonunion cases, prior to advancing the screw a bifaced curette may be inserted within the fracture space to freshen the fracture site. The screw(s) should be drawn up tightly to the inferior edge of C2. *Figure 7-20* shows the final position of an anterior odontoid screw.

At the end of the procedure confirm integrity of the transverse ligament by carefully flexing the neck under lateral fluoro.

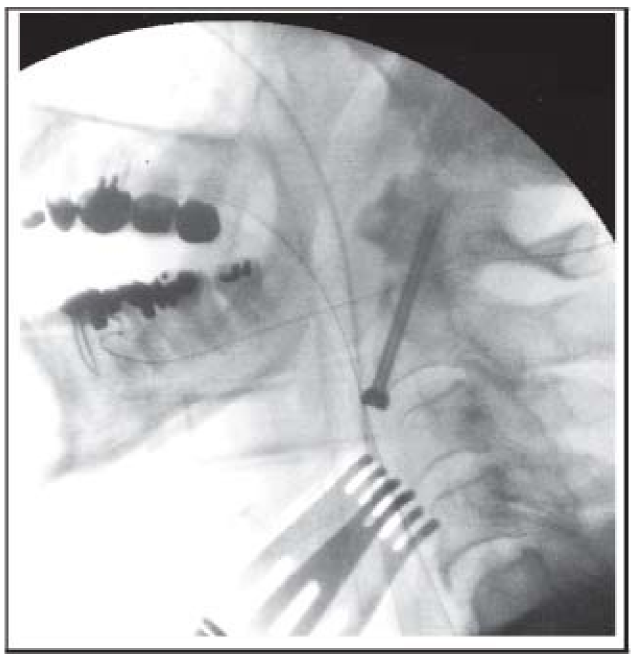

Figure 7-20 Final position of anterior odontoid screw

Postoperative immobilization: The immediate post-op strength of the odontoid + screw is only ≈ 50% of the normal odontoid. Therefore, a cervical brace is recommended for 6 weeks[91] (although some authors don't use one[93]). If the patient has significant osteoporosis, a halo brace is recommended.

Results: Healing takes ≈ 3 months (or longer with chronic nonunion). With fractures < 6 months old, the union rate was 95%. Chronic nonunions > 6

months old have a significant risk of hardware failure (screw breakage or pull-out), with a bony union rate of 31%, and 38% rate of presumed fibrous union[93]. Thus, in cases of chronic nonunion > 6 months old, C1-2 arthrodesis is probably a better choice unless the need to maintain motion is worth the risk of needing a second operation if this one fails.

The average technical complication rate is ≈ 6% (2% screw malposition, 1.5% screw breakout).

7.8.3. Atlantoaxial fusion (C1-2 arthrodesis)

The patient will lose about 50% of rotation of the head on the neck with this fusion.

INDICATIONS

1. instability of the C1-2 joints, including:
   A. atlantoaxial dislocation due to incompetence of the transverse atlantal ligament **(TAL)**:
      1. rheumatoid arthritis: symptomatic patients, or asymptomatic patients with subluxation ≥ 8 mm (*see page 496*)
      2. local infection
      3. trauma
      4. Down syndrome: due to laxity of the TAL (*see page 498*)
   B. incompetence of the odontoid process
      1. odontoid fractures meeting surgical criteria (*see page 964*), including
         a. Type II fractures with > 6 mm displacement
         b. instability at the fracture site in halo-vest traction
         c. chronic nonunion of odontoid fractures
         d. disruption of the transverse ligament
      2. following transoral odontoidectomy
      3. tumors destroying the odontoid process
2. vertebrobasilar insufficiency with head turning (bow hunter's sign): *see page 1159*

TECHNICAL CONSIDERATIONS

Come cases require incorporation of the occiput in addition to C1-2.

Surgical options include:

1. rigid instrumentation:
   A. C1-C2 fusion using polyaxial screws connected by rods:
      1. C1: screws placed in lateral masses. May be used in cases where the posterior arch of C1 is compromised
      2. C2 screw options:
         a. screws may be placed in pedicles (pars)
         b. screws may be placed in lateral masses
         c. crossed C2 laminar screws[96]
   B. C1-2 posterior transarticular facet screws **(TAS)**[97-99]
2. posterior cervical wiring and fusion: with the development of rigid fixation, these techniques have fallen by the wayside. While they are poor in limiting rotation, they are effective in limiting However, since the Dickman & Sonntag technique is effective in limiting extension, it has recently been used to offload C1 lateral mass screws which have a tendency to break at the point of entry to the bone
   A. interspinous fusion technique of Dickman and Sonntag: *see page 187*
   B. not presented here:
      1. Brooks fusion[100] (the Smith-Robinson technique as modified by Griswold[101]): C1 to C2 sublaminar wires with 2 wedge bone grafts
      2. Gallie fusion[40 (p 1477-93)] and its modifications: midline wire under the arch of C1 with an “H” bone graft
3. Halifax clamps with fusion[102]: these clamps are effective in minimizing movement in flexion, but are less stable in extension or with rotation
4. odontoid compression screw fixation: essentially only for odontoid Type II fractures < 6 months old with intact transverse ligament[103] (*see page 181*). Preserves more mobility than C1-2 fusion
5. combined anterolateral and posterior bone grafting[103]
6. combining anterior (transoral) decompression with posterior fusion: indicated when a significant anterior mass is present causing neural compression and/or making passage of sublaminar wires at C1 unsafe

7.8.3.1. Techniques of atlantoaxial fusion

Positioning

Patients are placed in a halo ring (with a gap in the back) and are then placed prone on the O.R. table on chest rolls. The halo ring is secured to the table using

a Mayfield adapter. The table will usually need to be positioned in a maximal reverse-Trendelenburg position to bring up the surgical area. The patient's feet are allowed to rest on a padded footplate on the table to prevent the patient from sliding down. Lateral intraoperative x-rays are taken after patient positioning.

Incision and approach

A midline skin incision is made from just below the inion to the spinous process of C5 or C6.

C1-2 TRANSARTICULAR FACET SCREWS (TAS)

May be used as an adjunct to posterior C1-2 wiring and bone graft (e.g. technique of Dickman and Sonntag, *see page 187*) to achieve immediate stabilization without the need for postoperative external orthosis, or in cases where the posterior arch of C1 is fractured or absent. ✖ A major risk of the procedure is vertebral artery **(VA)** injury. Therefore there is a growing interest in C1 lateral mass screws (*see page 185*).

Selection of candidates

May be appropriate in elderly patients or those with rheumatoid arthritis, in whom there may be slow fusion, or for those who have failed a previous attempt at C1-2 wiring/fusion. Also in young individuals who have ligamentous laxity.

All patients must have thin cut CT scans from the occipital condyles through C3 with sagittal reconstruction through the C1-2 facet on both sides to look for the presence of a vertebral artery in the intended path of the screw. Also, risk of VA injury can be reduced using CT scans reconstructed along the planned trajectory of the screw (aiming from a point 4 mm above the inferior C2 facet to a point in the anterior C1 button on CT[104]).

Technique summary

A number of instrumentation sets are available for the procedure, and each has its own nuances. The following is intended to primarily cover the basic procedure common to most or all (see reference by Apfelbaum[93] for details with that system).

Position:

Patient supine, with the head clamped in a Mayfield head-holder with a

slight military tuck of the chin. Lateral C-arm fluoroscopy is used for the procedure, and some have advocated biplane fluoro.

Approach:

Utilize a standard midline posterior laminectomy approach from occiput to the C3 spinous process. The lamina of C2 and the posterior arch of C1 are exposed to the lateral aspect of the C2 inferior articular facet. The lateral extent of the spinal canal is defined using a small angled curette. The C1-2 facet is curetted to facilitate arthrodesis and permits observation of the drill as it crosses the joint.

ENTRY 1-2 mm superior to the C2-3 facet on the midline axis of the pars interarticularis. The trajectory is determined fluoroscopically using a K-wire placed on the side of the neck as a guide, aiming it through the C2 inferior articular process, pars interarticularis, superior articular process and across the C1-2 articulation into the lateral mass of C1. This helps establish the appropriate entry site for the drill guide through a separate stab wound, usually around the T1-2 level, 2-3 cm off the midline.

TRAJ A pilot hole is then drilled using visual guidance to maintain a straight parasagittal course (it helps to stand on 1 or 2 footstools to eliminate some of the parallax error) and fluoroscopic guidance to maintain the trajectory towards the C1 lateral mass. An assistant can reduce any atlanto-axial translational malalignment using a towel clip on C1 or C2 just prior to the drill crossing the C1-2 facet joint. To minimize the risk of VA injury, keep the drill as far dorsally as possible within the pars interarticularis. The pilot hole is then tapped and a fully threaded titanium screw is placed. If brisk arterial bleeding (not bone bleeding) occurs after drilling or tapping the first side, the VA may have been injured. The screw may still be placed but the contralateral hole and screw should not be placed. A post-op arteriogram is then performed to assess for propagating thrombus or dissection. Barring any contraindications, the procedure is repeated on the contralateral side. After screw placement, then posterior bone fusion (e.g. technique of Dickman and Sonntag, *see page 187*) is performed. External immobilization is usually not employed post-op (the screws are considered to supply adequate *internal* immobilization).

Results

A fusion rate of up to 99% with no complications has been reported[97]. Injury to the vertebral artery is the main potential complication.

C1-2 LATERAL MASS SCREWS

Placement of polyaxial mini screws in C1 lateral mass and C2 pedicle with rod fixation. Originated by Goel and Laheri[105] in 1994 and promulgated in 2001 by Harms and Melcher[106].

Advantages over C1-2 transarticular screws (*see above*):

1. the more superior and medial trajectory should reduce the risk of VA injury[106]
2. may be used in the presence of C1-2 subluxation
3. may be usable in certain cases of aberrant VA course
4. in selected cases, this can be used for temporary fixation without fusion (since joint spaces remain intact) and the hardware may be removed after an appropriate time to reclaim motion in the C1-2 articulation

Booking the case - C1-2 lateral mass fusion

Also see defaults & disclaimers (*page v*) and pre-op assessment (*see below*).

1. position: prone, pin headholder
2. anesthesia: awake fiberoptic or nasotracheal intubation
3. equipment: C-arm or O-arm image guidance
4. implants:
   A. mini-polyaxial screws (smooth shank screws needed for C1)
   B. cable required for interspinous graft (optional, but recommended)
5. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery to place screws & rods from the back of the neck to stabilize, and usually to fuse the top 2 bones of the neck
   B. alternatives: nonsurgical management in a collar, in some cases screws may be temporary and no fusion would be done
   C. complications: screw breakage/pullout, failure to fuse which might require addition surgery, loss of some neck bending motion is expected (≈ 20% is typical)

Surgical technique (excerpted highlights[106, 107])

NB: if fusion is to accompany screw placement (i.e. permanent screw placement), strong consideration should be given to supplemental interspinous

fusion (if not contraindicated) (*see page 187*) to prevent fatigue breakage of C1 screws.

Applied anatomy: there is no true neural foramen at C1-2, the C2 nerve root lies on the posterior surface of the capsule of the C1-2 articular joint.

Pre-op assessment: It is mandatory to know the position of the VA on both sides (and in particular, the location of both foramina transversarium of C1), and the following bony information (requires thin-cut CT scan):

1. cranio-caudal thickness (height) of the posterior arch of C1 (in case the arch needs to be drilled to facilitate screw placement)
2. to determine screw length: distance from the planned entry point (*see below*) to the planned exit target (midposition of the anterior part of the superior C1 VB)
3. to estimate medio-lateral angle for screws

Approach: Completely expose the C1–C2 complex. Dissect over the superior surface of the C2 pars interarticularis to expose the C1–C2 joint to accurately locate the entry point for the C1 lateral mass screws. Bleeding is controlled with bipolar cautery and/or Gelfoam soaked in thrombin. Complete exposure of the posterior face of the inferior C1 facet also disconnects the C2 root from the underlying attachments and facilitates it's inferior mobilization.

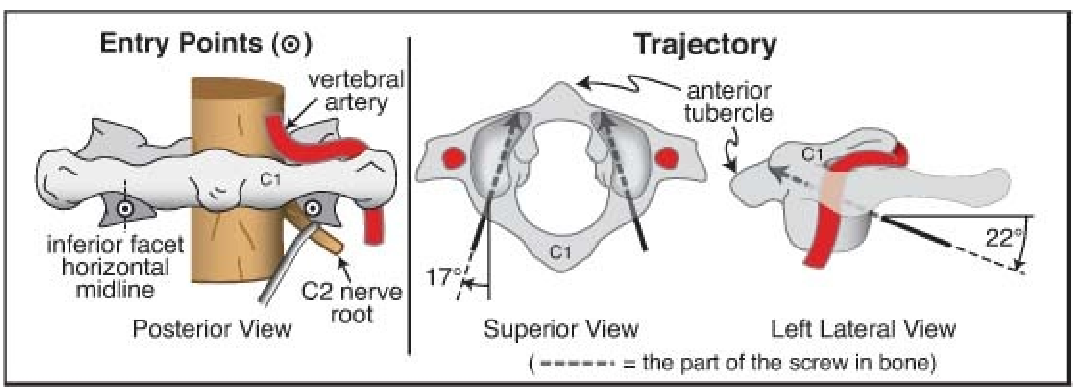

Figure 7-21 Screw entry point and trajectory for C1 lateral mass screws

1. **C1 lateral mass screws** ENTRY visualization commonly requires caudal retraction of the C2 dorsal root ganglion (occasionally this may not be feasible[107]; sacrificing the C2 root may be required but this can lead to post op pain and numbness[108]; technique is to divide the preganglionic nerve fibers and to close the dural defect[107]). The screw entry point is the midpoint of the inferior part of the C1 lateral mass (for both mediolateral

and cranio-caudal directions). An awl or a 1- to 2-mm high-speed drill is used to mark the position to prevent slippage while drilling the hole. Drilling a portion of the inferior arch of C1 is sometimes needed to allow screw placement (caution: the thickness of the arch in the cranio-caudal dimension varies widely, and the horizontal segment of the VA lies immediately above - use pre-op CT for planning)

2. **C1 screw** TRAJ averages ≈ 17° medially, ≈ 22° rostrally, TARGET the superior aspect of the anterior tubercle of C1 on lateral fluoro (*see Figure 7-21*)
3. **C1** SCREWS 3.5 or 4 mm diameter, length is determined from pre-op fine-cut CT to obtain bicortical purchase (✖ CAUTION: the ICA may be as close as 1 mm to the ideal exit site of the screw[109] ∴ some authors use only unicortical purchase). The screw needs to be proud to bring it up to the level of the C2 screw (it may actually be necessary to have the C1 screw protruding 1-2 mm more than the C2 screw in order to allow rod attachment[107]), and it should have an ≈ 8 mm un-threaded superficial portion to minimize irritation of the C2 nerve which could produce occipital neuralgia
4. C2 pedicle (pars) screws: placed as described on *page 187*
5. if a fusion is to be performed: the posterior arch of C1 and the C2 lamina are decorticated with a drill. Onlay fusion substrate is then placed, taking care not to compress the dura. Optional adjunct: intraarticular decortication and packing bone within the C1-2 joint

Post-op care

A cervical collar (soft or rigid, as preferred) for 4-6 weeks suffices.

INTERSPINOUS FUSION TECHNIQUE OF DICKMAN AND SONNTAG

A single bicortical graft is used, with multi-stranded cable passed sublaminar to C1 only. The bone graft is wedged between C1 and C2 (trapping it between loops of cable)[110, 111] (*see Figure 7-22*). Currently, this technique is infrequently used as the primary fixation for C1-2 fusion (unless technical difficulties prevent e.g. C1-2 lateral mass fusion). However, it may be most useful for limiting extension to offload C1 lateral mass screws to reduce the risk of screw breakage[112].

Cannot be used if the posterior ring of C1 or C2 is fractured.

Bone graft

Autologous bone is preferred. Bone is often taken from the posterior iliac crest (*see page 200*). A tricortical graft of ≈ 4 cm length and > 1 cm height is obtained. The top edged is removed to create a bicortical graft of ≈ 1 cm height.

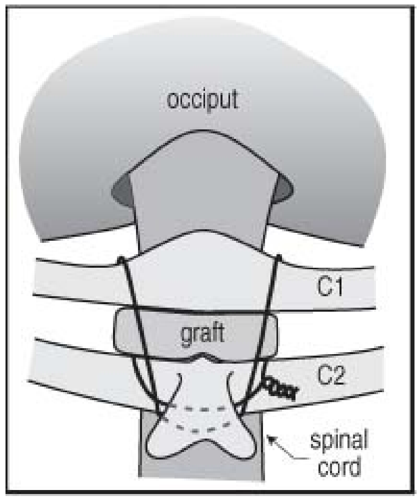

Figure 7-22 Dickman & Sonntag C1-2 interspinous fusion

7.8.4. C2 screws

Options:

1. pedicle screws (pars interarticularis screws): directed medially (*see below*)
2. lateral mass screws: directed laterally. Length is sized to fall short of foramen transversarium
3. C1-2 transarticular screws (*see page 184*): associated with more risk of VA injury
4. translaminar screws[113, 114]: 1 year stability appears to be less than C2 pedicle screws when used for subaxial fusions, but was ≈ as effective for axial fusions (C1-2 or C1-3)[115]. May be useful as a "bailout" for subaxial fusions when the C2 pars diameter is too small for pedicle screws[116]

C2 pedicle (pars) screws: Check CT scan or MRI to rule-out aberrant location of vertebral artery or unusual location of foramen transversarium before placing C2 pedicle screws. Some find image guided navigation systems to be helpful.

Technique:

1. ENTRY (*see Figure 7-23*) typically 3-4 mm above the inferior margin

of the C2 inferior facet, at the midpoint medio-laterally. Alternatively, use a location determined by palpating the pars with a Penfield 4, entering at the cranial and medial quadrant of the surface projection of the C2 pars[106]

2. TRAJ **20-30° medially** (through the central axis of the C2 pedicle)[117], **25° superiorly** (*see Figure 7-24*). To assist with trajectory, expose the proximal upper and medial border of the C2 pars interarticularis, and use a Penfield 4 to palpate during drilling (*see Figure 7-23*)
3. **procedure**: drill a shallow entry point, then drill with drill-stop set at 12 mm, monitoring progress at intervals under fluoro and palpating with probe, and if no breakout, then complete drilling by gradually increasing drilling depth by 2 mm increments until ≈ 30 mm depth is reached

- if withdrawal of the drill is followed by brisk bleeding, the screw should be inserted immediately to stop the bleeding. This bleeding may be from the vertebral artery; however, it is usually due to injury to the venous plexuses, and will not have any ill effects. In such cases it is best to not place the contralateral screw and to obtain an angiogram very soon postop

4. SCREWS **3.5 mm dia**. Screw length is not critical except when attempting to bridge a fracture gap (osteosynthesis) e.g. with a hangman's fracture in which case screws of 20-30 mm length are placed to avoid penetrating anterior C2 cortex (lag screws are used for this, or the proximal bone can be overdrilled); for most purposes screw lengths of 15-20 mm length are used

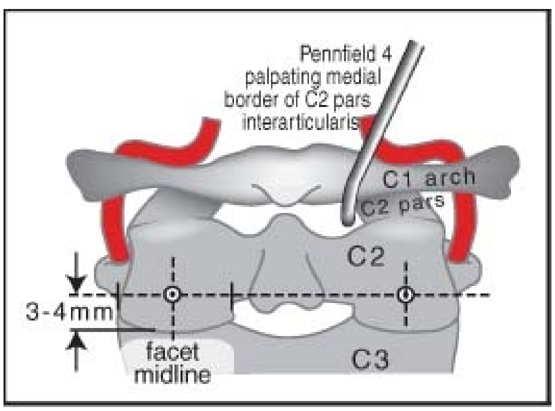

Figure 7-23 Entry point for C2 pedicle screw placement (posterior view)

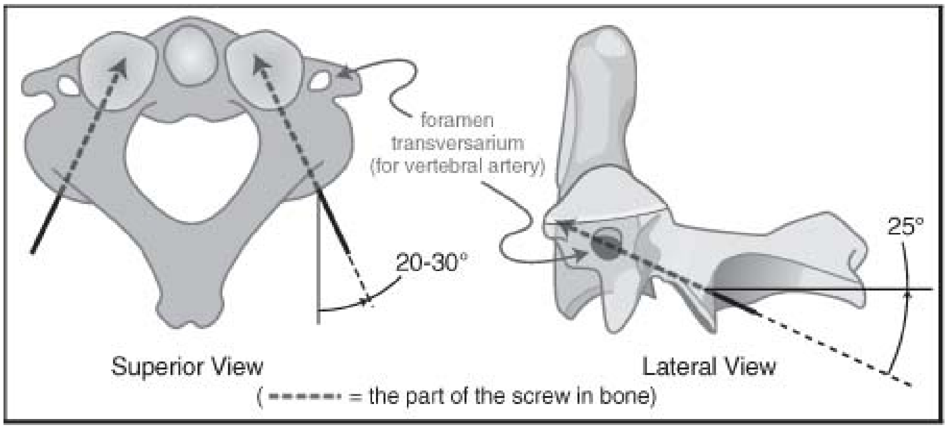

Figure 7-24 Screw trajectory for C2 pedicle screws

7.8.5. C3-6 fixation

LATERAL MASS SCREWS

May sometimes be used down to C7 (*see below*) or occasionally even T1 (*see below*).

Table 7-4 Comparison of methods for lateral mass screw placement for C3-6

Method	Entry point		Trajectory angle	
	Medio-lateral	Cranio-caudal	Medio-lateral	Cranio-caudal
An	1 mm medial to mid-point	midpoint	30° lateral	15° cephalad
Magerl	2 mm medial to midpoint	2 mm cranial to midpoint	20-25° lateral	parallel to facet joint*
Roy-Camille	midpoint	midpoint	0-10° lateral	0°

* angle can be determined by inserting probe into the joint

Technique:

A number of methods have been promulgated with various screw entry points and trajectories (some are shown in *Table 7-4*). Comparing 3 techniques[118] there was a lower risk of nerve injury with the following (method of An[119]):

1. ENTRY [119] **1 mm medial to the midpoint of the lateral mass** (*see Figure 7-25*). In the cranial-caudal direction, the midpoint is used. A Penfield 4 may be used to palpate the medial wall of the pars to help

determine entry point and trajectory

2. TRAJ **15° cephalad and 30° laterally** (*see Figure 7-25*)[119]. To get the lateral angulation, the holes are best drilled from the contralateral side of the patient, holding the drill shaft almost up against the spinous processes (if they are still present)

   A. SCREWS 3.5 mm diameter, 14-16 mm length (for C3-6)

   B. rod size: 3.5 mm diameter rods are usually used, and can be placed as far caudally as T3 as long as there is not gross instability (below T3, 5.5 mm diameter rods are used either via transitional rods or with rod connectors, e.g. "domino" connector)

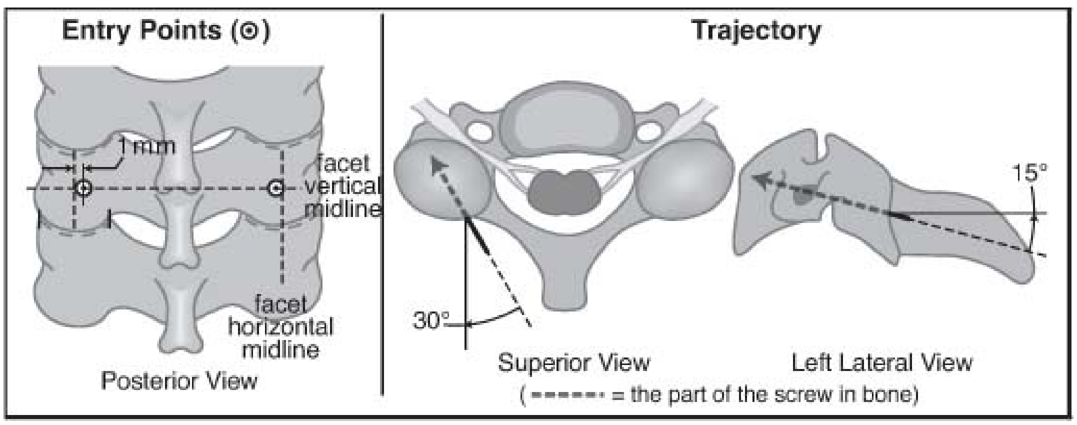

Figure 7-25 Screw entry point and trajectory for C3-6 lateral mass screws (method of An) 15°

Spinous process cables may optionally be used with intact spinous processes to help secure the bone graft[120].

TRANSARTICULAR SCREW FIXATION

An alternative to lateral mass fusion. First described in 1972 by Roy Camille. May be used alone or as an anchor point.

1. PROS:
   A. screws cross 4 cortical surfaces for better purchase
   B. compresses across the joint to promote fusion
   C. useful at cervico-thoracic junction where trajectory preserves facet capsule
   D. lower implant profile

2. CONS: cannot correct deformity
3. ENTRY midpoint of lateral mass
4. TRAJ perpendicular to joint, neutral to 5° lateral (to avoid VA and exiting root)
5. biomechanics: stability equivalent to lateral mass screws[121]
6. clinical: 25 patients (81 screws), 71 anchor, 10 fixation, 3.5 years F/U: solid fusion, no complications[122]

TRANSLAMINAR CERVICAL SCREW FIXATION

May be used in cervical or thoracic spine[123, 124].

1. indications: salvage technique when anatomy precludes pedicle screws
2. PROS:
   A. avoids complications related to pedicle screws
   B. no need for fluoroscopy (reduces radiation exposure)
3. CONS: requires intact posterior elements (cannot do with laminectomy)
4. ENTRY contralateral spinolaminar junction (at base of spinous process)
5. TARGET junction of the transverse process and the superior facet contralateral to the entry point
6. SCREWS 3.5-4.5 mm **x** 26 mm polyaxial screw
7. biomechanics: no data
8. clinical: 7 patients (C-T fixation), 14 months F/U, no hardware complications. Inconsequential ventral penetration in 5%[123]

7.8.6. C7 screws

C7 is a transitional level, and as a result either the lateral masses or the pedicles or both may be relatively small.

Screw fixation options:

1. **pedicle screws**: recommended especially when the C7 lateral mass is of inadequate size for lateral mass screws[119]. Placement with fluoroscopy may be difficult due to shoulder artifact on lateral fluoro, and direct visualization of the medial of the pedicle may be required as in the thoracic spine (*see page 190*)
2. **lateral mass screws** 117:

A. ENTRY as for C3-6 (*see above*)
B. TRAJ compared to C3-6 screws, slightly less lateral at ≈ 15° and a little less cephalad at ≈ 10°
C. SCREWS 3.5 mm diameter, 14 mm length

3. C7 transfacet screw[125]:
   A. PROS: reduced risk to spinal cord and nerve roots
   B. CONS: disrupts C7-T1 facet capsule, so T1 must be included in fusion. short screws result in low pullout strength ∴ may be best used as an intermediate anchor point and not an construct endpoint
   C. ENTRY 1-2 mm medial and superior to center of facet
   D. TRAJ 30° inferiorly and 20° laterally, TARGET goal is bicortical purchase
   E. SCREWS 3.5 mm diameter X 8-10 mm polyaxial screws
   F. biomechanics: equivalent to C7-T1 pedicle screws[126]
   G. clinical: 10 patients, long cervicalo-thoracic fixation, 6 months F/U, 3 patients with solid fusion

7.9. Surgical fusion of the thoracic spine

Pedicle screws

Preferable to lateral mass screws because the transverse processes (analogous to the lateral masses in the cervical spine) of most thoracic vertebrae are not as strong[120]. Thoracic pedicles are usually very narrow in the lateral dimension (the width is a little larger at the cranial end) and are very tall in cranio-rostral direction. Image guidance systems may also be helpful.

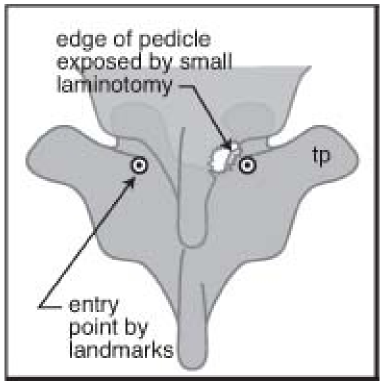

Figure 7-26 Entry point for thoracic pedicle screws (posterior view) tp = transverse process

Technique:

1. ENTRY medio-lateral: mid facet line. Craniocaudal: just where the superior facet joins the transverse process (*see Figure 7-26*). In the upper T-spine (above ≈ T5), because of the small pedicles and difficulty

visualizing the anatomy on fluoroscopy, the entry point and trajectory may be localized by palpating the medial and cephalad edges of the pedicle with a Penfield #4 dissector through a small laminotomy. If a single thickness rod or a transitional rod is being used, try to keep the entry points in line with cervical spine entry points. If a domino connector is being used to connect to a thicker rod, the entry point can be slightly lateral to those in the cervical spine.

2. TRAJ
   A. below T1: 5-10° medially and 10-20° caudad[120] (*see Figure 7-27*). A thoracic Lenke probe may be used as a pedicle finder.
   B. **T1**: if a lateral mass screw is placed at T1 (instead of a pedicle screw), aim almost straight down at the floor (with patient positioned horizontally, i.e. without Trendelenberg or reverse-Trendelenberg)
3. SCREWS smaller pedicles (usually T1-4, especially in females) usually require the smallest screw diameter (typically 4.5 mm). Others may accommodate 5.5 mm. Typical length: 20-25 mm

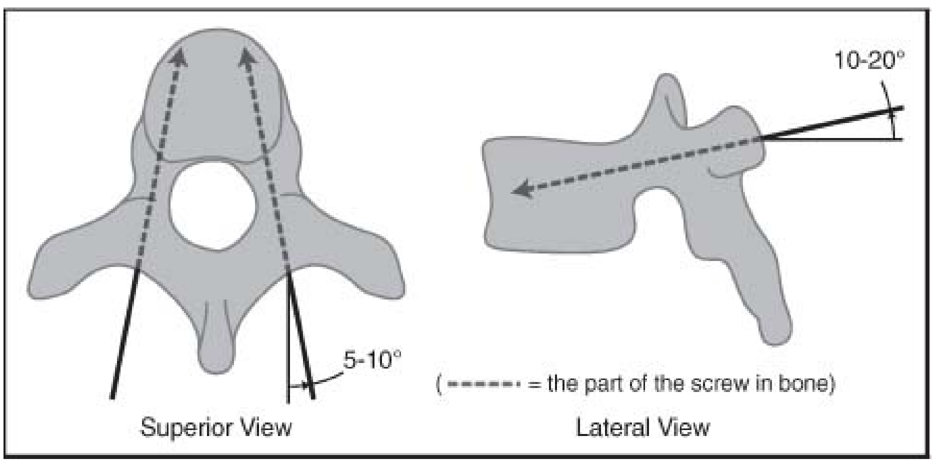

Figure 7-27 Screw trajectory for T1-T3 pedicle screws

4. **rod size**: when connecting to a cervical rod, down to ≈ T3 you can extend a 3.5 mm diameter cervical rod with some systems[A]. Below T3, ≈ 5.5 mm diameter rods (or 6.35 mm for scoliosis surgery) are usually used either via a transitional rod or using a domino connector to mate the two rods

A. e.g. Mountaineer by DePuy using a 4.35 diameter screw

7.10. Surgical fusion of the lumbar and lumbosacral spine

INSTRUMENTATION/FUSION PEARLS

1. a lumbar fusion that includes L1 should not be terminated at L1 or T12
2. the taller the disc space the less likely that posteriorly placed interbody grafts are well suited:
   A. the disc may not be significantly degenerated to require discectomy
   B. tall disc space means larger interbody implants which requires more retraction of nerve to insert (using a PLIF technique)
3. a long fusion should not be terminated at or near a vertebral level that is at the apex of scoliosis[127 (p 382)]
4. laminectomy without fusion should be avoided at the apex of scoliosis
5. posterior midline fusion: early experience with midline fusions resulted in lumbar spinal stenosis as a late complication. Therefore, current fusion techniques use postero-lateral fusion or interbody fusion (from anterior or posterior approach)

PEDICLE SCREWS

Pedicle screw pull out strength is determined in part by the major screw diameter which should be 70-80% of pedicle diameter (larger screws can break through the pedicle wall or can burst the pedicle). The minor diameter determines the strength of the screw and should be ≥ 5.5 mm in the adult lumbar spine. The length should allow penetration of 70-80% of the VB. Bicortical purchase or anterior VB penetration should be avoided to reduce the risk of injury to great vessels or abdominal viscera.

Open technique (*see below* for percutaneous placement):

1. ENTRY at the base of the transverse process, at the intersection of the center of the transverse process (in the rostral-caudal direction) and the sagittal plane through the lateral aspect of the superior facet. If a laminectomy has been performed at that level, the location of the pedicle is then verified by palpation using a probe within the spinal canal, otherwise fluoroscopy is used
2. TRAJ

A. the approximate mediolateral trajectory is shown in *Table 7-5*, and equals the lumbar vertebral number multiplied by 5° for each level from L1 to L5[128]. The angle of the screw in the rostral-caudal direction is determined by fluoroscopy, maintaining a course that is parallel to the vertebral end plate. A frameless stereotactic navigation system may help orient screw trajectory

B. **S2** screws are oriented laterally and superiorly and can be as long as 60 mm

3. SCREWS typical screw lengths vary from 40 to 55 mm (the goal is to cross ≈ 2/3 of the VB). S1 pedicle screws are usually only 35-40 mm long
4. rod diameter: typically 5-6.5 mm

X-ray verification once pedicle screws are placed: on AP view if the screw tip crosses the midline to the contralateral side, there is likely to be a breach of the medial pedicle (sensitivity 0.87, specificity 0.97, accuracy 0.98)[129], and if the screw does not pass medial to the medial pedicle wall there is likely to be lateral pedicle/VB violation (sensitivity 0.94, specificity 0.90, accuracy 0.96)[129]).

Table 7-5 Medial angles for lumbar pedicle screw

Level	Medial angle
L1	5° medially
L2	10° medially
L3	15° medially
L4	20° medially
L5 & S1*	25° medially
S2	40-45° laterally

* aim for sacral promontory

Percutaneous pedicle screws

The principles here are also employed in accessing the pedicles for e.g. vertebroplasty/kyphoplasty, percutaneous biopsy of pathology in the pedicle and/or vertebral body.

Basic principles:

1. requires AP and lateral fluoroscopy, or "O-arm" imaging (essentially an

image guided intraoperative CT scan). With fluoroscopy, biplane fluoro (1 C-arm dedicated for AP view, another for lateral) greatly expedites the procedure

2. this method can be employed essentially from T1 through S1 as long as adequate AP & lateral imaging of the involved level is possible. Using fluoro for upper thoracic placement (e.g. above ≈ T5) is challenging (small pedicles, and the shoulders interfere with x-ray)
3. the skin entry site is lateral to the lateral edge of the pedicle. This permits the needle to pass through the pedicle in a medial direction into the VB. The degree of angulation and therefore the distance off the midline for the entry site depends on the vertebral level being accessed (thoracic pedicles are oriented in a more AP direction, lumbar pedicles angulate medially inward) as well as the amount of overlying muscle/fat

Procedure

1. a needle, typically a Jamshidi needle, is place such that the tip is just short of entering the pedicle on the lateral fluoro (on left in *Figure 7-28*)
2. at this point, the needle tip should be at or just barely lateral to the lateral edge of the pedicle near the equator of the pedicle (on the right side, this would be at the "3:00" position, on the left side this would be at the "9:00" position)
3. the needle is advanced to just enter the pedicle on lateral fluoro, at this point it should be just within the pedicle margin at the 3:00 or 9:00 position (as shown on right in *Figure 7-28*)

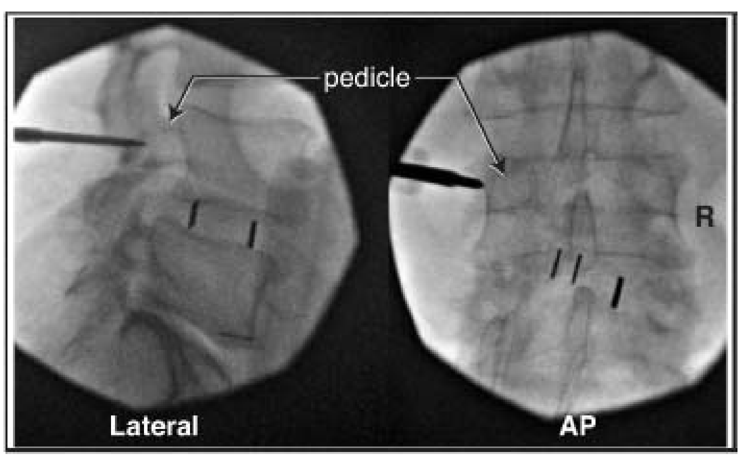

Figure 7-28 Pedicle cannulation - entering pedicle

4. continue advancing the needle into the pedicle. Intermediate fluoro images can be obtained (e.g. to monitor trajectory on the lateral fluoro), but the

next critical landmark is when the needle tip is just traversing the junction of the pedicle and the VB on the lateral fluoro (i.e. just entering the VB as shown on the left in *Figure 7-29*), it should be close to but never more medial than the medial border of the pedicleon the AP view (*see Figure 7-29*, right). If this criteria is maintained, the needle cannot breech the medial wall of the pedicle where it can threaten neural structures or compromise the purchase of the pedicle screw

5. subsequent steps differ for various procedures and manufacturers

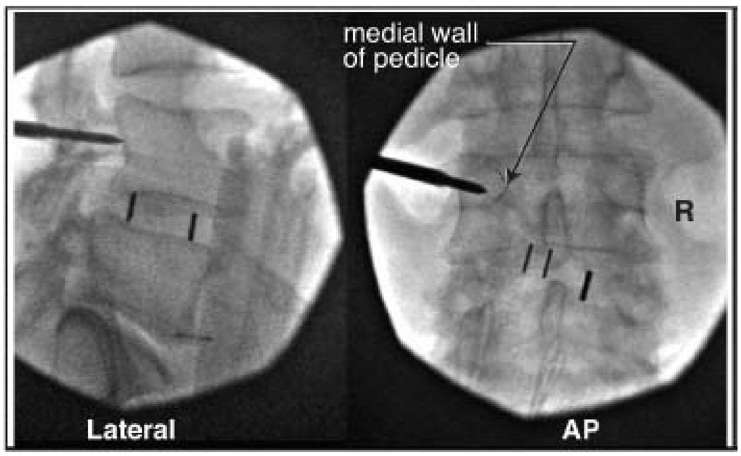

Figure 7-29 Pedicle cannulation - entering the vertebral body

Pedicle-screw rod diameters

Approximate weight guidelines for pedicle-screw rod diameters are shown in *Table 7-6*.

Table 7-6 Minimum recommended titanium rod diameter for lumbar pedicle-screw fixation

Patient weight		Rod diameter (mm)
(lbs)	(kg)	
30-90	12-40	4.5
90-225	40-100	5.5
> 225	> 100	6.35 (1/4 inch)

TRANSLAMINAR LUMBAR SCREW FIXATION

1. indications:
   A. short segment lumbar fusion

B. posterior component in a 360° fixation combined with interbody fusion

2. PROS:
   A. small incision, minimal soft tissue disruption
   B. decreased cost (fewer screws implanted)
   C. decreased blood loss
   D. adjacent facet joint spared
3. CONS:
   A. requires intact posterior elements (cannot use with laminectomy)
   B. cannot reduce
4. ENTRY skin incision 5-7 off midline, screw entry into bone in contralateral spinous process. Can be placed bilaterally
5. drill between the tables of the lamina across the center of the facet joint, terminating at the base of the transverse process
6. SCREWS 4.5 mm diameter fully threaded screws (no polyaxial head)
7. biomechanics: equivalent to bilateral pedicle screws[130]. Limited in extension[131]
8. clinical: 476 patients, 10 years mean F/U, 74% good outcomes[131]

POSTERIOR LUMBAR INTERBODY FUSION (PLIF & TLIF)

Bilateral laminectomy and aggressive discectomy followed by the placement of bone grafts into the decorticated disc space. It has been advocated to reduce the movement in an abnormal "motion segment" (defined as the area between two vertebra). Relatively contraindicated with well preserved disc-space height.

Many PLIFs when studied ≈ 1 year later show re-collapse of the disc space, which raises the question as to whether the PLIF has any benefit over simple discectomy.

Transforaminal lumbar interbody fusion **(TLIF)**: a variation on a PLIF where the graft is placed from one side (via the "neural foramen) after complete removal of the facet joint on that side. Requires much less nerve root retraction than PLIF, and is often advantageous for re-operations where going through the foramen avoids the scar tissue.

Stand-alone PLIFs or TLIFs may be associated with progressive spondylolisthesis at that level and are usually supplemented with pedicle screws/rods.

LATERAL LUMBAR INTERBODY FUSION (LLIF)[132]

Trademarked names include "extreme-lateral" **(XLIF™)** or "direct-lateral" lumbar interbody fusion **(DLIF™)**. A retroperitoneal approach. Indirectly decompresses nerves by distracting the disc space. Indicated for some cases of spinal stenosis (in patients who have had previous posterior spine surgery in the same area, the LLIF avoids the difficulty of dealing with scar tissue and the inherent increased risk of CSF leak from dural tear), can also correct some scoliosis and can be used to remove damaged or malpositioned lumbar disc replacement devices[133]. The need for additional stabilization (e.g. with a lateral plate, or facet screws, or pedicle screws (unilateral or bilateral) is not yet resolved, and may not be needed in all cases. For cases without instability, a lateral plate applied through the same exposure when it can be done should suffice. If there is instability, posterior stabilization with facet screws or pedicle screws are recommended. Access is best from L1-5. For L1-2, one can retract the 12th rib, or go between 11th & 12th rib, or excise the 12th rib. Iliac crest prevents access to L5-S1 (axial-LIF may be used here) and occasionally to L4-5 (*see below*). Above T11, enter on right (check pre-op MRI for anomalous position of aorta). ✖ With <u>thoracic</u> lateral interbody fusions, DO NOT penetrate the contralateral anulus. Difficult in grade II or higher spondylolisthesis. Intraoperative EMG monitoring is critical, so anesthesiologist needs to use only <u>short-acting</u> neuromuscular blockage at beginning of case. In males, implants are typically 55 mm in length (oriented along patient's lateral axis) if placed in the midposition of the VB, or 45 mm in the anterior portion (lengths are 10% shorter in females)[134].

Contraindications:

1. cases requiring direct decompression
2. prior retroperitoneal surgery on the planned side of LLIF (can still be done on contralateral side, sometimes may still be feasible on ipsilateral side)
3. cannot access L5-S1 (NB: a sacralized L5 may cause the L5-S1 disc space to look like L4-5 and may not be accessible)
4. may not be able to access L4-5 if the iliac crest extends more than ≈ halfway up the L4 VB. Sometimes it is necessary to position the patient on the O.R. table with the table flexed and a bump under the hip to see if the space will "open up" and permit access
5. anomalous vascular anatomy interfering with approach: check position of great vessels on pre-op MRI

Relative contraindications:

1. osteoporosis: may also be contraindication to lateral plates
2. active infection
3. “pinpoint” central canal stenosis (some of these cases can still respond)

Complications:

1. thigh numbness: due to genitofemoral nerve trauma: cannot be monitored with EMG. Usually transient, resolves in ≈ 2 weeks
2. thigh flexion weakness: due to psoas injury. Risk increases if > 2 levels are done. Usually transient, resolves in 1-8 weeks
3. quadriceps weakness: due to nerve root/plexus injury (probably from psoas retraction - shorter operations may have lower risk) or psoas hematoma. Onset may be delayed 1-2 d post op. Incidence < 1%. May improve slowly over a long time (> 9 months)
4. vascular injuries

Booking the case - lateral interbody fusion

Also see defaults & disclaimers (*page v*) and pre-op orders (*see below*).

BOOKING

1. position: lateral decubitus, typically left-side up unless specified otherwise
2. equipment: C-arm
3. implants: interbody graft. For spondylolisthesis: pedicle screws may be needed, alternatively, interspinous clamps may be used
4. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the side to place a spacer between two of the vertebrae (backbones) to make more space for the nerves and to stop painful movement, screws/plates etc. will then need to be placed either from the side through the same opening or sometimes from the back
   B. alternatives: nonsurgical management, open surgery through the back
   C. complications: thigh weakness (usually temporary), knee weakness (uncommon), thigh numbness, graft subsidence/migration, failure to achieve desired relief

ANTERIOR LUMBAR INTERBODY FUSION (ALIF)

Relatively contraindicated in males because of risk of retrograde ejaculation in 1-2% (as high as 45% in some reviews). Other risks: injury to great vessels,

especially with calcified arteries, especially at L4-5.

AXIAL LUMBAR INTERBODY FUSION (AX-LIF)

Axial lumbar interbody fusion (Ax-LIF) AKA AxiaLIF™ (by TranS1). Initially developed for indirect decompression at L5-S1, can be extended to include L4-5 with L5-S1 in patients with favorable anatomy (permitting a straight trajectory from tip of coccyx through L5-S1 and L4-5). Minimally invasive through incision in gluteus, threaded spacer is inserted through the S1 vertebral body across the disc space. Differential thread pitches produce disc-space distraction. Not intended as a standalone, supplemental fixation (*see below*) provides the required rotational stability:

1. if facets and pars are intact: can use percutaneous facet-pedicle screws (*see below*) for a single level (L5-S1)
2. if bilateral pars defects, or for a 2-level Ax-LIF, pedicle screws/rods (placed open or percutaneously) are recommended (especially in heavier patients)
3. spinous process clamp(s)

Booking the case - axial lumbar interbody fusion

Also see defaults & disclaimers (*page v*) and pre-op orders (*see below*).

1. position: prone, with the knees dropped <u>below</u> the level of the hips (e.g. either a Jackson or Andrews table, or OSI table with a sling to permit the knees to drop)
2. equipment: 2 C-arms for biplane fluoro (required)
3. implants:
   A. TranS1 AxiaLIF™ and facet screws (i.e. trans-facet pedicle screws)
   B. for 2-level Ax-LIF or if pars defect: also schedule a separate vendor for per-cutaneous pedicle screws/rod
4. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: minimally invasive surgery to place a screw to increase the space around the nerves and to stabilize the spine using an incision near the tail-bone, combined with surgery through the back to place screws and possibly short rods
   B. alternatives: nonsurgical management, open surgery on the back
   C. complications: (usual spine surgery complications - *see page v*), bowel

injury (0.6% risk) which could necessitate a (temporary) colostomy

Pre-op:

1. MRI of the lumbar spine without contrast (or CT if MRI contraindicated) that goes all the way down through the tip of the coccyx with axial, sagittal and coronal views. Assesses whether a workable trajectory can be achieved (*see below*), also rule's out Tarlov's cyst, low aortic bifurcation, large midline vessels at S1-2 or other vascular anomalies
2. bowel prep the day before surgery: (reduces bacterial count and decompresses the rectum) e.g. GoLytely 4 L po (drink 8 oz every 15 minutes), or MagCitrate for patients with chronic constipation. ✖ Do not use Fleets Phospo-Soda if renal insufficiency (risk of acute phosphate nephropathy) or if CHF
3. pre-op antibiotics prior to skin incision. One of the following regimens:
   A. ertapenem (Invanz®) 1 gm IV
   B. cefazolin (Kefzol®, Ancef®) + metronidazole (Flagyl®)[135], or, if ß-lactam allergic, then metronidazole + (ciprofloxacin 500 mg IV or levofloxacin 750 mg IV)[135]
   C. cefoxitin (Mefoxin®) 2 gm IV 30-60 minutes pre-op, repeat q 6 hours **x** 24 hours post-op

✖ Contraindications:

1. vascular: aortic bifurcation below L5-S1 disc space or large midline vessels at S1
2. prior retroperitoneal surgery (renal surgery, proctectomy,) AP resection, low anterior resection, history of pelvic XRT e.g. for cancer of rectum, anus or prostate)
3. severe sacral lordosis/hook-like coccyx may prevent this approach (assess trajectory on pre-op planning to determine if patient is a candidate for this)
4. relative contraindications: Crohn's proctitis, ulcerative colitis, diverticulitis, full-thickness rectal prolapse
5. use in osteoporotic patients has not been evaluated

Technique

Details will not be covered here. Some points of importance:

1. setup: biplane fluoro is required
2. patient position: prone, with the knees dropped below the level of the hips

3. skin ENTRY point: 1 cm lateral to the tip of the coccyx, 1-2 cm caudal to the paracoccygeal notch
4. bone entry point: at the S1-S2 interspace in the midline
5. TRAJ (the manufacturer's template may help):
   A. for a single level (L5-S1) Ax-LIF: the trajectory should pass through the L5-S1 disc at about the midpoint of the AP diameter of the disc
   B. for a 2-level Ax-LIF: the trajectory usually passes through the anterior third of the L4-5 disc (*see Figure 7-30*)
6. grafting usually employs a mixture of (optional) rhBMP together with granules of tricalcium phosphate and hydroxyapatite

Complications

Bowel perforation: This complication, while not unique to this procedure, is most often considered in the context of this operation. Incidence is 31/5290 procedures (0.6%) according to TranS1 company literature. A high (intraabdominal or intraperitoneal) rectal perforation will present with findings of an acute surgical abdomen (abdominal pain, fever, tachycardia, hypotension, signs of peritonitis = rigidity/guarding, elevated WBC, free air on abdominal x-ray). Patients with a low (extraperitoneal/retroperito-neal) injury are not as ill on presentation and may have malaise, low-grade fever, and possibly bloody or purulent anal discharge.

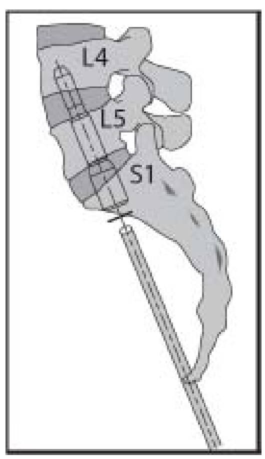

Figure 7-30 Schematic showing a favorable trajectory for a 2-level

Management of rectal perforation:
1. if suspected at the time of surgery:
   A. with the patient still in the jack-knife position a flexible or rigid

sigmoidoscopy can identify most injuries

B. alternatively, 100-200 cc of Gastrografin® can be instilled into the rectum via a Foley catheter, and fluoroscopy is used to visualize 360° of the rectum (using AP and lateral views). The patient may need to be placed in Trendelenburg to get the contrast to contact the dorsal rectum

C. abdominal CT scan (the most sensitive test for free air) or CXR: free air under the diaphragm indicates peritoneal compromise, but with AxiaLIF does not necessarily mean bowel perforation

2. if bowel injury is suspected hours to days post-op, order either:
   A. abdominal and pelvic CT using rectal Hypaque®/Gastrografin®[136]
   B. alternatively, a Hypaque/Gastrografin enema with x-ray or fluoro imaging

If rectal perforation is demonstrated:

1. make patient NPO and start IV fluids
2. broad spectrum IV antibiotics are started immediately
3. STAT general surgery consultation: make sure the surgeon understands the procedure so he will know where to look for the injury. A diverting colostomy (often temporary) may be required. A handful of patients with no systemic or peritoneal signs of infection have been managed with antibiotics, bowel rest and close observation

TRANSFACET PEDICLE SCREWS

Screws place directly across the lumbar facet joint into the pedicle of the level below. No rod is needed. Immobilizes only, does not provide any decompression, distraction or fusion. Therefore not intended for use as a standalone. Can be placed percutaneously.

Indications

Placement is optimal for L3-4, L4-5 or L5-S1. Difficulty increases in upper lumbar levels.

May be used as adjunct to:

1. ALIF
2. LLIF (when lateral plate not used)
3. contralateral to TLIF (pedicle screws could be used on the side of the TLIF, or a spinous process clamp could be used)
4. axial-LIF (Ax-LIF)

Contraindications

A transfacet pedicle screw cannot be used where the facet has been removed (e.g. for a TLIF) or with a pars defect in the upper of the two levels to be fused.

Technique

1. placed percutaneously or via an open procedure usually in the prone position
2. approximate skin incision site: a single midline ≈ 1.5 cm vertical incision is used
   A. for L5-S1 or L4-5: incision at L3 spinous process
   B. for L3-4: incision at L2 spinous process
3. use AP & lateral fluoro to guide trajectory
   A. AP fluoro: lay a guidewire on the patient's back and orient it to pass through the desired pedicle. Use a skin marker on the patient's back to mark the guidewire's trajectory
   B. lateral fluoro: initial bony target is the midpoint of the inferior facet of the upper level. The tip of the guidewire should contact the bone directly posterior to the inferior endplate of the upper level

FACET FUSION

A bone dowel (e.g. TruFUSE® by MinSURG) is placed into a predrilled opening in the facet joint to promote fusion across the joint. Marketed as a possible standalone.

S2 SCREWS

May be directed medially (analogous to pedicle screws), or more commonly, directed laterally and superiorly into the ala. In either case, bicortical purchase is necessary.

The main structure to avoid is penetrating the sacroiliac **(SI)** joint with the screw.

ILIAC SCREWS

Wide exposure is needed. On the initial few cases, the surgeon may be better served by exposing all the way to the posterosuperior aspect of the sciatic notch so that the screw trajectory can be aimed using a palpating finger.

A small amount of bone is removed just below and medial to the posterior

superior iliac spine. This prevents the head of the screw from being too superficial which may cause discomfort or skin breakdown. An offset adapter is usually required to connect to rods passing through pedicle screws in the levels above.

TARGET Aim towards the acetabulum to pass approximately 1 cm superior to the sciatic notch on AP fluoro. Avoid penetrating the cortex, especially in the sciatic notch.

SCREWS Length 50-70 mm (the screw should end just above midpoint of the the sciatic notch, or a little medial to that). Diameter: 6-8 mm.

7.11. Bone graft

7.11.1. Use of bone graft extenders/substitutes as an adjunct to fusion

PRACTICE GUIDELINE 7-1 BONE GRAFT EXTENDERS & SUBSTITUTES

Level I[137]: autologous bone or recombinant human bone morphogenic protein (rhBMP-2) bone graft substitute is recommended in the setting of an ALIF in conjunction with a threaded titanium cage

Level III[137]:

- rhBMP-2 in conjunction with hydroxyapatite and tricalcium phosphate may be substituted for autograft in some cases of posterolateral fusion
- calcium phosphate is recommended as a bone graft extender, especially when combined with autologous bone

Assessing surgical lumbar fusion: See *PRACTICE GUIDELINE 7-2*.

PRACTICE GUIDELINE 7-2 RADIOGRAPHIC ASSESSMENT OF FUSION

Level I[138]: static x-rays alone are not recommended

Level II[138]:

- in the absence of rigid instrumentation, lack of motion between vertebrae on lateral flexion/extension x-rays is highly suggestive of successful fusion

✖ technetium-99 bone scanning is not recommended

Level III[138]: radiographic techniques, often in combination, may be used when failed lumbar fusion is suspected, including: static and flexion/extension x-rays, CT scan

PRACTICE GUIDELINE 7-3 CORRELATION BETWEEN FUSION & OUTCOME

Level III[139]: the correlation between fusion and clinical outcome is not strong, and in any given situation fusion status may be *unrelated* to outcome

7.11.2. Bone graft properties

Used mostly for spine fusions. Components of bone graft that are important for fusion:

1. **osteoinduction**: recruitment of mesenchymal cells and the stimulation of these cells to develop into osteoblasts and osteoclasts
2. **osteogenesis**: formation of new bone by host or graft mesenchymal stem cells transformed into osteoblasts
3. **osteoconduction**: the structure of the graft that acts as a scaffold upon which new bone and blood vessels form
4. mechanical stability: the structural anatomical biomechanical support provided, e.g. following discectomy, corpectomy or resection of vertebral tumor

Table 7-7 summarizes the properties of various bone graft materials (adapted[196-198]). See the sections that follow for more details.

Table 7-7 Characteristics of bone graft materials (see text for details)

Material	Mechanical stability	Osteogenic	Osteo-inductive	Osteo-conductive
Cancellous autograft	±	++++	++	++++
Cortical autograft	+++	+	+	+
Vascularized autograft	+++	+++	++	+++
Allograft	+	–	±	+
Bone marrow aspirate	–	+	±	+
Demineralized bone matrix (DBM)	–	–	+	+
Bone morphogenic protein (BMP)	–	–	++++	–
Collagen	–	–	–	–
Ceramics	+	–	–	+++

Key: – no effect, ± minimal or no effect, + mild, ++ moderate, +++ strong, ++++ very strong effect

Autograft: Common donor sites: iliac crest, rib[199], fibula, bone removed during decompression. Characteristics:

1. PROS: no histocompatibility or disease transmission issues
2. CONS:
   A. persistent post-op donor site pain: occurs in as many as 34% of patients (the severity of which was graded as “unacceptable” in 3%)[200]
   B. increased surgical risks of:
      1. blood loss
      2. wound infection
      3. fracture
      4. cosmetic deformity
      5. increased operative time to procure
      6. numbness from nerve injury (e.g. cluneal nerves *see below*)
      7. hematoma
3. subtypes
   A. cancellous bone: provides all graft components except mechanical stability
   B. cortical bone:
      1. provides superior and immediate mechanical strength
      2. has diminished osteoinduction and osteoconduction capacity
   C. corticocancellous bone: e.g. tricortical iliac crest wedge. Contains all bone graft components
   D. vascularized autograft:
      1. technically challenging
      2. best suited for areas that are scarred, irradiated, or that span long segments
   E. autologous bone marrow:
      1. source of osteoprogenitor cells and osteoinductive substrates
      2. diminished donor site risks
      3. no osteoconductive nor structural properties

Allograft: Acquired through organ procurement agencies. Primarily frozen or freeze dried. Donor sites include: ilium, tibia, fibula, femur, rib.

1. PROS: eliminates risks associated with harvesting autograft
2. CONS:
   A. small but real risk of disease transmission
   B. provide only osteoconduction (lacks osteoinduction and osteogenesis)
   C. availability may vary from time-to-time

3. subtypes
   A. tricortical block, bicortical plug, or unicortical dowel
   B. corticocancellous: matchsticks, crushed
   C. cancellous: cubes, block, crushed, bone powder
4. uses: allografts are acceptable for structural grafts such as in anterior spinal interbody fusion, where compressive forces are applied to the graft. However, for onlay grafts such as for posterior cervical fusion, the lack of osteoinductive and osteogenetic properties is a critical shortcoming

Demineralized bone matrix (DBM): Prepared by acid extraction, reducing antigenicity, but preserving some osteoconductive and variable osteoinductive properties.

1. available as putty, gel, chips, granules or powder
2. primarily used as an adjunct to other grafting materials
3. CONS:
   A. increased cost
   B. variable efficacy between preparations and batches of the same preparation
   C. no mechanical or structural properties

Bone morphogenic proteins (BMP): (AKA bone morpho *genetic* proteins). Biological compounds that induce the transformation of mesenchymal stem cells into osteoblasts (osteoinduction) with the potential to induce ectopic bone formation. There are ≈ 20 different proteins from the transforming growth factor-ß family. Produced using recombinant DNA technology.

1. a carrier matrix is required to retain the soluble factor at the graft site (i.e. to prevent the BMP from diffusing into adjacent tissues, thereby reducing the desired effect and possibly inducing bone growth at undesired foci)
2. FDA approved in U.S. only for ALIF. Other uses are "off label"
3. available preparations: rhBMP-2 (Infuse® by Medtronic)
4. PROS: increases fusion rates
5. CONS:
   A. expensive
   B. ectopic bone formation, bone resorption (so-called osteolysis) or remodelling at the graft site[201]
   C. in anterior cervical spine surgery: neck swelling with airway compromise, hematoma, painful seroma[201]

Collagen: Used primarily as a carrier for other osteoinductive, osteoconductive, or osteogenetic materials and as a composite with other graft extenders

1. PROS: contributes to vascular ingrowth, mineral deposition, and growth factor binding
2. CONS:
   A. minimal structural support
   B. potential immunogenicity

Ceramics: Includes tricalcium phosphate, calcium carbonate & hydroxyapatite.

1. PROS: no risk of disease transmission
2. CONS: only recommended for use as bone graft extenders (i.e. must be combined with autograft, bone marrow aspirate, BMP…)

7.11.3. Bone graft procurement

ILIAC CREST

ANTERIOR ILIAC BONE GRAFT

Should be obtained at least ≈ 3-4 cm lateral to the anterior superior iliac spine **(ASIS)** to avoid the lateral femoral cutaneous nerve and to reduce the risk of avulsion fractures of the remaining ilium. When a tricortical graft is taken, keep the dissection in the subperiosteal plane and avoid electrocautery on the medial (inner) surface when detaching the iliacus muscle to avoid injury to the ilioinguinal, iliohypogastric and lateral femoral cutaneous nerves.

POSTERIOR ILIAC CREST BONE GRAFT

May be used to obtain corticocancellous strips or plates for onlay bone grafts, or tricortical grafts which may be used as strut grafts or for C1-2 arthrodesis.

Posterior bone grafts are taken from the medial 6-8 cm of the iliac crest to avoid the superior cluneal nerves (which cross the posterior iliac crest ≈ 8 cm lateral to the posterior superior iliac spine) with resultant buttock numbness or the development of painful neuromas. A vertical incision just medial to the posterior superior iliac spine usually works well.

The spine may sometimes be found on corpulent patients by locating the "dimple of Venus" (fossae lumbales laterales - indentation sometimes visible superior to the gluteal cleft, directly superficial to the sacroiliac joint) and

incising slightly lateral to it. Avoid mistaking the sacrum for the iliac spine.

The gluteus maximus is dissected off the lateral surface subperiosteally. To avoid fractures extending into the iliac crest, a wide osteotome should be used to create a “stop cut”; alternatively, a sagittal saw may be used. Avoid penetration through the inner cortical surface of the crest so as not to enter the pelvis and possibly cause an intraabdominal hematoma. Another potential complication is fracture extension into the greater sciatic notch with possible injury to the gluteal arteries and sciatic nerve among others. Once the graft is removed and cancellous bone is gouged out, the exposed bone surfaces should be waxed and closed system drainage should be used to reduce the risk of local hematoma formation.

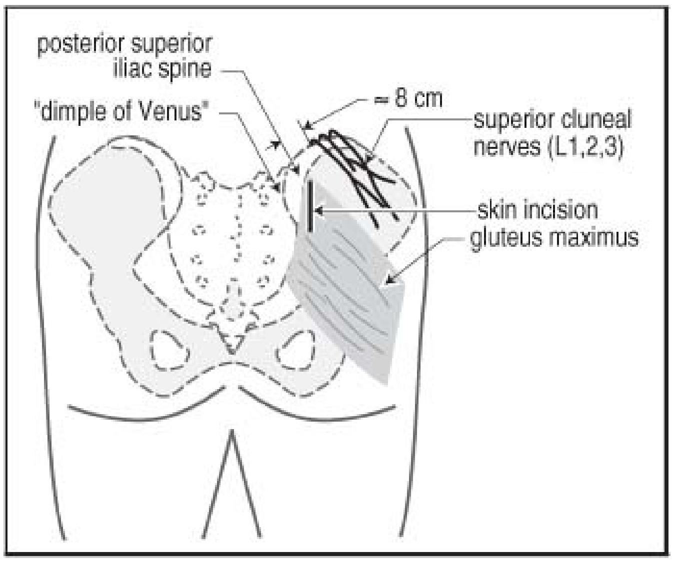

Figure 7-31 Posterior iliac crest bone donor site

FIBULA

Autogenous fibular graft provides a high arthrodesis rate[202], but may be associated with significant morbidity, and so may be best reserved for salvage procedures[203]. Preserve the proximal fibular head to avoid injury to the peroneal nerve. At least 7 cm of distal fibular should be maintained to preserve ankle stability[199].

7.12. Percutaneous access to the CSF

7.12.1. Percutaneous ventricular puncture

Indications

In pediatrics, may be used to remove hemorrhagic ventricular fluid following intraventricular hemorrhage, or to obtain CSF specimen in cases of suspected ventriculitis. May be used emergently in pediatrics or adult as a temporizing measure in patient herniating from obstructive hydrocephalus.

Peds

Shave hair. 5 minute Betadine® prep.

The right side is preferred. Enter through coronal suture just lateral to anterior fontanelle **(AF)** using a 20-22 Ga. spinal needle. If a CT scan has been done, it may be used to help judge angulation (usually varies between contra- and ipsilateral medial canthus and intersection with EAM).

Adult[140]

Only used emergently. Takes advantage of thin orbital roof in adult.

Prep conjunctiva and skin with antiseptic (e.g. ophthalmic betadine). Elevate the eyelid and depress the globe. Using a 16-18 Ga. spinal needle, penetrate the anterior third of orbital roof (1-2 cm behind orbital rim) with firm pressure (may need gentle tapping). Aim at coronal suture in the midline. The frontal horn should be about 3-4 cm deep.

7.12.2. Subdural tap

Indications

Utilized in pediatrics. Used to be done for diagnostic purposes, but this has been supplanted by CT, MRI & ultrasound. Currently, this procedure may be used emergently for decompression, to drain subdural collections and to obtain fluid for diagnostic tests, such as culture (repeat taps may be used, but surgery should be considered after ≈ 5-6).

Technique

Shave hair. Prep 5 minutes with povidone iodine (Betadine®). Using a short 20-21 Ga. spinal needle (spinal needle is recommended because the stylet may

reduce the risk of implanting epidermal cells into the CNS), penetrate the lateral margin of the anterior fontanelle **(AF)** or coronal suture at least 2 cm off midline. Remove the stylet and aspirate. With bilateral fluid collections, bilateral taps should be done.

7.12.3. Lumbar puncture

Contraindications

1. known or suspected intracranial mass } risk of tonsillar herniation (*see below*)
2. non-communicating hydrocephalus } risk of tonsillar herniation (*see below*)
3. infection in region desired for puncture: choose another site if possible
4. coagulopathy
   A. platelet count should be > 50,000/mm^3 (*see page 34*)
   B. patient should not be on anticoagulants because of risk of epidural hematoma (*see page 515*) or subarachnoid hemorrhage[141] with secondary cord compression
5. use caution in suspected aneurysmal SAH: excessive lowering of the CSF pressure increases the transmural pressure (pressure across the aneurysm wall) and may precipitate rerupture
6. caution in patients with complete spinal block: 14% will deteriorate after LP[142]

- elevated ICP and/or papilledema by themselves are NOT contraindications (e.g. LP is actually used diagnostically and as a treatment in idiopathic intracranial hypertension, *see below*)

Technique

Background and anatomy

The spinal cord and column are the same length in a 3-month fetus. After that, the spinal column grows faster than the cord. As a result, the conus medullaris is located rostral to the termination of the thecal sac in the adult, situated between the middle thirds of the vertebral bodies of L1 and L2 in 51-68% of adults (the most common location), T12-L1 in ≈ 30%, and L2-3 in ≈

10% (with 94% of cords terminating within the territory of L1 and L2 vertebral bodies)[143]. The thecal sac ends ≈ S2. The **intercristal line** (connecting the superior border of the iliac crests) crosses the spine at the L4 spinous process or between the L4 and L5 spinous processes in most adults.

Procedure

Position: the procedure is usually performed in the lateral decubitus position. As the needle is advanced, it is helpful to have the patient bring the knees up and to flex the neck in order to open up the spaces between the posterior elements of the spine.

For diagnostic LP, a 20 Ga spinal needle is often selected. Larger needles (e.g. 18 Ga) may be used e.g. with pseudotumor cerebri to encourage post-procedure drainage of CSF into the soft tissues of the back.

The back is prepped and draped to create a sterile working area.

Entry point: in an adult, use the L4-5 interspace in most cases (located at or just below the intercristal line) or 1 level higher (L3-4). Peds: L4-5 is preferred over L3-4.

The needle is always advanced with the <u>stylet in place</u> at least through the skin and some subcutaneous tissue to avoid introducing epidermal cells which may cause iatrogenic <u>epidermoid tumors</u> (see *Complications following LP* below). The needle is aimed slightly cranially (to parallel the spinous processes) and usually a little down towards the bed (aiming towards the umbilicus). If a Quincke LP (standard) needle is used, the bevel is turned parallel to the length of the spinal column to reduce the risk of post-LP H/A (see *needle type*, page 204). In general, if bone is encountered it is more often due to deviation from a true midline trajectory rather than a failure to aim correctly in the rostral-caudal direction. The needle should be withdrawn to just below the skin surface before attempting a new trajectory.

If during insertion of the needle the patient experiences pain radiating down one LE, this usually indicates that a nerve root has been encountered. The needle should be withdrawn immediately and reinserted aiming more towards the side <u>contralateral</u> to the extremity that experienced the pain. The stylet is removed at intervals during the insertion to look for CSF (a distinct pop is sometimes felt as the needle penetrates the dura).

Once CSF flows, the needle is connected to a manometer through a 3-way stopcock, the pressure is measured and recorded (*see below*), and CSF is drained into sterile tubes (1-2 ml for each tube) for laboratory analysis (*see below*). The practitioner should also note the color of the fluid (clear, blood tinged,

xanthochromic…) and the clarity (clear, cloudy, purulent…).

At the end of the procedure, the stylet should be replaced before the needle is withdrawn (to reduce post-LP H/A, *see below*).

Opening pressure

The opening pressure **(OP)** should be measured and recorded for every LP. To be meaningful, the patient should be lying down and as relaxed as possible (should not be in forced fetal position), with the bed flat. The variation of pressure with respirations is usually a good indication of a communicating fluid column (the fluctuation is inphase with the respiratory pressures in the inferior vena cava, rising with inspiration and falling with expiration[144]). **Normal values**: in the left lateral decubitus position, average OP = 12.2 ± 3.4 cm H_2O (8.8 ± 0.9 mm Hg)[145]. Also, see *Table 14-1*, page 297 for peds.

Queckenstedt's test: if a subarachnoid block is suspected (e.g. from spinal tumor), compress the jugular vein **(JV)** first on one side then on both (do not compress carotid arteries). If there is no block, the pressure will rise to 10-20 cm of fluid, and will drop to the original level within 10 seconds of release of the JV[146 (p 11)]. Do not do JV compression if intracranial disease is suspected.

Laboratory analysis

Routinely, three tubes are sent for analysis as shown in *Table 7-8*. See *Table 14-5*, page 299 for interpreting the results of the laboratory analysis.

If the tap is possibly *traumatic* (i.e. bloody), or if having an accurate cell count is essential (e.g. to R/O SAH) then 4 tubes are collected, and the first and last are sent for cell counts and are compared (see *Traumatic tap*, page 298).

If special cultures are required (e.g. acid fast, fungal, viral) they are also specified on the tube for culture & sensitivity (C & S).

If CSF for *cytology* is desired (e.g. to R/O carcinomatous meningitis or CNS lymphoma), then at least 10 ml of CSF must be sent in one tube to pathology.

Table 7-8 Routine tests for CSF

Test	If there is no concern about possible traumatic tap	If there is concern about traumatic tap
cell count		Tube 1
gram stain + C & S	Tube 1	Tube 2
protein and glucose	Tube 2	Tube 3
cell count	Tube 3	Tube 4

COMPLICATIONS FOLLOWING LP

The overall risk of disabling or persistent symptoms (defined as severe H/A lasting > 7 days, cranial nerve palsies, major exacerbation of pre-existing neurological disease, prolonged back pain, aseptic meningitis, and nerve root or peripheral nerve injuries) has been estimated at 0.1-0.5%[147]. Severe side effects, which include brainstem herniation, infection, subdural hematoma or effusion, and SAH, are rare[148 (p 171-2)].

Possible complications include:

1. tonsillar herniation
   A. acute herniation in the presence of mass lesion (*see below*)
   B. chronic tonsillar herniation (acquired Chiari 1 malformation): reported after multiple traumatic LPs with presumed post-LP CSF leak[149]
2. infection (spinal meningitis)
3. "spinal headache": usually positional (diminishes with recumbency) (*see below*)
4. spinal epidural hematoma: usually seen only with coagulopathy (*see page 515*)
5. spinal epidural CSF collection: may be fairly common in patients with post-LP H/A. Usually resolves spontaneously
6. epidermoid tumor: risk may be increased by advancing LP needle without stylet (transplanting a core of epidermal tissue)[150-152]
7. impinging nerve root with needle: usually causes transient radicular pain, may cause permanent radiculopathy in some
8. <u>intracranial</u> subdural hygroma or hematoma[153, 154] (rare)
9. vestibulocochlear dysfunction[155]:
   A. subclinical (demonstrated on audiogram) or moderate reduction in hearing may occur, and seems to correlate with post-procedure CSF leakage
   B. sudden hearing loss may occur. Perform audiogram to quantify loss. Treat with bedrest for several days, prednisone 60 mg/d tapered over 2-3 weeks
   C. pathogenesis: reduced CSF pressure may reduce perilymph pressure through the cochlear aqueduct[156], producing endolymphatic hydrops
10. ocular abnormalities
    A. abducens palsy: almost invariably unilateral. Often delayed 5-14 days postLP, usually recovers after 4-6 wks[157]

11. dural sinus thrombosis[158] (usually with underlying thrombophilia)

RISK OF ACUTE TONSILLAR HERNIATION FOLLOWING LUMBAR PUNCTURE

The question of when to do LP first (to save time) and when to obtain CT scan first to R/O intracranial mass (for safety) before performing an LP is controversial.

Issues

The time delay to initiating antibiotics is the most important variable in the out-come of meningitis. Time may be more crucial in community acquired meningitis, than in post-op neurosurgical meningitis.

The theoretical risk in performing an LP with an intracranial mass is that the resultant shift in pressure may precipitate tonsillar herniation.

Starting antibiotics without first having a CSF specimen risks the difficulties in managing partially treated meningitis, or a suboptimal choice of antibiotic medication.

Clinical evaluation for possible contraindication to LP is unreliable. Papilledema takes a minimum of 6 hrs to develop after the onset of increased ICP, and in most cases it requires up to 24 hrs. Therefore, its absence does not insure normal intracranial pressure. Furthermore, papilledema may be seen in conditions where there is not a contraindication to LP (e.g. idiopathic intracranial hypertension, where LP is one of the accepted treatments, *see page 713*).

The ready availability of CT scans, often within the emergency department itself, may involve a delay of only a few minutes, if qualified personnel to interpret the study are also immediately available.

Historical information

Herniation following LP was more common prior to ≈ 1950, long before CT scans were available, where the procedure was performed even when some patients had clear evidence of ↑ ICP, large bore spinal needles (12-16 gauge) were more commonly employed, and large quantities of CSF were removed for therapeutic purposes. In a 1969 report of 30 patients who deteriorated after LP[159], 73% had localizing signs (hemiparesis, anisocoria…) and 30% had papilledema. None of 5 patients with cerebral abscess deteriorated after the first of multiple LPs.

In a series of 129 patients with ↑ ICP[160], the complication rate reported was 6%; however, some of these complications were probably unrelated to LP, and

many of these patients were in extremis. In 7 series totalling 418 patients, a complication rate of 1.2% was calculated[160].

> Σ Herniation as a result of LP is consistently reported only in patients with severe non-infectious processes, often with accompanying signs of mass effect (localizing signs, papilledema…). Thus, in cases of suspected meningitis in the absence of focal findings and papilledema, if a CT scan cannot be performed and interpreted within a few minutes, the benefits of performing an LP with a needle ≤ 20 gauge and removing only a few ml of CSF and starting empiric antibiotics probably outweigh the small risk of herniation. In the unlikely event that there is acute deterioration associated with the withdrawal of a few ml of CSF, the (anecdotal) recommendation is to immediately replace the fluid through the LP needle.

HEADACHE FOLLOWING LUMBAR PUNCTURE

For characteristics of the H/A and treatment *see page 58*. Risk of post-LP H/A **(PLPHA)** is related to a number of factors including:

Factors outside the control of the physician:

1. age: ↑ in younger patients
2. sex: ↑ in females
3. prior headache history (including previous PLPHA)
4. body size: ↑ with small body mass index = weight/height^2[161]
5. pregnancy

Variables that have been shown to influence the incidence of PLPHA:

1. needle size: larger needles carry increased risk[162]
2. bevel orientation: orienting the bevel parallel to the longitudinally running fibers of the dura reduces the risk of PLPHA[163]
3. replacing the stylet prior to needle removal lowers the incidence[161]
4. the number of dural punctures (may not be totally under the physician's control)

Variables that may or may not influence the incidence of PLPHA:

1. needle type
   A. Quincke needle: bevelled edge with cutting tip (the standard LP needle). Incidence of PLPHA with 20 and 22 gauge Quincke needles: 36%[164])
   B. atraumatic needles: a number of types are available. Most are "pencil pointed" and may produce a hole with a lower incidence of transdural leak[165]. Unproven[161]

Factors found <u>not</u> to affect the incidence of PLPHA:

1. the position of the patient after LP (does not seem to prevent PLPHA, but may delay the onset of symptoms[166, 167])
2. volume of fluid removed at the time of LP
3. hydration following LP[161]

7.12.4. Lumbar drainage

Insertion of a catheter into the lumbar subarachnoid space for the purpose of draining CSF. Usually connected to a closed drainage system similar to that for an EVD. Generally used for periods of only a few days or so.

INDICATIONS

1. to reduce CSF pressure on a site of CSF leak/fistula. Example situations:
   A. dural breach during spine surgery or craniotomy (especially posterior fossa)
   B. for spontaneous CSF fistula (rare): *see page 301*
2. to reduce intracranial pressure in cases of communicating hydrocephalus: e.g. drain test for NPH (*see page 332*), or when an infected shunt has been removed
3. to reduce CSF pressure to attempt to increase perfusion of the spinal cord: e.g. during surgery for abdominal aortic aneurysm, or following spinal cord injury

CONTRAINDICATIONS

As with lumbar puncture (*see above*).

INSERTION TECHNIQUE

Positioning, entry site, and trajectory are all similar to lumbar puncture (*see above*). Instead of a spinal needle, a Tuohy needle is used. The bevel is inserted parallel to the fibers of the dura (rostro-caudal). The needle is then rotated 90° (usually pointing rostrally) and the catheter is threaded into the needle. ✖ If the catheter does not thread, the needle must be withdrawn together with the catheter - attempting to withdraw the catheter through the needle will shear off the catheter at the tip of the needle.

MANAGEMENT

The orders for the nursing staff to maintain the catheter include:

1. instructions as to how to regulate the CSF drainage. Most commonly one of:
   A. by pressure: accomplished by specifying a height of the drip chamber, usually at the level of the tragus or shoulder
   B. by withdrawing a specified amount of CSF per hour: usually 10-20 cc. This method reduces the risk of overdrainage if the dip chamber is too low
2. instructions for the exit site: usually treated as an arterial-line

COMPLICATIONS

1. infection
2. overdrainage: usually as a result of the drainage bag being too low when using the pressure drainage method described above (either from falling to the floor, or not being raised when the patient sits or stands up) or from catheter disconnection. Can cause:
   A. subdural hematoma from tearing of bridging veins from downward displacement of the brain
   B. headache
3. pneumocephalus: usually from placing the drain height below the site of a fistula, and air is drawn in through the fistula tract
   A. tension pneumocephalus: usually with a ball-valve effect at the fistula site
4. catheter pull out: frequently occurs simply as a result of patient movement in bed or with patient transfers

7.12.5. C1-2 puncture and cisternal tap

Indications

Situations where CSF specimen is required but access via LP is difficult or contraindicated (lumbar arachnoiditis, marked obesity…), or to instill contrast to demonstrate the rostral extent of a block documented by dye injected via LP. Spinal headache is less common with these procedures than with LP. C1-2 puncture is safer than cisternal tap.

✖ Contraindicated: in patient with Chiari malformation (often present in myelomeningocele) due to low lying cerebellar tonsils and medullary kink.

Normal CSF values for glucose and protein differ only slightly from CSF

obtained by lumbar puncture. Opening pressures averaged 18 cm of fluid with lateral puncture.

C1-2 PUNCTURE

AKA lateral cervical puncture. Equipment: LP tray (useful for the specimen tubes, extension tube for contrast injection under fluoroscopy, lidocaine, and spinal needle) with a standard 20 Ga spinal needle, contrast if needed (e.g. Iohexol®). It is preferred to perform the procedure under fluoro, however it has also been described without fluoroscopic guidance with a completely cooperative patient[168].

Patient position: supine in bed without a pillow, with the head straight up. Avoid any head rotation which may bring the vertebral artery **(VA)** into the needle path[169].

Place head within lateral fluoroscopy unit (since this is rarely available, a C-arm fluoro positioned horizontally may be used).

If iodinated dye is being injected for myelography, the head should be elevated to prevent contrast from running into posterior fossa; in cases with cervical spine injury, one can put the entire bed in reverse Trendelenburg.

Entry point: 1 cm caudal and 1 cm posterior (dorsal) to the tip of the mastoid process. **Needle insertion**: use a 25 Ga. needle to anesthetize the skin at the entry point. Under fluoro, advance a larger needle (e.g. 21 Ga.) towards the C1-2 interspace while injecting local anesthetic: aim for a target in the middle of the posterior third of the bony spinal canal (or, alternatively, 2-3 mm anterior to the posterior margin of the bony canal) ("**X**" in *Figure 7-32*). Leave this needle in as a marker. Insert the 20 Ga. spinal needle parallel to the marker needle. Verify the course with fluoro. If fluoro is not used, insert the spinal needle at the entry point, and advance it parallel to the plane of the bed, perpendicular to the neck[168]. If the needle penetrates deeply without encountering bone or CSF, it is most likely that the tip is too par posterior. If bone is encountered, redirect the needle in the rostrocaudal plane.

Several "pops" may be felt, and the stylet should be removed after each to check for CSF return. The subarachnoid space is ≈ 5-6 cm deep to the skin surface in most adults[170]. The needle must be supported more than with a lumbar puncture.

To inject iodinated contrast, use e.g. ≈ 5 ml of 180 mg% Iohexol® for cervical myelogram, watch dye on fluoro (should be able to see it in subarachnoid space).

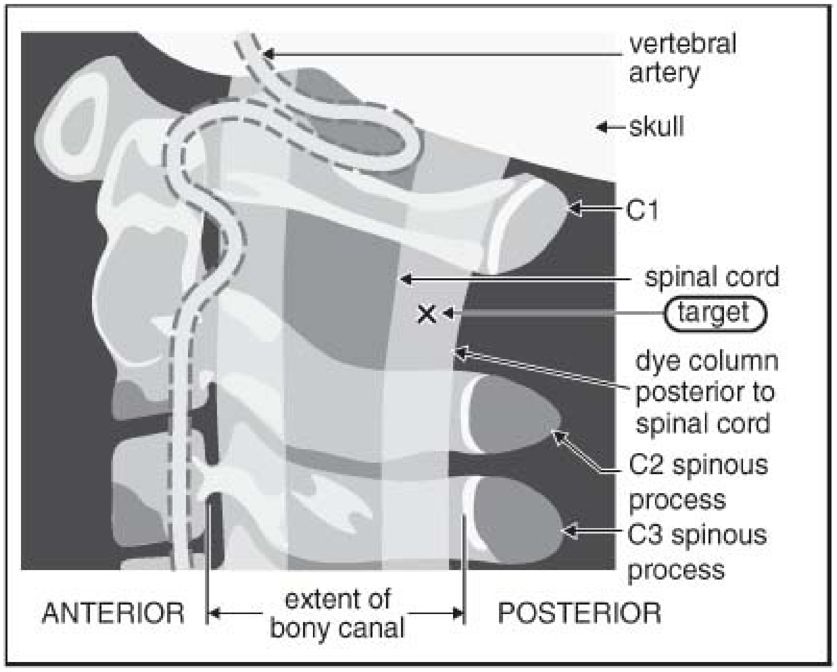

Figure 7-32 C1-2 puncture target*

* left lateral view through upper C-spine: composite diagram of a myelogram and vertebral arteriogram illustrating the relative location of the spinal cord, CSF space, and VA. Only bony landmarks will be visible with fluoroscopy

Risks

Case report of a death from subdural hematoma due to puncture of an anomalous vertebral artery[171] (found in ≈ 0.4% of population). If the VA is penetrated, the needle is withdrawn and local pressure is applied. Penetration of the upper spinal cord/lower medulla (risk of serious neurologic sequelae, even from this, is small). Herniation (as with LP) when there is increased ICP.

CISTERNAL TAP

Suboccipital access to the cisterna magna. Usually done with patient sitting, with neck slightly flexed[172]. Overlying hair should be shaved. Local anesthetic is infiltrated. A 22 gauge spinal needle is inserted exactly in the midline between the inion and the C2 spinous process, directed superiorly towards the glabella until the needle strikes the occiput or enters the cisterna magna. If the occiput is encountered, the needle is withdrawn slightly and reinserted directed slightly inferiorly, the process is repeated ("walking down the occiput") until the cisterna magna is entered (a "pop" will be felt).

The distance from the skin surface to the cisterna magna is 4-6 cm, and from

the dura to the medulla is ≈ 2.5 cm. However, due to tenting of the dura, the needle may be very close to the medulla before entering the subarachnoid space.

Risks

1. hemorrhage in the cisterna magna: may be due to perforation of a large vessel[168]
2. piercing the medulla oblongata: may cause vomiting, respiratory arrest…
3. positioning may compromise blood flow in the vertebral artery in elderly patients

7.13. CSF diversionary procedures

7.13.1. Ventricular catheterization

★ Most common insertion sites[173 (p 151-3)]:

1. **occipital-parietal** region: commonly used for CSF shunt
   A. entry site: a number of means have been described, including:
      1. **Frazier burr hole**: placed prophylactically before p-fossa crani for emergency ventriculostomy in event of post-op swelling. Location: 3-4 cm from midline, 6-7 cm above inion[40 (p 520)] (caution: an error in locating the inion could put the catheter in an undesirable location if this method alone is used)
      2. **parietal boss**: flat portion of parietal bone
      3. follow point from mid-pupillary line parallel to sagittal suture until it intersects line extending posteriorly from the top of the pinna
      4. ≈ 3 cm above and ≈ 3 cm posterior to top of pinna
   B. trajectory: insert the catheter parallel to skull base:
      1. initially aim for middle of forehead
      2. if this fails, aim for ipsilateral medial canthus
   C. insertion length: ideally, the tip should be just anterior to the foramen of Monro in the frontal horn[174]. Ventriculoscopic guidance (if available) increases the accuracy to a significant degree. In the absence of this:
      1. intracranial length should be ≈ two thirds of the length of the skull (this is short enough to prevent penetration of frontal brain

parenchyma, but long enough to take tip beyond the foramen of Monro to prevent catheter from ending up in the temporal horn where choroid plexus increases the chance of obstruction)
    2. in adults without macrocrania the inserted length is usually ≈ 12 cm when the burr hole is in line with the axis of the lateral ventricle[175] (lengths > 12 cm are rarely required). In hydrocephalic infants usually ≈ 7-8 cm is required
    3. use the stylet for the initial ≈ 6 cm of insertion, then remove it and insert the remaining length (keeps the catheter straight during penetration of occipital parenchyma and prevents the tip from dropping into the temporal horn where there is choroid plexus, also the temporal horn may collapse and occlude the catheter when the HCP is resolved)
2. **Keen's point** (posterior parietal): (placement in trigone) 2.5-3 cm posterior and 2.5-3 cm superior to pinna (was the usual site of occurrence of cerebral abscesses arising from otitis media, and was often used to tap these)
3. **Dandy's point**: 2 cm from midline, 3 cm above inion (may be more prone to damage visual pathways than above)

★ 4. **Kocher's point** (coronal): places catheter in frontal horn. The right side is usually used. Commonly employed for ICP monitors
   A. entry site: 2-3 cm from midline which is approximately the mid-pupillary line with forward gaze, 1 cm anterior to coronal suture (to avoid motor strip)
   B. trajectory: direct catheter perpendicular to surface of brain, which can be approximated by aiming in coronal plane towards medial canthus of ipsilateral eye and in AP plane towards EAM
   C. insertion length: advance catheter with stylet until CSF is obtained (should be < 5-7 cm depth; this may be 3-4 cm with markedly dilated ventricles). Advance catheter without stylet 1 cm deeper. ✖ CAUTION: if CSF is not obtained until very long insertion length (e.g. ≥8 cm) the tip is probably in a cistern (e.g. prepontine cistern) which is undesirable

7.13.2. Ventriculostomy/ICP monitor

AKA intraventricular catheter **(IVC)** or external ventricular drainage **(EVD)**.

Insertion technique

Unless contraindicated (e.g. right ventricular bleed), the right (non-dominant) side is preferred. Clip the hair around the planned incision site and the exit site for the tunneled catheter (avoid shaving which degrades the skin's barrier function against infection). Five minute Betadine prep.

Site: approximately Kocher's point (*see above*). To avoid motor strip, enter 1-2 cm anterior to coronal suture (estimated position of coronal suture: follow line up midway between lateral canthus and EAM), and to avoid the sagittal sinus, 2-3 cm lateral to mid-line (2 fingerbreadths or ≈ 3 cm is commonly employed as an approximation). Incision oriented in sagittal plane (in case it needs to be incorporated in flap); elevate periosteum; place self-retaining retractor; make twist drill hole. Bone-wax edges to stop bone bleeding; cauterize dura with bipolar coagulator; incise dura in cruciate fashion with #11 scalpel blade; cauterize incised dural edges and then pia/arachnoid with bipolar.

For ventriculostomy: insert catheter perpendicular to brain surface[176] to a depth of 5-7 cm (most catheters are marked at 5 and 10 cm). With any ventricular enlargement, CSF should flow at least by 3-4 cm depth (with normal ventricles, this may be 4-5 cm). If no CSF is encountered here and the catheter is passed further until CSF is obtained, it is unlikely to be due to catheterization of frontal horn of lateral ventricle (in this case, at ≈ 9-11 cm the tip will often be in the pre-pontine cistern, a subarachnoid space, which is undesirable). If unsuccessful after a maximum of three attempted passes, then place a subarachnoid bolt or intraparenchymal monitor.

For (Richmond) subarachnoid bolt: screw in until tip is flush with inner table.

Removal

Patients receiving anticoagulants need to have normal coagulation and platelet function before discontinuing the catheter to reduce the risk of intracranial hemorrhage. For heparin and LMW heparin, stop the drug 24 hours prior to discontinuing the drain.

Sump drainage"

The tip of a 25 gauge butterfly may be bent at a 90° angle, and inserted into a sub-cutaneous reservoir for prolonged ventricular drainage[177]. In one series OF 34 patients, this was used for prolonged periods (up to 44 days) with acceptably low infection rate[178]. The use of a one-way valve, continuous antibiotics (ampicillin and cloxacillin) and meticulous technique was credited for the lack

of infection.

7.13.3. Ventricular shunts

Booking the case - ventricular shunt

Also see defaults & disclaimers (*page v*).

1. position: supine with shoulder roll
2. implants: need to specify shunt manufacturer and valve type (e.g. programmable, low profile…) desired
3. equipment:
   A. C-arm for ventriculo-atrial shunts
   B. endoscopic display (e.g. if NeuroPen is used)
   C. image guided navigation system (infrequently used)
4. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery to insert a permanent drainage tube from the brain to the abdomen, outside of the lungs, vein near the heart (as appropriate) to drain excess cerebrospinal fluid
   B. alternatives: nonsurgical management (rarely effective for hydrocephalus), third ventriculostomy (for certain cases)
   C. complications: infection, suboptimal position which might require re-operation, failure to relieve hydrocephalus/symptoms, subdural hematoma, bleeding in the brain, shunts are mechanical devices and will eventually fail (break, block up, move…) and need repair/replacement (sometimes sooner rather than later). Abdominal shunts: risk of bowel injury (which could require further surgery)

Ventricular catheter

Occipital burr hole is used in most cases for insertion site of ventricular catheter (see *Ventricular catheterization* *page 207* for technique). Some prefer a frontal burr hole (Kocher's point) citing a lower incidence of failure from choroid plexus occlusion (this is controversial). The use of flanged catheters (designed to keep choroid plexus away from catheter holes) is discouraged because these actually have a higher incidence of choroid plexus occlusion and these catheters can become so entangled that removal is impossible without

significant risk of hemorrhage.

An inverted "J" shaped incision is used to keep hardware from lying directly under the skin incision (minimizes risk of skin breakdown and also creates additional barrier to infection of subjacent hardware). CSF should be sent for culture at the time of insertion since it has been estimated that in ≈ 3% of patients the CSF is already infected. 4 mg of preservative-free gentamicin may instilled into the ventricular catheter by the technique of **barbotage**, (a technique to administer a drug while reducing the amount of drug lost in the dead space of the catheter: a portion of the antibiotic solution is injected into the CSF, then a lesser amount of CSF is aspirated, a second portion is then injected and the process is repeated until all of the medication is administered).

If you think the catheter is in the ventricle, but you don't get CSF flow, it may be due to low pressure, you can compress the jugular veins or lower the head of the bed to try and induce CSF flow.

Connectors

If a connector must be used near the clavicle, placing it below the clavicle increases the risk of disconnection vs. placing the connector above the clavicle.

DISTAL CATHETER PLACEMENT

All things being equal, the general order of preference for distal catheter placement:

1. peritoneal cavity: *see below*
2. pleural space: (not for age ≤ 7 years - *see page 316*). For technique, *see below*
3. right atrium or superior vena cava: *see page 210*
4. less frequently used distal shunt sites
   A. gall bladder
   B. internal jugular vein (with the catheter pointing "upstream")
   C. superior sagittal sinus

VENTRICULOPERITONEAL SHUNT

Peritoneal catheter

For small children, use at least 30 cm length of intraperitoneal tubing to

allow for continued growth (120 cm total length of peritoneal tubing was associated with a lower revision rate for growth without significant increase in other complications[179]). A silver clip is placed at the point where the catheter enters the peritoneum so that the amount of residual intraperitoneal catheter can be determined on later films (more important in growing children).

Distal slits on the peritoneal catheter may increase the risk of distal obstruction[180], and some authors recommend that they be trimmed off. Wire reinforced catheters should not be used because of excessively high rate of viscus perforation, and this tubing was designed to prevent kinking which is not a problem with modern shunts.

Open technique: A vertical incision lateral and superior to the umbilicus is one of several choices. The following layers should be identified as they are traversed to avoid confusing preperitoneal fat with omentum and erroneously placing the tip in the preperitoneal space:

1. subcutaneous fat
2. anterior sheath of the abdominis rectus muscle (anterior rectus sheath)
3. abdominis rectus muscle fibers: should be split longitudinally
4. posterior rectus sheath
5. preperitoneal fat (may be very well developed in a few individuals, but is essentially nonexistent in most)
6. peritoneum (usually closely adherent to the posterior rectus sheath)

Trocar technique:

1. place a Foley catheter to decompress the bladder
2. 1 cm skin incision above and lateral to the umbilicus
3. pull abdominal skin anteriorly (away from patient)
4. insert trocar aiming toward the ipsilateral iliac crest
5. feel 2 “pops” of penetration: 1 = anterior rectus sheath, 2 = posterior rectus sheath/peritoneum
6. peritoneal catheter should feed easily through trocar

VP SHUNT, POST-OP ORDERS (ADULT)

1. flat in bed (to avoid overshunting and possible subdural hematoma) with gradual mobilization
2. if peritoneal end is new or revised, do not feed until bowel sounds resume (usually at least 24 hrs, due to ileus from manipulation of peritoneum)
3. shunt series (AP & lateral skull, and chest/abdominal x-ray) as baseline for

future comparison (some surgeons obtain these films immediately post-op in case some immediate revision is indicated, e.g. ventricular catheter tip in temporal horn)

VENTRICULOPLEURAL SHUNT INSERTION[181]

Not for age ≤ 7 years (*see* *page 316*). A 3 cm horizontal incision is made just below the level of the breast either in the midclavicular line or in the anterior axillary line. Divide the subcutaneous tissue, deep fascia, and pectoralis muscle. The external and internal intercostal muscles are divided along the superior margin of the inferior of the two ribs exposed (to avoid the neurovascular bundle running along the inferior margin of each rib). A self retaining retractor between the ribs aids the exposure. The parietal pleura is visualized with the visceral pleura sliding underneath with each respiration. The pleura is not opened until the catheter is brought out subcutaneously at this incision. Have the anesthesiologist hold respirations, and nick the parietal pleura (or use a blunt-tip hemostat to pop through) to admit the catheter. Allow the lung to drop away and insert 20-40 cm of tubing into the pleural cavity. If the pleural opening is lax around the catheter, it can be snugged with a 4-0 absorbable suture. Have the anesthesiologist provide a valsalva maneuver before cinching down the pleural suture, and again before closing the deep muscle layer. A chest tube is usually not required. A maneuver that may sometimes be helpful is to place a red-rubber catheter next to the shunt tube at the same time (to permit the escape of air from the pleural space). Begin closing, but prior to placing the last deep suture, have the anesthesiologist perform a valsalva maneuver and pull the red-rubber catheter and close the last stitch (the red tubber catheter permits air to exit the pleural space). Check a CXR in the recovery room for significant pneumothorax.

VENTRICULO-ATRIAL SHUNT INSERTION

Open method

The common facial vein **(CFV)** is located by making a diagonal cervical incision across the anterior border of the sternocleidomastoid at or just below the level of the angle of the mandible (the CFV may be as far as ≈ 2 cm below this point). The platysma is divided, and the CFV is located as it joins the internal jugular vein **(IJV)** at the level of the hyoid bone. The CFV is cannulated with the atrial tubing, and is secured with a snug ligature close to the junction with the IJV. If the CFV is not suitable, a purse string suture is placed directly in the IJV,

and the IJV is then opened in the center of the purse string and cannulated.

Percutaneous method

May be utilized in adults (and possibly peds). The IJV is catheterized using the Seldinger technique[182] with a guide-wire and needle through a stab wound at the anterior margin of the SCM. Fluoroscopy is used to place the tip of the wire at the desired location (*see below*). A No. 13 French peel-away introducer and dilator are then inserted over the wire, which is then bent at the skin edge and withdrawn[183] (for a pediatric case: may use a No. 7 French introducer with a 1.5 mm O.D. lumboperitoneal catheter for the distal atrial catheter). The atrial catheter is cut to the length of the wire distal to the bend, and the catheter is then threaded into the introducer. The position of the catheter tip should again be confirmed (e.g. with radioopaque contrast under fluoroscopy). A short skin incision is then made starting at the point where the catheter penetrates the skin to permit subcutaneous tunnelling of the tubing.

Location of distal tip

Placement pointer: if the catheter repeatedly goes down the wrong vessel (e.g. the subclavian vein), a “J” guidewire may help. Also, rotating the head to a more neutral position sometimes works.

The ideal location of the distal tip is in the superior vena cava **(SVC)** near the right atrium so that the turbulent blood flow will reduce the risk of thrombus formation. The tip may enter the right atrium, but must not penetrate the tricuspid valve. A number of methods for optimal placement of the distal shunt tip may be employed, and include:

1. using an intraoperative chest x-ray to locate the tip between the level of T6-T8 vertebra in an adult. In a growing child, initially insert to ≈ T10 level. This method is subject to error due to malalignment of the x-ray beam (parallax error)
2. locating the tip near the level described above, then inject iodinated contrast (e.g. 20 ml of Omnipaque 180 (iohexol), *see page 122*) under intraoperative fluoroscopy to locate the tip in SVC
3. fill the catheter with normal or 3% saline and use the catheter as an EKG electrode. The P-wave changes from a downward to a biphasic morphology as the tip enters the atrium. A sharp upward deflection occurs as the tricuspid valve is approached[184]. Some recommend advancing the tip to maximal P-wave amplitude and then backing off a centimeter or two

4. fill the catheter with heparinized saline (1-5 U per cc NS) and measure the pressure as the tip is advanced[185], leave tip just short of where atrial pressure tracing occurs
5. utilizing intraoperative echocardiography[186]

A growing patient is followed with annual CXRs. When the catheter tip is above ≈ T4, the catheter must be lengthened or converted to a VP shunt.

7.13.4. Ventricular access device

An indwelling ventricular catheter connected to a reservoir that is situated under the scalp for the purpose of chronic access to the intrathecal space (usually the ventricular system), or some other compartment. Sometimes referred to as an Ommaya® reservoir.

INDICATIONS

Indications for insertion:

1. administration of intrathecal **(IT)** antineoplastic chemotherapy:
   A. for CNS neoplasms, including: carcinomatous meningitis, CNS lymphoma or leukemia (*see page 675*)
   B. IT chemotherapy is often used for the following even in the *absence* of CNS involvement because of the high relapse rate in the CNS: acute lymphoblastic leukemia, lymphoblastic lymphoma, Burkitt's lymphoma
2. administration of intrathecal antibiotic for chronic meningitis
3. chronic removal of CSF from infants with intraventricular hemorrhage
4. for fluid aspiration from a chronic tumor cyst that is resistant to therapy (radiation or surgery)

BOOKING THE CASE - VENTRICULAR ACCESS DEVICE

Also see defaults & disclaimers (*page v*).

1. position: supine
2. equipment
   A. endoscopic display (e.g. if NeuroPen is used)
   B. C-arm (optional) to verify position of ventricular catheter

C. image guided navigation system (if used)
3. implants: need to specify reservoir manufacturer
4. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery to insert a tube into the fluid space within the brain (ventricle) which is connected to a port under the skin so that fluids can be removed or injected (usually medication)
   B. alternatives: sometimes fluid can be removed and medication can be injected using a lumbar puncture (spinal tap). The effectiveness of this may not be the same as the operation being discussed here
   C. complications: infection, suboptimal position which might require re-operation, subdural hematoma, bleeding in the brain, this is a mechanical device and may eventually fail (break, block up…) and need repair/replacement

TECHNIQUE OF INSERTION[187]

Preferably placed in the right frontal region, unless indicated otherwise (e.g. for tumor cyst). Usually placed under endotracheal general anesthesia, although local anesthesia occasionally may be used (e.g. for patients too ill to tolerate general anesthesia).

Patient position: supine, head midline, neck flexed 5°.

Incision: inverted "U", slightly larger than the reservoir (the original Ommaya® reservoir is 3.4 cm diameter), with the center over the coronal suture approximately 3 cm from midline (roughly centered near Kocher's point, *see page 207*). A circle of pericranium of diameter equal to that of the reservoir is excised and saved. Alternatively, the pericranium may be flapped separately in the opposite direction (i.e. a right-side-up "U"), and closed over the reservoir to help secure it in position.

Make a burr hole over the coronal suture 3 cm off midline. A cruciate incision in the dura is made large enough to visualize the cortical surface, minimal cortical bipolar coagulation is used, and a pial/cortical incision is made to avoid surface vessels.

One may inject 15-20 cc of filtered air into the ventricles with a ventricular needle prior to the catheter insertion to guide the tip of the catheter with intraoperative lateral skull x-rays (intraoperative pneumoencephalogram). The trajectory is towards a point intersecting a plane 2 cm anterior to the EAM aiming minimally towards the midline (1-2°). Alternatively, one may aim perpendicular to the surface of the skull[176]. A total length of **≈ 7.25 cm** of catheter is fixed to the base of the reservoir which allows the catheter to lie on

the floor of the anterior horn of the lateral ventricle in most adults. This location can be verified with intraoperative pneumoencephalography[187] or with ventriculoscopic techniques.

The excised pericranium is placed over the dura, and the reservoir is sutured to the pericranium. Note: the dome of the original Ommaya® reservoir has a low resistance, and may be easily collapsed if too much tension is placed on the overlying scalp. If early use of the reservoir is desired (i.e. within 48 hrs post-op), the skin closure should be performed with a running nonabsorbable suture (e.g. nylon) and coated with collodion, and the surgical site can then be left without a gauze dressing for easier access to the reservoir. A skin tattoo can be created over the center of the reservoir (to assist in localizing the reservoir for injection) using India ink and a pricking the skin with a sterile needle.

RESERVOIR PUNCTURE

The scalp is prepped with antimicrobial scrub, and using sterile technique, a 25 gauge or smaller butterfly needle is introduced at an oblique angle, preferably with a non-coring needle. The original (Ommaya®) reservoir has firm plastic bottom surface which can be penetrated if too much force is applied.

7.13.5. Third ventriculostomy

See page 315 for indications and complications.

Older techniques include a subfrontal approach, opening the chiasmatic and lamina terminalis cisterns, and making a 5-10 mm opening in the lamina terminalis. Stereotactic third ventriculostomy (using contrast ventriculography[188] or CT guided) has also been described. Current technique consists of fenestrating the floor of the third ventricle using the ventriculoscope.

Ventriculoscopic technique

1. equipment: requires a rigid endoscope (does not work well with flexible)
2. image guided stereotactic technology helps immensely with the trajectory, but once you've entered the third ventricle, you must navigate by visual landmarks and cannot rely on image guidance because of the limitations of the accuracy
3. burr hole: 2-3 cm lateral to the midline just anterior to the coronal suture
4. pass through the foramen of Monro
5. the floor of the third ventricle is inspected and must be thin enough and

translucent enough to permit visualization of the basilar artery and mammillary bodies. If these structures cannot be visualized then the procedure should be aborted

6. the location of the opening is chosen:
   A. in the midline
   B. in the region of the tuber cinereum (prominence of the base of the hypothalamus, extending ventrally into the infundibulum and pituitary stalk)
   C. posterior to the infundibular recess
   D. anterior to the mammillary bodies
   E. anterior to the tip of the basilar artery
7. an effective technique consists of “rubbing through” the floor of the third ventricle either with a probe or with the tip of the scope itself. Alternatively, electrocautery may be used to thin down the lamina. ✖ Do not use laser due to possibility of injury to basilar artery[189]!
8. the opening can be enlarged with the use of a Fogarty catheter if needed. The balloon is inflated distal to the opening in the floor and is then withdrawn through the opening
9. the opening does not need to be large (unlike e.g. fenestrating an arachnoid cyst): ≈ 4-5 mm is usually adequate[190, 191]
10. after penetrating through the floor of the third ventricle, make certain that you can see vessels (sometimes the arachnoid is not perforated, or there is a second membrane or webs of membranes that need to be lysed)

Complications

(also, *see page 315*)

1. injury/perforation of the basilar artery
2. injury to the pituitary stalk or pituitary gland

7.13.6. LP shunt placement

TECHNIQUE OF INSERTION[192]

1. position: lateral decubitus position, both knees flexed (right side up preferred)
2. prep back, flank and abdomen

3. 1 cm skin incision over L4-5 or L5-S1 (in obese patients, use larger skin incision carried down to fascia overlying spinous processes. This may also be superficially incised between spinous processes to aid insertion)
4. tilt table to 30° reverse-Trendelenburg to expand lumbar subarachnoid space
5. insert 14 gauge Tuohy needle into subarachnoid space, with opening directed rostrally (caudal placement also acceptable). Confirm placement by CSF flow
6. remove trocar, insert shunt tubing such that **≤ 8 cm** of catheter (for L4-5 insertion) lies within spinal canal (minimizes conus medullaris irritation)
7. needle then withdrawn over catheter
8. make flank incision, pass tunneler from flank to back incision. Feed catheter from back to flank. Withdraw tunneler over catheter
9. abdominal placement:
    A. open: incision made through peritoneum. Catgut (or other absorbable suture) purse-string placed in peritoneal opening
    B. trocar
10. pass tunneler from abdominal incision to flank incision. Feed catheter from flank to abdomen. Withdraw tunneler over catheter
11. verify CSF flow. Place catheter inside peritoneum. For open technique: cinch purse-string snugly, but loose enough to allow catheter to slide with gentle pushing
12. snug fitting retaining sleeve placed around catheter at all three incisions, and secured to subcutaneous tissue with non-absorbable suture

LUMBOPERITONEAL (LP) SHUNT EVALUATION

When problems develop, evaluation of function may be more difficult than with VP shunt. Evaluation may include:

1. **abdominal x-rays**: AP & lateral x-rays can rule out breakage or migration of a shunt component
2. **noncontrast brain CT**: can rule-out complication such as subdural hematoma
3. **LP**: perform LP just above or below level of lumbar catheter. The pressure may be 0 or negative, and it may be necessary to aspirate CSF to confirm placement
    A. can give indirect evidence of shunt function by measuring the CSF pressure, which should be low if the shunt is working (only helpful in

cases where the shunt was placed for elevated CSF pressure, e.g. pseudotumor cerebri; not helpful in NPH).

B. "shunt-o-gram": inject contrast into subarachnoid space through LP needle

1. radionuclide: inject radio-isotope via LP and look for subsequent tracer activity in peritoneal cavity (*see page 324*)
2. with water-soluble contrast[193]: inject 10 ml of iohexol and monitor the flow of contrast fluoroscopically as the patient is brought vertical. Coughing or valsalva maneuver will accelerate the flow of contrast

4. **shunt tap**: if an antechamber has been installed, it is accessed after cleaning the skin with antiseptic using a 22 Ga. or smaller needle placed perpendicular to the dome to prevent leakage. If there is no access chamber, it is sometimes possible to tap the tubing itself with a 27 gauge butterfly needle

7.14. Sural nerve biopsy

Although a number of peripheral nerves may be biopsied, the sural nerve fulfills the criteria of being well studied, expendable with minimal deficit, easily accessible, and often involved in the pathologic process in question.

Indications

Nerve biopsy plays a small role in diagnosing peripheral neuropathies, but may be very accurate for vasculitis, amyloidosis, Hansen's disease, metachromatic and globoid leukodystrophy, neoplastic infiltration of peripheral nerve, and relapsing polyneuritis[194 (p 316)]. May help distinguish the two types of Charcot-Marie-Tooth syndrome. May show demyelination in diabetic amyotrophy (*see page 796*).

Anatomy

The sural nerve is formed by the merging of the distal portion of the medial sural cutaneous nerve (one of the terminal branches of the tibial nerve) and the anastomotic ramus of the common peroneal nerve. It is entirely sensory except for some unmyelinated autonomic fibers. It supplies cutaneous sensation to the posterolateral third of the leg, the lateral heel and foot, and the little toe. At the

level of the ankle it lies between the Achilles tendon and the lateral malleolus. This location is constant, superficial, and relatively protected from external trauma which might otherwise confuse the analysis.

Technique

Modified technique[195 (p 771-2)]. Usually done under local anesthesia with sedation. Position: patient prone or three-quarters prone, pillow between the legs. The leg to be biopsied is uppermost and is flexed 90° at the knee to relax tension on the nerve, the ankle is slightly everted. Compressing the calf distends the lesser saphenous vein **(LSV)** at the lateral malleolus **(LM)**, which (when visible) reliably locates the sural nerve usually deep and anterior to the vein. A sterile Penrose drain is useful as a temporary tourniquet for this purpose during surgery.

After prepping, drape the limb with a sterile stockinette or similar drape, infiltrate local anesthetic subcutaneously just posterior to the LM and proximally, paralleling the Achilles tendon for ≈ 10 cm. A 7-10 cm incision is made overlying the course of the LSV beginning usually just posterior to and ≈ 1 cm proximal to the LM. The vein can be seen through the translucent Scarpa's fascia. The fascia is incised over the vein which is gently retracted to reveal the nerve usually deep to the vein. A common pitfall is to go too deep, the nerve is fairly superficial; it is not necessary to go through the thick fascia. If at any time you see tendons to the toes, you have gone too deep.

To differentiate the sural nerve from the LSV (which may resemble the nerve in some cases): the nerve has many branches at acute angles especially proximal to the LM, vs. the vein which has right angle branches. A nerve stimulator and/or frozen section may also be helpful (frozen section just to verify that the biopsied structure is a nerve) and one or the other is *highly recommended* to avoid potentially embarrassing explanations and the possible need to repeat the procedure.

After exposing at least 3-5 cm of the nerve, anesthetize the proximal portion with 0.5% lidocaine using a 27 Ga. needle and cut it sharply just distal to the infiltration site (note: sometimes a biopsy of only a portion of the nerve's fascicles may suffice: this is accomplished by opening the epineurium for the length of the exposure and teasing out a fascicle with minimal branching). Cut the nerve with slight tension on it to allow the ends to retract deep to the skin incision to prevent the formation of a scar neuroma. Some pathologists request that the proximal end of the nerve be marked, e.g. with a suture.

An elastic pressure dressing is applied after closure.

If it is desired to obtain a biopsy of the sural nerve higher up for comparison, it may be accessed in the mid upper calf between the heads of the gastrocnemius muscle. Here it may be as deep as ≈ 2 cm. Gently tugging on the exposed nerve in the ankle may help in localization.

Post op care: Pressure dressing should be worn for protection for two weeks. The patient is allowed to walk but should restrict their activity for 2-3 days. If nonabsorbable sutures are used instead of subcuticular closure, they should be left in place 10-14 days.

NERVE HANDLING

For light microscopy which suffices in most cases, immerse the nerve in formalin. For electron microscopy, glutaraldehyde is used. For biochemical and immunofluorescence studies, use rapid freezing.

RISKS OF PROCEDURE

1. sensory loss in the sural nerve distribution is *expected*, but often does not persist for more than several weeks (unless the underlying disease process prevents this)
2. problems with wound healing: the ankle is a notorious region for poor circulation and the loss of sensation (from the disease or biopsy) may render the area subject to repeated trauma without the patient being aware. Furthermore, many patients with an undiagnosed systemic disease requiring a sural nerve biopsy will have poor wound healing (a significant number are also diabetic)
3. failure to make a diagnosis: although biopsy may be able to exclude some contingencies, it often does not make a specific diagnosis

7.15. Nerve blocks

Also see *Occipital nerve block*, page 805.

7.15.1. Stellate ganglion block

✖ Do not perform stellate ganglion block bilaterally (can cause bilateral laryngeal paralysis → respiratory compromise). Stellate ganglion is actually

closer to C7 than C6, but risks at C7 are much higher (closer to pleura → pneumothorax, vertebral artery → arterial injection → seizures and/or hematoma, recurrent laryngeal nerve → unilateral vocal cord paralysis → hoarseness (common), brachial plexus → UE weakness). Other complications: intradural injection → spinal anesthesia, phrenic nerve block.

Technique

Patient supine; interscapular roll; head tilted backward, mouth slightly open to relax strap muscles. Displace SCM and carotid sheath laterally, insert 1.5 inch 22 Ga. needle to contact **Chassaignac's tubercle** (anterior tubercle of transverse process of C6) AKA **carotid tubercle** (the most prominent in the C-spine) usually at the level of the cricoid cartilage, approximately 1.5-2 inches above clavicle.

Withdraw needle 1-2 mm and aspirate (do not inject intravascularly). Inject small test dose, then full 10 ml of 0.5% bipuvicaine (Marcaine®) or 20 ml of 1% lidocaine. Remove needle and elevate patient's head on pillow to facilitate spread.

Verify block by Horner's syndrome, and anhidrosis and increased warmth of ipsilateral hand.

7.15.2. Lumbar sympathetic block

Technique

Patient prone on fluoro table. Use local anesthetic to allow insertion of 20-22 gauge spinal needles (10 to 12.5 cm long) at L2, L3 and L4 levels. Needle inserted 4.5-5 cm lateral to spinous process until transverse process contacted, then redirected caudally and inserted to a depth 3.5-4 cm deeper than transverse process. Final needle tip position should be just anterolateral to vertebral bodies. At each level, instill ≈ 8 ml of 1% lidocaine local after verifying that nothing can be aspirated.

Keep patient on bed rest for several hours, then ambulate with assist; watch for orthostatic hypotension due to vascular pooling in blocked lower extremity.

7.15.3. Intercostal nerve block

Indications

1. postthoracotomy pain
2. intercostal neuralgia
3. postherpetic neuralgia
4. pain from rib fractures

Procedure

In order to obtain good anesthesia, the following should be noted:

1. a good site for injection is in the posterior axillary line **(PAL)** because
   A. this is proximal to the origin of the lateral cutaneous nerve (which originates ≈ in the anterior axillary line)
   B. this avoids the scapula for nerves above ≈ T7
   C. this reduces the risk of pneumothorax from injecting closer to the spine (the latter requires a longer needle path and there is increased difficulty palpating landmarks)
2. due to overlap, at least 3 intercostal nerves usually need to be blocked to achieve at least some area of anesthesia; it is usually necessary to block 1-2 intercostal nerves both above and below the affected dermatome
3. the intercostal nerves lie on the undersurface of the corresponding rib in close proximity to the pleura; the order of structures from top down is: rib, vein, artery, nerve

Technique

1. after raising a skin wheal at the desired level in the PAL, insert a 22 Ga. or smaller needle directly against the rib
2. walk the needle down the rib millimeter by millimeter until the needle just slips under the rib; to avoid pleural puncture, do not advance the needle more than one-eighth inch deep to the anterior surface of the rib
3. aspirate to be certain that there is no air (from lung penetration) or blood (from entering the intercostal artery or vein)
4. if no air or blood returns, inject 3-5 ml of local anesthetic
5. if there is any question about lung penetration, obtain a portable CXR to R/O pneumothorax

8. Developmental anomalies

8.1. Arachnoid cysts

8.1.1. Arachnoid cysts, intracranial

Key concepts:

- a congenital abnormality, most common in middle fossa, cerebellopontine angle **(CPA)**, suprasellar region, and posterior fossa
- usually an incidental finding
- imaging often shows remodeling of bone; imaging characteristics exactly mimic CSF on CT or MRI in most cases
- recommendation for incidentally discovered arachnoid cyst in adults: a single follow-up imaging study in 6-8 months is usually adequate to rule-out any increase in size. Subsequent studies only if concerning symptoms develop

AKA **leptomeningeal cysts**, distinct from *posttraumatic* leptomeningeal cysts (AKA growing skull fractures, *see page 892*), and unrelated to infection. Arachnoid cysts **(AC)** are congenital lesions that arise during development from splitting of arachnoid membrane (thus they are technically *intra-arachnoid* cysts) and contain fluid that is usually identical to CSF. They do not communicate with the ventricles or subarachnoid space. May be unloculated or may have septations. Typically lined with meningothelial cells positive for epithelial membrane antigen **(EMA)** and negative for carcinoembryonic antigen (CEA). AC may also occur in the spinal canal.

"Temporal lobe agenesis syndrome" is a label that had been used to describe the findings with middle cranial fossa ACs. This term is now obsolete since brain volumes on each side are actually the same[1], bone expansion and shift of brain matter account for the parenchyma that appears to be replaced by the AC.

Two types of histological findings[2]:

1. “simple arachnoid cysts”: arachnoid lining with cells that appear to be capable of active CSF secretion. Middle fossa cysts seem to be exclusively of this type
2. cysts with more complex lining which may also contain neuroglia, ependyma, and other tissue types

EPIDEMIOLOGY OF INTRACRANIAL ARACHNOID CYSTS

Incidence: 5 per 1000 in autopsy series. Comprise ≈ 1% of intracranial masses.

Male:female ratio is 4:1. More common on the left side.

Bilateral arachnoid cysts may occur in Hurler syndrome (a mucopolysaccharidosis).

Table 8-1 Distribution of arachnoid cysts[6]

Location	%
sylvian fissure	49%
CPA	11%
supracollicular	10%
vermian	9%
sellar & suprasellar	9%
interhemispheric	5%
cerebral convexity	4%
clival	3%

DISTRIBUTION

Almost all occur in relation to an arachnoid cistern (exception: intrasellar, the only one that is extradural), *see Table 8-1*.

Epidermoid cysts in the cerebellopontine angle **(CPA)** may mimic an arachnoid cyst, but are high signal on DWI MRI (*see page 690*).

For the differential diagnosis of midline posterior fossa arachnoid cysts, (*see page 240*).

PRESENTATION

Most ACs are asymptomatic. Those that become symptomatic usually do so in early childhood[3]. The presentation varies with location of the cyst, and oftentimes appear mild considering the large size of some.

Typical presentations are shown in *Table 8-2*[3] and include:

1. symptoms of intracranial hypertension (elevated ICP): H/A, N/V, lethargy
2. seizures
3. sudden deterioration:
   A. due to hemorrhage (into cyst or subdural compartment): middle fossa cysts are notorious for hemorrhage due to tearing of bridging veins. Some sports organizations do not allow participation in contact sports for these patients
   B. due to rupture of the cyst
4. as a focal protrusion of the skull
5. with focal signs/symptoms of a space occupying lesion
6. incidental finding discovered during evaluation for unrelated condition
7. suprasellar cysts may additionally present with[4]:
   A. hydrocephalus (probably due to compression of the third ventricle)
   B. endocrine symptoms: occurs in up to 60%. Includes precocious puberty
   C. head bobbing (the so-called “bobble-head doll syndrome”[5]): considered suggestive of suprasellar cysts, but occurs in as few as 10%
   D. visual impairment

Table 8-2 Typical presentations of arachnoid cysts

Middle fossa cysts	Suprasellar cysts with hydrocephalus	Diffuse supra- or infratentorial cysts with hydrocephalus
seizures headache hemiparesis	intracranial hypertension craniomegaly developmental delay visual loss precocious puberty bobble-head doll syndrome	intracranial hypertension craniomegaly developmental delay

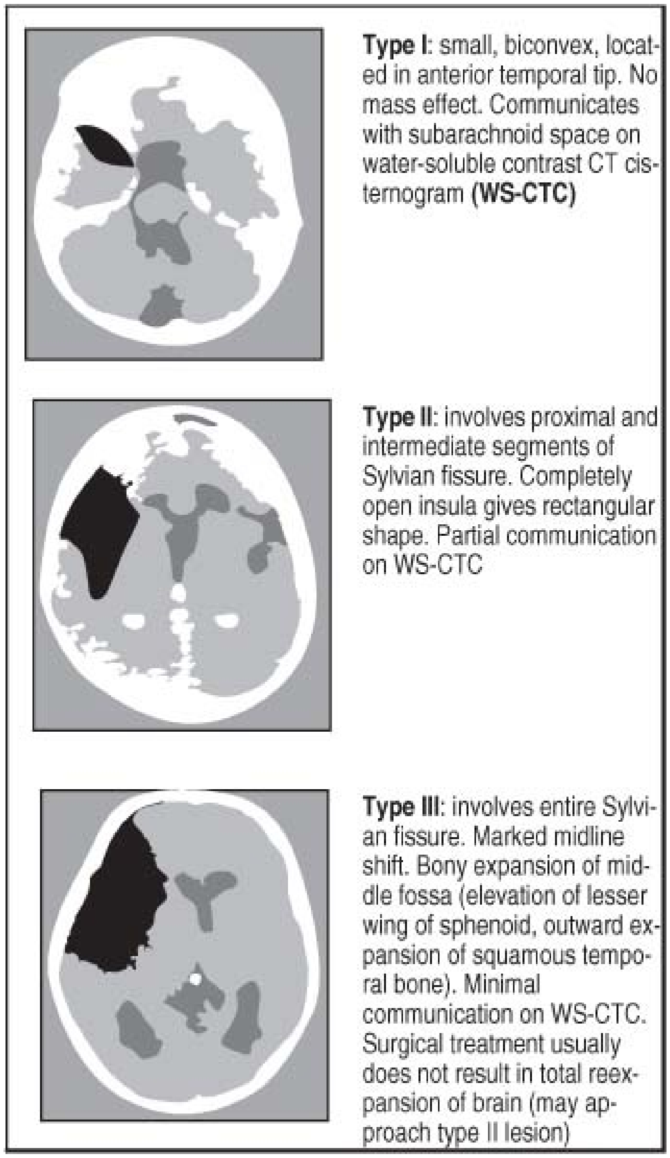

Figure 8-1 CT Classification of Sylvian fissure cysts[7]

EVALUATION

Routine evaluation with CT or MRI is usually satisfactory. Further evaluation with CSF contrast or flow studies (cisternograms, ventriculograms…) are only occasionally necessary for the diagnosis of midline suprasellar and posterior fossa lesions[3] (for Differential diagnosis, *see Intracranial cysts*, page 1217). See *Figure 8-1* for classification for middle fossa cysts.

CT SCAN

Smooth bordered non-calcified extraparenchymal cystic mass with density

similar to CSF and no enhancement with IV contrast. Expansion of nearby bone by remodelling is usually seen, confirming their chronic nature. Often associated with ventriculomegaly (in 64% of supratentorial and 80% of infratentorial cysts).

Convexity or middle fossa cysts exert mass effect on adjacent brain and may compress ipsilateral lateral ventricle and cause midline shift. Suprasellar, quadrigeminal plate, and midline posterior-fossa cysts may compress the third and fourth ventricle and cause hydrocephalus by obstructing the foramina of Monro or the Sylvian aqueduct.

MRI

Better than CT in differentiating the CSF contained in arachnoid cysts from the fluid of neoplastic cysts. May also show cyst walls.

Cisternograms and/or ventriculograms

Using either iodinated contrast or radionuclide tracers. Variable rate of opacification has resulted in difficulty correlating results with operative findings. Some cysts are actually diverticula, and may fill with radiotracer or contrast.

Treatment

Many (but not all) authors recommend not treating arachnoid cysts that do not cause mass effect or symptoms, regardless of their size and location. For incidentally discovered arachnoid cyst in an adult not considered for surgery: a single follow-up imaging study in 6-8 months is usually adequate to rule-out any changes (since they may grow in size). Subsequent studies may be done if concerning symptoms develop. Pediatric patients may need to be followed until adulthood.

Surgical treatment options are summarized in *Table 8-3*.

Table 8-3 Surgical treatment options for arachnoid cysts

Procedure	Advantages	Disadvantages
drainage by needle aspiration or burr hole evacuation	• simple • quick	• high rate of recurrence of cyst and neurologic deficit
craniotomy, excising cyst wall and fenestrating it into basal cisterns	• permits direct inspection of cyst (may help with diagnosis) • loculated cysts (rare) treated more effectively • avoids permanent shunt (in some cases)	• subsequent scarring may block fenestration allowing reaccumulation of cyst • flow through subarachnoid space may be deficient; many patients develop shunt dependency post-op • significant morbidity and mortality (may be due to abrupt decompression)

	• allows visualization of bridging vessels (small advantage)	
endoscopic cyst fenestration through a burr hole[8]	• as above	• as above
shunting of cyst into peritoneum or into vascular system	• definitive treatment • low morbidity/mortality • low rate of recurrence	• patient becomes "shunt dependent" • risk of infection of foreign body (shunt)

CYST SHUNTING

Probably the best overall treatment. For shunting into peritoneum, use a low pressure valve. If there is concurrent ventriculomegaly, one may simultaneously place a ventricular shunt (e.g. through a "Y" connector). Ultrasound, ventriculoscope, or image guidance may assist in locating suprasellar cysts. Shunting of middle fossa ACs may also be accomplished through the lateral ventricle, thus shunting both compartments[9].

✖ NB: in running the shunt tubing from the middle fossa, it should be routed behind the ear (do not tunnel caudally in front of ear to avoid injury to facial nerve).

SUPRASELLAR CYSTS

Treatments proposed include:

1. transcallosal cystectomy[10]
2. percutaneous ventriculo-cystostomy: procedure of choice of Pierre-Kahn et al.[4]. Performed via a paramedian coronal burr hole through the lateral ventricle and foramen of Monro (may be facilitated by using a ventriculoscope[8])
3. subfrontal approach (for fenestration or removal): dangerous and ineffective[4]

✖ ventricular drainage: ineffective (actually promotes cyst enlargement)

OUTCOME

Even following successful treatment a portion of the cyst may remain due to the remodeling of the bone and chronic shift of brain contents. Hydrocephalus may develop following treatment. Endocrinopathies tend to persist even after successful treatment of suprasellar cysts.

8.1.2. Arachnoid cysts, spinal

Almost always dorsal, most common in thoracic spine. With a ventral cyst, consider a neurenteric cyst (*see below*). Most are actually extradural and these are sometimes referred to as arachnoid diverticula - these may be associated with kyphoscoliosis in juveniles or with spinal dysraphism. Intradural arachnoid cysts may be congenital or may follow infection or trauma.

Usually asymptomatic, even if large.

TREATMENT

When indicated, treatment options include:

1. percutaneous procedures: may be done under MRI[11] or CT guidance. CT guidance usually requires use of intrathecal contrast to delineate the cyst
   A. needle aspiration
   B. needle fenestration[11]
2. open surgical resection or fenestration

8.2. Intracranial lipomas

Intracranial and intraspinal lipomas are felt to be of maldevelopmental origin[12 (p 706)] and may arise from failure of involution of the primitive meninges[13].

Epidemiology of intracranial lipomas

Incidence: 8 in 10,000 autopsies. Usually found in or near the midsagittal plane, particularly over the corpus callosum (lipomas in this region are frequently associated with agenesis of the corpus callosum, *see page 246*). The tuber cinereum and quadrigeminal plate are less frequently affected[14]. Rarely, the CP angle or cerebellar vermis may be involved. May occur in isolation, but also has been described in association with a number of congenital anomalies, including: trisomy 21, Pai's syndrome, frontal encephalocele, facial anomalies…. Other midline abnormalities may also be found: agenesis of the corpus callosum, myelomeningocele, and spina bifida[13].

Evaluation

May be diagnosed by CT, MRI (study of choice), and by ultrasound in

infants.

CT: Low density, may have peripheral calcification (difficult to appreciate on MRI)[13]. Differential diagnosis on CT: primarily between dermoid cyst, teratoma[15] and germinoma[13].

MRI: characteristic finding is a midline lesion with signal characteristics of fat (high intensity on T1WI, low intensity on T2WI).

Presentation

Often discovered incidentally. Large lipomas may be associated with seizures, hypothalamic dysfunction, or hydrocephalus (possibly from compression of the aqueduct). Associated findings that may or may not be directly related: mental retardation, behavioral disorders and headache.

Treatment

Direct surgical approach is seldom necessary for intracranial lipomas[15]. Shunting may be required for cases where hydrocephalus results from obstruction of CSF circulation[15].

8.3. Hypothalamic hamartomas

Key concepts:

> - rare, non-neoplastic congenital malformation, usually occurs in tuber cinereum
> - may be parahypothalamic (pedunculated) or intrahypothalamic (sessile)
> - presentation: precocious puberty, seizures (usually starting with gelastic seizures (brief unprovoked laughter)), developmental delay
> - treatment: GnRH analogs for precocious puberty. Latero-basal craniotomy for pedunculated lesions, transcallosal interforniceal approach for intrahypothalamic lesions, option of endoscopic approach for lesions ≤ 1.5 cm dia, stereotactic radiosurgery may be an alternative

Hypothalamic hamartomas[A] **(HH)** AKA diencephalic hamartomas or hamartomas of the tuber cinereum. Rare, non-neoplastic congenital malformations arising from inferior hypothalamus or tuber cinereum (floor of

the third ventricle between the infundibular stalk and the mammillary bodies). May occur as part of **Pallister-Hall syndrome** (genetics: AD inherited defect in GL[13] gene resulting in abnormally short GL[13] protein which participates in normal shaping of many organs).

A. hamartoma: an abnormal conglomeration of cells normally found in the same area

Clinical findings

1. specific types of seizures:
    A. **gelastic seizures** (brief episodes of unprovoked laughter[16]) are the most characteristic type and are the earliest seizure manifestation. Present in up to 92% of patients[17]. They are resistant to medical management and can lead to cognitive and behavioral deficits[18]. Not pathognomonic. A neocortical origin has been described[19]
    B. **epileptic encephalopathy**: gelastic fits gradually increase in frequency and other seizure types accrue: complex partial seizures, drop attacks, tonic seizures, tonic-clonic seizures, and secondarily generalized seizures. This phase is associated with marked deterioration of cognitive and behavioral abilities. Develops in 52% by a mean age of 7 years[17]
2. **precocious puberty**: believed to be due to release of gonadotropin-releasing hormone **(GnRH)** found within hamartoma cells[20]. HH are the most common CNS tumor to cause precocious puberty, other causes include: other CNS tumors (astrocytoma, ependymoma, pineal tumors (*see page 692*), optic/hypothalamic gliomas (especially in NFT patients)), CNS XRT, hydrocephalus, CNS inflammation, septo-optic dysplasia (*see page 247*), and chronic hypothyroidism
3. developmental delay: primarily in patients with seizure disorder (severity correlates with duration of seizures). 46% of patients have borderline intellectual function (mental retardation)
4. behavioral disturbances[21]: aggressive behavior, rage attacks…

Imaging

MRI: nonenhancing, isointense on T1WI, slightly hyperintense or isointense

on T2WI[22].

Pathology

Two subtypes of hypothalamic hamartomas[17, 22]:

1. **pedunculated** or parahypothalamic: narrower base attached to the floor of the hypothalamus (not arising within hypothalamus). No distortion of 3rd ventricle. Generally associated with precocious puberty more than seizures
2. **intrathalamic** or sessile: within hypothalamus (distorting the 3rd ventricle) or broad attachment to hypothalamus. More often associated with seizures. 66% have developmental delay, 50% have precocious puberty

Microscopic pathology: Clusters of disorganized small neurons surrounded by large pyramidal like neurons in an astrocyte-rich neuropil[23] (in contrast to the usual ganglion cells surrounded by oligodendrocytes found in the hypothalamus).

Treatment

Precocious puberty usually responds well to GnRH analogs[24].

Indications for surgery:

1. precocious puberty that fails to respond to medical therapy (GnRH analogs)
2. seizures that cannot be adequately controlled medically. Post-op seizure control is related to completeness of resection
3. neurologic deficit from mass effect of the tumor

Options:

1. surgical resection
   A. pedunculated lesions: approaches include[25] subtemporal, subfrontal, pterional, orbitozygomatic (most commonly recommended). Risks: cranial neuropathy, CVA[25]
   B. sessile lesions with intraventricular component: transcallosal anterior interforniceal approach[26-28]. Risks: memory impairment (forniceal injury), endocrine disturbances, weight gain[26, 28]
   C. neuroendoscopic approach: considered for HH $\leq$ 1.5 cm diameter[29]. Risks: 25% incidence of thalamic cerebrovascular injury

2. stereotactic radiosurgery: especially for small sessile lesions, subtotal resection, or patients refusing or not candidates for surgery. In small series, 3-year outcome showed improvement similar to surgical resection with less neurologic and endocrinologic morbidity[30, 31]

8.4. Neurenteric cysts

No uniformly accepted nomenclature. Working definition: CNS cyst lined by endot-helium primarily resembling that of the GI tract, or less often, respiratory tract. Congenital. Not true neoplasms. Most common alternate term: **enterogenous cyst**. Less common terms include: teratomatous cyst, intestinoma, archenteric cyst[32], enterogene cyst, and endodermal cyst. Usually affect the upper thoracic and lower cervical spine[33]. Associated developmental vertebral anomalies (e.g. diastematomyelia) are common[34]. Rarely intracranial (*see below*). Spinal neurenteric cysts **(NEC)** may have a fistulous or fibrous connection to the GI tract (through a spinal dysraphism) and some call these **endodermal sinus cysts**. Occurs as a result of persistence of the neurenteric canal (temporary duct between the notochord and the primitive gut (amniotic and yolk sacs) formed during week 3 of embryogenesis).

Intracranial neurenteric cysts: Rare, most common in p-fossa. Initially, may be difficult to rule-out metastasis from an extremely well-differentiated primary adenocarcinoma of unknown origin (absence of progressive disease suggests NEC). Locations:

1. posterior fossa
   A. cerebellopontine angle **(CPA)**[32]: usually intradural, extraaxial (case report of extradural lesion with bone destruction[35])
   B. in midline anterior to brainstem[33]
   C. cisterna magna[36]
2. supratentorial: only 15 case reports as of 2004[37]. Locations: suprasellar[38] (possible confusion with Rathke's cleft cyst), frontal lobe intraparenchymal[37], quadrigeminal plate region, dural-based extra-axial. Source of endoderm is controversial since the primitive foregut extends cranially only to the midbrain[39]. Theory: colloid cysts, Rathke cleft cysts, and supratentorial NECs may all arise from remnants of Seesel's pouch, a transient endodermally derived diverticulum of the cranial end of the

embryonic foregut[40]

Clinical

Most commonly present during the first decade of life[34]. Pain or myelopathy from the intraspinal mass are the most common presentations in older children and adults. Neonates and young children may present with cardiorespiratory compromise from an intrathoracic mass, or with cervical spinal cord compression[34]. Meningitis may occur from the fistulous tract, especially in newborns and infants.

Imaging

Intracranial NEC:

- CT: usually low density, nonenhancing[41]
- T1WI MRI: isointense or slightly hyperintense to CSF (may be hyperintense if there are blood products). T2WI isointense to CSF[41]. Nonenhancing

Histology

Most are simple cysts lined by cuboidal-columnar epithelium and mucin secreting goblet cells. Less common types of epithelium described include: stratified squamous and pseudostratified columnar, and ciliated epithelial cells. Mesodermal components may be present, including smooth muscle and adipose tissue, and some have called these teratomatous cysts[42, 43] which is not to be confused with teratomas which are true germinal cell neoplasms. May be histologically identical to colloid cysts.

Treatment

Spinal NEC: Surgical removal usually reverses the symptoms. Recurrence is uncommon with complete removal of cyst wall.

Intracranial NEC: Capsule adherent to brainstem may prevent complete resection, which predisposes to delayed recurrence. Apparently successful treatment by evacuation of contents and marsupialization has been reported (5 cases, mean follow-up: 5 yrs[44]). Incomplete removal requires long-term follow-up. Hydrocephalus is shunted if indicated.

8.5. Craniofacial development

8.5.1. Normal development

FONTANELLES

Anterior fontanelle: the largest fontanelle. Diamond shaped, 4 cm (AP) **x** 2.5 cm (transverse) at birth. Normally closes by age 2.5 yrs.

Posterior fontanelle: triangular. Normally closes by age 2-3 mos.

Sphenoid and mastoid fontanelles: small, irregular. Normally, former closes by age 2-3 mos, latter by age 1 yr.

CRANIAL VAULT

Growth: largely determined by growth of brain; 90% of adult head size is achieved by age 1 yr; 95% by age 6 yrs. Growth essentially ceases at age 7 yrs. By end of 2nd yr, bones have interlocked at sutures and further growth occurs by accretion and absorption.

Skull is unilaminar at birth. Diplöe appear by 4th yr and reach a maximum by age 35 yrs (when diploic veins form).

Mastoid process: formation commences by age 2 yrs, air cell formation occurs during 6th yr.

8.5.2. Craniosynostosis

Originally called craniostenosis. Incidence: ≈ 0.6/1000 live births.

Primarily a prenatal deformity, postnatal craniosynostosis **(CSO)** occurs uncommonly (postnatal causes consist primarily of positional alterations which may not represent true synostosis). CSO is rarely associated with hydrocephalus **(HCP)**[45]. The assertion that CSO may follow CSF shunting for HCP is unproven (*see page 328*). Other causes for failure of normal skull growth include lack of brain growth due to any of the causes of arrested development of the cerebral hemispheres (lissencephaly, micropolygyria, some cases of hydranencephaly…).

Treatment is usually surgical. In most instances, the indication for surgery is for cosmesis and to prevent the severe psychological effects of having a disfiguring deformity. However, with multiple CSO, brain growth may be

impeded by the unyielding skull. Also, ICP may be pathologically elevated, and although this is more common in multiple CSO[46], elevated ICP occurs in ≈ 11% of cases with a single stenotic suture. Coronal synostosis can cause amblyopia. Most cases of single suture involvement can be treated with linear excision of the suture. Involvement of multiple sutures or the skull base usually requires the combined efforts of a neurosurgeon and craniofacial surgeon, and may need to be staged in some cases. Risks of surgery include: blood loss, seizures, stroke.

DIAGNOSIS

Many cases of "synostosis" are really due to positional flattening (e.g. "lazy lamb-doid", *see below*). If this is suspected, instruct parents to keep head off of flattened area and recheck patient in 6-8 weeks: if it was positional, it should be improved, if it was CSO then it usually declares itself. The diagnosis of CSO may be aided by:

1. palpation of a bony prominence over the suspected synostotic suture (exception: lambdoidal synostosis, *see below*)
2. gentle firm pressure with the thumbs fails to cause relative movement of the bones on either side of the suture
3. plain skull x-rays:
   A. lack of normal lucency in center of suture. Some cases with normal x-ray appearance of the suture (even on CT) may be due to focal bony spicule formation[47]
   B. beaten copper calvaria (*see page 231*), sutural diastasis and erosion of the sella may be seen in cases of increased ICP[48]
4. CT scan:
   A. helps demonstrate cranial contour
   B. may show thickening and/or ridging at the site of synostosis
   C. will demonstrate hydrocephalus if present
   D. may show expansion of the frontal subarachnoid space[49]
   E. three-dimensional CT may help better visualize abnormalities
5. in questionable cases, a technetium bone scan can be performed[50]:
   - there is little isotope uptake by any of the cranial sutures in the first weeks of life
   - in prematurely closing sutures, increased activity compared to the other (normal) sutures will be demonstrated
   - in completely closed sutures, no uptake will be demonstrated
6. MRI: usually reserved for cases with associated intracranial abnormalities.

Often not as helpful as CT

7. measurements, such as occipito-frontal-circumference may not be abnormal even in the face of a deformed skull shape

Increased ICP

Evidence of increased ICP in the newborn with craniosynostosis include:

1. radiographic signs (on plain skull x-ray or CT, *see above*)
2. failure of calvarial growth (unlike the non-synostotic skull where increased ICP causes macrocrania in the newborn, here it is the synostosis that *causes* the increased ICP and lack of skull growth)
3. papilledema
4. developmental delay

TYPES OF CRANIOSYNOSTOSIS

SAGITTAL SYNOSTOSIS

The most common CSO affecting a single suture; 80% male. Results in **dolichocephaly** or **scaphocephaly** (boat shaped skull) with frontal bossing, prominent occiput, palpable keel-like sagittal ridge. OFC remains close to normal, but the biparietal diameter is markedly reduced.

Surgical treatment

Skin incision may be longitudinal or transverse. A linear "strip" craniectomy is performed, excising the sagittal suture from the coronal to the lambdoid suture, preferably within the first 3-6 months of life. The width of the strip should be at least 3 cm, no proof exists that interposing artificial substances (e.g. silastic sheeting over the exposed edges of the parietal bone) retards the recurrence of synostosis. Great care is taken to avoid dural laceration with potential injury to the underlying superior sagittal sinus. The child is followed and reoperated if fusion recurs before 6 months age. After ≈ 1 yr age, more extensive cranial remodelling is usually required.

CORONAL SYNOSTOSIS

Accounts for 18% of CSO, more common in females. In **Crouzon's syndrome** this is accompanied by abnormalities of sphenoid, orbital and facial bones (hypoplasia of mid-face), and in Apert's syndrome is accompanied by

syndactyly[51]. Unilateral coronal CSO → **plagiocephaly** with forehead on affected side flattened or concave above eye (normal side falsely appears to bulge abnormally), supra-orbital margin higher than normal side (on skull x-ray → **harlequin eye sign**). The orbit rotates out on the abnormal side, and can produce amblyopia. Without treatment, flattened cheeks develop and the nose deviates to the normal side (root of nose tends to rotate towards deformity).

Bilateral coronal CSO (usually in craniofacial dysmorphism with multiple suture CSO, e.g. Apert's) → **brachycephaly** with broad, flattened forehead (**acrocephaly**). When combined with premature closure of frontosphenoidal and frontoethmoidal sutures, results in foreshortened anterior fossa with maxillary hypoplasia, shallow orbits, progressive proptosis.

Surgical treatment

Simple strip craniectomy of the involved suture has been used, often with excellent cosmetic result. However, some argument that this may not be adequate has been presented. Therefore, a more current recommendation is to do frontal craniotomy (uni- or bilateral) with lateral canthal advancement by taking off orbital bar.

METOPIC SYNOSTOSIS

At birth, the frontal bone consists of two halves separated by the frontal or metopic suture. Abnormal closure results in a pointed forehead with a midline ridge (**trigonocephaly**). Many of these have a 19p chromosome abnormality and are retarded.

LAMBDOID SYNOSTOSIS

Epidemiology

Long considered a clinical rarity with a reported incidence range 1-9% of CSO[52], recent reports suggest a higher incidence of 10-20%[53] which may be due to an actual increased incidence, or simply to increased awareness or changing diagnostic criteria. More common in males (male:female = 4:1), and the right side is involved in 70% of cases. Usually presents between 3-18 months of age, but may be seen as early as 1-2 months of age.

Controversy exists regarding the actual criteria for this condition, and some authors differentiate between those cases which appear to have a primary abnormality of the lambdoid suture from those which may be due to positional

flattening, the so-called "**lazy lambdoid**". Others do not make this distinction, and sometimes refer to the condition as occipital plagiocephaly to avoid the need to implicate abnormalities of the lambdoid suture.

Positional flattening (or molding) may be produced by:

1. decreased mobility: patients who constantly lie supine with the head to the same side, e.g. cerebral palsy, mental retardation, prematurity, chronic illness
2. abnormal postures: congenital torticollis[54], congenital disorders of the cervical spine
3. intentional positioning: trend since 1992 to place newborns in a supine sleeping position to reduce the risk of sudden infant death syndrome **(SIDS)**[55], sometimes with a foam wedge to tilt the child to one side to reduce the risk of aspiration
4. intrauterine etiologies[56]: intrauterine crowding (e.g. from multiparous births or large fetal size), uterine anomalies

Clinical findings

Flattening of the occiput. May be unilateral or bilateral. If unilateral, it is sometimes termed **lambdoid plagiocephaly** which when severe also produces bulging of the ipsilateral forehead resulting in a "rhomboid" skull with the ipsilateral ear located anterior and inferior to the contralateral ear. The contralateral orbit and forehead may also be flattened. This may be confused with hemifacial microsomia or with plagiocephaly seen in unilateral coronal craniosynostosis. Bilateral lambdoid synostosis produces brachycephaly with both ears displaced anteriorly and inferiorly[52]. Unlike the palpable ridge of sagittal or coronal synostosis, an indentation may be palpated along the synostotic lambdoid suture (although a perisutural ridge may be found in some).

Diagnostic evaluation

The physical exam is the most important aspect of diagnosis. Skull x-ray may help differentiate (*see below*). If the skull x-ray is equivocal, prevent the infant from laying on the affected side for several weeks. A bone scan should be obtained if no improvement occurs (*see below*). In definite cases of synostosis, and for some cases of refractory positional flattening (which usually corrects with time, but may take up to 2 years) surgical treatment may be indicated.

Skull x-ray: Shows a sclerotic margin along one edge of the lambdoid suture in

70% of cases. Local “beaten copper cranium” **(BCC)** occasionally may be seen due to indentations in the bone from underlying gyri which may be due to locally increased ICP. BCC produces a characteristic mottled appearance of the bone with lucencies of varying depth having round and poorly marginated edges. BCC correlates with generalized ↑ ICP only when it is seen with sellar erosion and sutural diastasis[48].

CT scan: Bone windows may show eroded or thinned inner table in the occipital region in 15-20% of cases[53], > 95% are on the side of the involvement. The suture may appear closed. Brain windows show parenchymal brain abnormalities in < 2%: heterotopias, hydrocephalus, agenesis of the corpus callosum; but ≈ 70% will have significant expansion of the frontal subarachnoid space (may be seen in synostosis of other sutures, *see above*).

Bone scan: Isotope uptake in the lambdoid suture increases during the first year, with a peak at 3 months of age[57] (following the usual inactivity of the first weeks of life). The findings with synostosis are those typical for CSO (*see page 229*).

Treatment

Early surgical treatment is indicated in cases with severe craniofacial disfigurement or those with evidence of increased ICP. Otherwise, children may be managed non-surgically for 3-6 months. The majority of cases will remain static or will improve with time and simple nonsurgical intervention. Approximately 15% will continue to develop a significant cosmetic deformity.

Nonsurgical management[58]:

Although improvement can usually be attained, some degree of permanent disfigurement is frequent.

Repositioning will be effective in ≈ 85% of cases. Patients are placed on the unaffected side or on the abdomen. Infants with occipital flattening from torticollis should have aggressive physical therapy and resolution should be observed within 3-6 months.

More severe involvement may be treated with a trial of molding helmets[59] (however, no controlled study has proven the efficacy).

Surgical treatment:

Required in only ≈ 20% of cases. The ideal age for surgery is between 6 and 18 months. The patient is positioned prone on a well-padded cerebellar headrest (the face should be lifted and gently massaged every ≈ 30 minutes by the

anesthesiologist to prevent pressure injuries).

Surgical options range from simple unilateral craniectomy of the suture to elaborate reconstruction by a craniofacial team.

Linear craniectomy extends from the sagittal suture to the asterion is often adequate for patients ≤ 12 weeks of age without severe disfigurement. Great care is taken to avoid dural laceration near the asterion which is in the region of the transverse sinus. The excised suture demonstrates an internal ridge. Better results are obtained with earlier surgery, more radical surgery may be necessary after the age of 6 months.

Average blood loss for uncomplicated cases is 100-200 ml and therefore transfusion is often required.

MULTIPLE SYNOSTOSES

Fusion of many or all cranial sutures → **oxycephaly** (tower skull with undeveloped sinuses and shallow orbits). These patients have elevated ICP.

CRANIOFACIAL DYSMORPHIC SYNDROMES

Over 50 syndromes have been described, *Table 8-4*, shows a few selected ones.

A number of craniosynostosis syndromes are due to mutations in the FGFR (fibro-blast growth factor receptor) genes. FGFR generelated craniosynostosis syndromes include some classic syndromes (Apert, Crouzon, Pfeiffer…) as well as several newer entities (Beare-Stevenson, Muenke, Jackson-Weiss syndromes). All exhibit autosomal dominant inheritance.

Table 8-4 Selected craniofacial dysmorphic syndromes (modified[60 (p 123-4)])

Syndrome	--- Genetics ---		Craniofacial findings	Associated findings
	Sporadic	Inherited		
Crouzon (cranio-facial dysostosis)	yes (25%)	FGFR AD*	CSO of coronal & basal skull sutures, maxillary hypoplasia, shallow orbits, proptosis	HCP rare
Apert (acrocephalosyndactyly)	yes (95%)	FGFR AD	same as Crouzon	syndactyly of digits 2,3,4; shortened UE, HCP common
Kleeblattschadel	yes	AD	CSO with trilobular skull	isolated, or with Apert's or thanatophoric dwarfism

* abbreviations: AD = autosomal dominant; FGFR = fibroblast growth factor receptor gene-related; CSO = craniosynostosis; HCP = hydrocephalus; UE = upper extremities

8.5.3. Encephalocele

Cranium bifidum is a defect in the fusion of the cranial bone, it occurs in the mid-line, and is most common in the occipital region. If meninges and CSF herniate through the defect, it is called a meningocele. If meninges and cerebral tissue protrude, it is called an encephalocele.

Encephalocele AKA **cephalocele** is an extension of intracranial structures outside of the normal confines of the skull. One case was seen for every five cases of spinal myelomeningoceles[61]. A nasal polypoid mass in a newborn should be considered an encephalocele until proven otherwise. See also *Differential diagnosis,* page 1229.

CLASSIFICATION

System based on Suwanwela and Suwanwela[62]:

1. occipital: often involves vascular structures
2. cranial vault: comprises ≈ 80% of encephaloceles in Western hemisphere
   A. interfrontal
   B. anterior fontanelle
   C. interparietal: often involves vascular structures
   D. temporal
   E. posterior fontanelle
3. fronto-ethmoidal: AKA sincipital; 15% of encephaloceles; external opening into face in one of the following 3 regions:
   A. nasofrontal: external defect in the nasion
   B. naso-ethmoidal: defect between nasal bone and nasal cartilage
   C. naso-orbital: defect in the anteroinferior portion of medial orbital wall
4. basal: 1.5% of encephaloceles; (*see below*)
   A. transethmoidal: protrudes into nasal cavity through defect in cribriform plate
   B. spheno-ethmoidal: protrudes into posterior nasal cavity
   C. transsphenoidal: protrudes into sphenoid sinus or nasopharynx through patent craniopharyngeal canal (foramen cecum)
   D. fronto-sphenoidal or spheno-orbital: protrudes into orbit through superior orbital fissure
5. posterior fossa: usually contains cerebellar tissue and ventricular component

BASAL ENCEPHALOCELE

The only group that does not produce a visible soft tissue mass. May present

as CSF leak or recurrent meningitis. May be associated with other craniofacial deformities, including: cleft lip, bifid nose, opticnerve dysplasia, coloboma and microphthalmia, hypothalamic-pituitary dysfunction.

Iniencephaly is characterized by defects around the foramen magnum, rachischisis and retrocollis. Most are stillborn, some survive up to age 17.

ETIOLOGY

Two main theories:

1. arrested closure of normal confining tissue allows herniation through persistent defect
2. early outgrowth of neural tissue prevents normal closure of cranial coverings

TREATMENT

Occipital encephalocele

Surgical excision of the sac and its contents with water-tight dural closure. It must be kept in mind that vascular structures are often included in the sac. Hydrocephalus is often present and may need to be treated separately.

Basal encephalocele

Caution: a transnasal approach to a basal encephalocele (even for biopsy alone) may be fraught with intracranial hemorrhage, meningitis, or persistent CSF leak. Usually a combined intracranial approach (with amputation of the extracranial mass) and trans-nasal approach is used.

OUTCOME

Occipital encephalocele

The prognosis is better in occipital meningocele than in encephalocele. The prognosis is worse if a significant amount cerebral tissue is present in the sac, if the ventricles extend into the sac, or if there is hydrocephalus. Less than ≈ 5% of infants with encephalocele develop normally.

8.6. Chiari malformation

The term "Chiari malformation" (after pathologist, Hans Chiari) is preferred for type 1 malformations, with the commonly used term "Arnold-Chiari malformation" reserved for type 2 malformation.

The Chiari malformations consists of four types of hindbrain abnormalities, probably unrelated to each other. The majority are types 1 or 2 (*see Table 8-5*), a very limited number of cases comprise the remaining types.

Table 8-5 Comparisons of Chiari type 1 and 2 anomalies (adapted[63])

Finding	Chiari type 1 (*see below*)	Chiari type 2 (*see page 238*)
caudal dislocation of medulla	unusual	yes
caudal dislocation into cervical canal	tonsils	inferior vermis, medulla, 4th ventricle
spina bifida (myelomeningocele)	may be present	rarely absent
hydrocephalus	may be absent	rarely absent
medullary "kink"	absent	present in 55%
course of upper cervical nerves	usually normal	usually cephalad
usual age of presentation	young adult	infancy
usual presentation	cervical pain, suboccipital H/A	progressive hydrocephalus, respiratory distress

TYPE 1 CHIARI MALFORMATION

Key concepts:

- a heterogeneous entity with the common feature of impaired CSF circulation through the foramen magnum
- cerebellar tonsillar herniation on MRI: criteria vary, > 5 mm below the foramen magnum is often cited, but is neither essential nor diagnostic of the condition
- treatment, when indicated, is surgical, but aspects of what that surgery should entail are controversial (enlargement of foramen magnum is usually involved)
- associated with syringomyelia in 30-70% which almost always improves with treatment of the Chiari malformation

AKA primary cerebellar ectopia[64], AKA adult Chiari malformation (since it tends to be diagnosed in the 2nd or 3rd decade of life). A heterogeneous group of conditions, with the underlying commonality of disruption of normal CSF flow through the foramen magnum **(FM)**. Some cases are congenital, but others are acquired.

Classically described as a rare abnormality restricted to caudal displacement of cerebellum with tonsillar herniation below the foramen magnum (see *MRI* below for criteria) and "peg-like elongation of tonsils". Unlike Chiari type 2, the medulla is not caudally displaced (some authors disagree on this point[65]), the brainstem is not involved, lower cranial nerves are not elongated, and upper cervical nerves do not course cephalad. Syringomyelia[A] of the spinal cord is present in 30-70%[66]. Hydrocephalus occurs in 7-9% of patients with Chiari type 1 malformation and syringomyelia[66].

A. true hydromyelia probably doesn't occur. CSF flow has not been documented in man, and it is generally not possible to find communication between the syrinx and the central canal in Chiari 1 patients

Cerebellar tonsil descent below FM with impaction, while common, is no longer a sine qua non of diagnosis.

Etiology: may be associated with

1. a small posterior fossa
   A. underdevelopment of the occipital bone
   B. low lying tentorium (the roof of the p-fossa)
   C. thickened or elevated occipital bone (the floor of the p-fossa)
   D. space occupying lesion in p-fossa: arachnoid cyst (retrocerebellar or supracerebellar[67]), tumor (e.g. FM meningioma or cerebellar astrocytoma), hypervascular dura
2. has been described with just about anything that takes up intracranial space
   A. chronic subdural hematomas
   B. hydrocephalus
3. following lumboperitoneal shunt (*see page 317*) or multiple (traumatic) LPs[68]: acquired Chiari 1 malformation (usually asymptomatic)
4. arachnoid web or scar or fibrosis around brainstem and tonsils near FM

5. abnormalities of the upper cervical spine
    A. hypermobility of the craniovertebral junction
    B. Klippel-Feil syndrome
    C. occipitalization of the atlas
    D. anterior indentation at foramen magnum: e.g. basilar invagination or retroversion of the odontoid process
6. Ehlers-Danlos syndrome
7. craniosynostosis: especially cases involving all sutures
8. retained rhomboid roof: rare

Epidemiology

Average age at presentation is 41 years (range: 12-73 yrs). Slight female preponderance (female:male = 1.3:1). Average duration of symptoms clearly related to Chiari malformation is 3.1 yrs (range: 1 month-20 yrs); if nonspecific complaints, e.g. H/A, are included, this becomes 7.3 years[69]. This latency is probably lower in the MRI era.

Clinical

Patients with Chiari type 1 malformation may present due to any or all of the following:

1. compression of brain stem at the level of the foramen magnum
2. hydrocephalus
3. syringomyelia
4. isolation of the intracranial pressure compartment from the spinal compartment causing transient elevations of intracranial pressure
5. 15-30% of patients with adult Chiari malformation are asymptomatic[70]

Symptoms

The most common symptom is pain (69%), especially headache which is usually felt in the suboccipital region (*see Table 8-6*). H/A are often brought on by neck extension or valsalva maneuver. Weakness is also prominent, especially unilateral grasp. Lhermitte's sign may also occur. Lower extremity involvement usually consists of bilateral spasticity.

Table 8-6 Presenting symptoms in Chiari 1 malformation (71 cases[65])

Symptom	%

pain	69%
H/A	34%
neck (suboccipital, cervical)	13%
girdle	11%
arm	8%
leg	3%
weakness (1 or more limbs)	56%
numbness (1 or more limbs)	52%
loss of temperature sensation	40%
painless burns	15%
unsteadiness	40%
diplopia	13%
dysphasia	8%
tinnitus	7%
vomiting	5%
dysarthria	4%
miscellaneous	
dizziness	3%
deafness	3%
fainting	3%
facial numbness	3%
hiccough	1%
facial hyperhidrosis	1%

Table 8-7 Presenting signs in Chiari I malformation (127 patients[69])

Sign	%
hyperactive lower extremity reflexes	52%
nystagmus*	47%
gait disturbance	43%
hand atrophy	35%
upper extremity weakness	33%
“cape” sensory loss	31%
cerebellar signs	27%

hyperactive upper extremity reflexes	26%
lower cranial nerve dysfunction	26%
Babinski sign	24%
lower extremity weakness	17%
dysesthesia	17%
fasciculation	11%
Horner's sign	6%

* classically: downbeat nystagmus on vertical movement, and rotatory nystagmus on horizontal movement; also includes oscillopsia[72]

Signs

See *Table 8-7*. Three main patterns of clustering of signs[65]:

1. foramen magnum compression syndrome (22%): ataxia, corticospinal and sensory deficits, cerebellar signs, lower cranial nerve palsies. 37% have severe H/A
2. central cord syndrome (65%): dissociated sensory loss (loss of pain & temperature sensation with preserved touch & JPS), occasional segmental weakness, and long tract signs (syringomyelic syndrome[71]). 11% have lower cranial nerve palsies
3. cerebellar syndrome (11%): truncal and limb ataxia, nystagmus, dysarthria

Downbeat nystagmus is considered a characteristic of this condition. 10% will have a normal neurologic exam with occipital H/A as their only complaint. Some patients may present primarily with spasticity.

Natural history

The natural history is not known with certainty (only 2 reports on "natural history"). A patient may remain stable for years, with intermittent periods of deterioration. Rarely, spontaneous improvement may occur (debated).

Evaluation

Plain x-rays

Of 70 skull x-rays, only 36% were abnormal (26% showed basilar impression, 7% platybasia, and 1 patient each with Paget's and concave clivus); in 60 C-spine x-rays, 35% were abnormal (including assimilation of atlas,

widened canal, cervical fusions, agenesis of posterior arch of atlas).

MRI

Diagnostic test of choice. Easily shows many of the classic abnormalities described earlier, including tonsillar herniation, as well as hydrosyringomyelia which occurs in 20-30% of cases. Also demonstrates ventral brain stem compression when present. Other findings include: hydrocephalus, empty sella.

Tonsillar herniation: Criteria for the descent of the tonsillar tips below the foramen magnum **(FM)** to diagnose Chiari type 1 malformation have gone through a number of reconsiderations.

Σ Tonsillar herniation identified radiographically is of limited prognostic value in diagnosing Chiari I malformation, and requires clinical correlation.

Initially, > **5 mm** was defined as clearly pathologic[73] (with 3-5 mm being borderline). Barkovich[74] found tonsillar positions as shown in *Table 8-8*, and *Table 8-9* shows the effect of utilizing 2 vs. 3 mm as the lowest normal position.

Table 8-8 Location of cerebellar tonsils below foramen magnum[74]

Group	Mean*	Range
normal	1 mm above	8 mm above to 5 mm below
Chiari I	13 mm below	3-29 mm below

* based on measurements in 200 normals and 25 Chiari I patients taken in relation to the lower part of the foramen magnum

Table 8-9 Criteria for Chiari I[74]

Criteria for lowest extent of tonsils accepted as normal	Sensitivity for Chiari I	Specificity for Chiari I
2 mm below FM	100%	98.5%
3 mm below FM	96%	99.5%

The tonsils normally ascend with age[75] as shown in *Table 8-10*.

Patients with syringohydromyelia without hindbrain herniation that responded to p-fossa decompression have been described[76] (so-called "**Chiari zero malformation**"). Conversely, 14% of patients with tonsillar herniation > 5 mm are asymptomatic[77] (average extent of ectopia in this group was 11.4 ± 4.86 mm).

Potentially more significant than the absolute tonsillar descent is the amount of compression of the brainstem at the FM, best appreciated on axial T2WI MRI though the FM. Complete obliteration of CSF signal and compression of the brainstem at the FM by impacted tonsils is a common significant finding.

Cine MRI: AKA CSF flow study. May demonstrate blockage of CSF flow at FM. Not widely available. Accuracy is not high, therefore usually does not alter management.

Table 8-10 Tonsillar position relative to FM at various ages[75]

Age (years)	Normal (mm)*	2 S.D.† (mm)
0-9	–1.5	–6
10-19	–0.4	–5
20-29	–1.1	
30-39	0.0	–4
40-49	0.1	
50-59	0.2	
60-69	0.2	
70-79	0.6	
80-89	1.3	–3

* negative number indicates distance below FM

† S.D. = standard deviation. Descent > 2 S.D. beyond normal is suggested as a criteria for tonsillar ectopia

Myelography

Only 6% false negative. Must run dye all the way up to the foramen magnum.

CT

CT has difficulty evaluating the foramen magnum region due to bony artifact. When combined with intrathecal iodinated contrast (myelogram), reliability improves. Findings: tonsillar descent and/or ventricular dilatation.

TREATMENT

Indications for surgery

Since patients respond best when operated on within 2 years of the onset of symptoms (see *Operative results* below), early surgery is recommended for symptomatic patients. Asymptomatic patients may be followed and operated upon if and when they become symptomatic. Patients who have been symptomatic and stable for years may be considered for observation, with surgery indicated for signs of deterioration.

Surgical techniques

The most frequently performed operation is posterior fossa decompression (suboccipital craniectomy), with or without other procedures (usually combined with dural patch grafting and cervical laminectomy of C1, sometimes to C2 or C3). Options for grafts: same incision (pericranium), separate incision (e.g. or fascia lata), and allograft (avoided by many authors because of dissatisfaction with ability to provide water-tight closure and because of infectious risks.

Goals of surgery: decompress the brain stem and reestablish normal flow of CSF at the craniocervical junction.

The patient is positioned prone on chest rolls with the head in a Mayfield head-holder or in a horseshoe headrest. Flex the neck to open the interspace between the occiput and posterior arch of C1. The shoulders are retracted inferiorly with adhesive tape. If a fascia lata graft is to be taken, elevate one thigh on a sandbag. A midline incision from inion to ≈ C2 spinous process is made. The removal of bone above the foramen magnum should be ≈ 3 cm high by ≈ 3 cm wide (keep the posterior-fossa part of these operations small, the main thrust is to open the foramen magnum to decompress the tonsils and an upper cervical laminectomy; the compression is <u>not</u> in the p-fossa). Excessive removal of occipital bone may allow the cerebellar hemispheres to herniate through the opening, and create additional problems. If a pericranial graft is to be taken, it should be harvested at this time to reduce the amount of blood entering the subsequent dural opening[78].

Pericranial graft can be procured without extending the incision about the inion using the technique of Dr. Robert Ojemann[78] with subgaleal dissection and using a monopolar cautery with a bent tip to incise the periosteum and then a Penfield #1 dissector to free it from the bone surface.

Open the dura in a "Y" shaped incision, and excise the triangular top flap. CAUTION: the transverse sinuses are usually abnormally <u>low</u> in Chiari malformations. Suture the patch graft to provide more room for the contents

(tonsils + medulla).

An option that is sometimes used in pediatrics is to not initially open the dura but to lyse constricting bands over the dura at the foramen magnum and then and use intraoperative ultrasound to determine if there is adequate room for CSF flow, the dura is then opened only if there is not.

Historical procedures that have been appended to the above: plugging the obex (with muscle or teflon), drainage of syrinx if present (fenestration, usually through dorsal root entry zone, with or without stent or shunt), 4th ventricular shunting, terminal ventriculostomy, and opening foramen of Magendie if obstructed (see reference for illustrations[71]). Current recommendations are that these or other additional procedures beyond dural patch grafting are usually not warranted.

Some authors repeatedly admonish not to attempt to remove adhesions binding the tonsils together (to avoid injuring vital structures, including PICAs). Others recommend cautiously separating the tonsils and even shrinking them down with bipolar cautery.

In cases with ventral brain-stem compression, some authors advocate performing a transoral clivus-odontoid resection as they feel these patients may potentially deteriorate with posterior fossa decompression alone[79]. Since this deterioration was reversible with odontoidectomy, it may be reasonable to perform this procedure on patients who show signs of deterioration or progression of basilar impression on serial MRIs after posterior fossa decompression.

Operative findings

See Table 8-11. Tonsillar herniation is present in all cases (by definition); the most common position being at C1 (62%). Fibrous adhesions between dura, arachnoid and tonsils with occlusion of foramina of Luschka and Magendie in 41%. The tonsils separated easily in 40%.

Table 8-11 Operative findings in Chiari I (71 patients[65])

Finding	%
tonsillar descent	100%
below foramen magnum	4%
C1	62%
C2	25%

C3	3%
unspecified level	6%
adhesions	41%
syringomyelia	32%
dural band (at foramen magnum or C1 arch)	30%
vascular abnormalities*	20%
skeletal abnormalities	
inverted foramen magnum	10%
keel of bone	3%
C1 arch atresia	3%
occipitalization of C1 arch	1%
cervicomedullary “hump”	12%

* vascular abnormalities: PICA dilated or abnormal course in 8 patients (PICA often descends to lower margin of tonsils[71]); large dural venous lakes in 3

SURGICAL COMPLICATIONS

After suboccipital craniectomy plus C1-3 laminectomy in 71 patients, with dural patch grafting in 69, one death due to sleep apnea occurred 36 hrs post-op. Respiratory depression was the most common post-op complication (in 10 patients), usually within 5 days, mostly at night. Close respiratory monitoring is therefore recommended[65]. Other risks of the procedure include: CSF leak, herniation of cerebellar hemispheres, vascular injuries (to PICA…).

OPERATIVE RESULTS

See *Table 8-12*. Patients with pre-op complaints of pain generally respond well to surgery. Weakness is less responsive to surgery, especially when muscle atrophy is present[79]. Sensation may improve when the posterior columns are unaffected and the deficit is due to spinothalamic involvement alone.

Rhoton feels that the main benefit of operation is to arrest progression.

The most favorable results occurred in patients with cerebellar syndrome (87% showing improvement, no late deterioration). Factors that correlate with a worse outcome are the presence of atrophy, ataxia, scoliosis, and symptoms lasting longer than 2 years[79].

Table 8-12 Long-term follow-up after surgery for Chiari I malformation (69 patients, 4 years mean F/U[65])

early improvement of pre-op symptoms	82%
percent of above that relapsed*	21%
early improvement of pre-op signs	70%
no change from pre-op status	16%
worse than pre-op	0

* these patients deteriorated to pre-op status (none deteriorated further) within 2-3 years of surgery; relapse occurred in 30% with foramen magnum compression syndrome, and in 21% with central cord syndrome

TYPE 2 (ARNOLD)-CHIARI MALFORMATION

Key concepts:

- usually associated with myelomeningocele, often accompanied by hydrocephalus
- pathology includes: caudally displaced cervicomedullary junction, small posterior fossa, tectal beaking. Is probably not due to tethering
- major clinical findings: swallowing difficulties, apnea, stridor, opisthotonos, downbeat nystagmus
- when symptomatic: always check the shunt first! Then, consider surgical decompression (which cannot correct intrinsic brainstem abnormalities)

Usually associated with myelomeningocele **(MM)**, or rarely spina bifida occulta.

PATHOPHYSIOLOGY

Probably does not result from tethering of the cord by the associated MM. More likely due to primary dysgenesis of the brainstem with multiple other developmental anomalies[80].

Major findings

Caudally dislocated cervicomedullary junction, pons, 4th ventricle and medulla. Cerebellar tonsils located at or below the foramen magnum. Replacement of normal cervicomedullary junction flexure with a “kink-like deformity”.

Other possible associated findings:

1. beaking of tectum
2. absence of the septum pellucidum with enlarged interthalamic adhesion:

absence of the septum pellucidum is thought to be due to necrosis with resorption secondary to hydrocephalus, and not a congenital absence[81] (p 178)

3. poorly myelinated cerebellar folia
4. hydrocephalus: present in most
5. heterotopias
6. hypoplasia of falx
7. microgyria
8. degeneration of lower cranial nerve nuclei
9. bony abnormalities:
   A. of cervicomedullary junction
   B. assimilation of atlas
   C. platybasia
   D. basilar impression
   E. Klippel-Feil deformity: *see page 253*
10. hydromyelia
11. craniolacunia of the skull (*see below*)

PRESENTATION

Findings are due to brain stem and lower cranial nerve dysfunction. Onset is rare in adulthood. The presentation of neonates differs substantially from older children, and neonates were more likely to develop rapid neurological deterioration with profound brain stem dysfunction over a period of several days than were older children in whom symptoms were more insidious and rarely as severe[82].

Findings include[82, 83]:

1. swallowing difficulties (neurogenic dysphagia) (69%)[84]. Manifests as poor feeding, cyanosis during feeding, nasal regurgitation, prolonged feeding time, or pooling of oral secretions. Gag reflex often decreased. More severe in neonates
2. apneic spells (58%): due to impaired ventilatory drive. More common in neonates
3. stridor (56%): more common in neonates, usually worse on inspiration (abductor and occasionally adductor vocal cord paralysis seen on laryngoscopy) due to 10th nerve paresis; usually transient, but may progress to respiratory arrest

4. aspiration (40%)
5. arm weakness (27%) that may progress to quadriparesis[85]
6. opisthotonos (18%)
7. nystagmus: especially downbeat nystagmus
8. weak or absent cry
9. facial weakness

DIAGNOSTIC EVALUATION

Skull films

May demonstrate cephalofacial disproportion from congenital HCP. **Craniolacunia** (AKA **lückenschädel**) in 85% (round defects in the skull with sharp borders, separated by irregularly branching bands of bone; <u>not</u> due to increased ICP). Low lying internal occipital protuberance (foreshortened posterior fossa). Enlarged foramen magnum in 70%; elongation of upper cervical lamina[63].

CT and/or MRI findings

- primary findings
  - A. "Z" bend deformity of medulla*
  - B. cerebellar peg
  - C. tectal fusion ("tectal beaking")
  - D. enlarged massa intermedia (interthalamic adhesion)*
  - E. elongation/cervicalization of medulla
  - F. low attachment of tentorium
- associated findings
  - A. hydrocephalus
  - B. syringomyelia in the area of the cervicomedullary junction (reported incidence in pre MRI era[79] ranges from 48-88%)
  - C. trapped fourth ventricle
  - D. cerebellomedullary compression
  - E. agenesis/dysgenesis of corpus callosum*

* items with an asterisk are best appreciated on MRI

Laryngoscopy

Performed in patients with stridor to rule out croup or other upper respiratory tract infection.

TREATMENT

- insert CSF shunt for hydrocephalus (or check function of existing shunt)
- if neurogenic dysphagia, stridor, or apneic spells occur, expeditious posterior fossa decompression is recommended (*see below*) (required in 18.7% of MM patients[83]); before recommending decompression, always make sure the patient has a functioning shunt!

Surgical decompression

NB: it has been argued that part of the explanation for the poor operative results in infants is that many of the neurological findings may be due in part to intrinsic (uncorrectable) abnormalities which surgical decompression cannot improve[86, 87]. A dissenting view is that the histologic lesions are due to chronic brain stem compression and concomitant ischemia, and that expeditious brain stem decompression should be carried out when any of the following critical warning signs develop: neurogenic dysphagia, stridor, apneic spells[82].

Surgical technique:

Decompression of cerebellar tonsils, usually with dural graft to decompress dura. Patients is placed prone, with the neck flexed. A suboccipital craniectomy is combined with a cervical laminectomy which must be carried down to the bottom of the tonsillar tip[85]. A thick constricting dural band is usually found between the C1 arch and foramen magnum. The dura is opened in a “Y” shaped incision. Caution when opening the dura above the level of the foramen magnum in infants as they have a well developed occipital sinus and may have large dural lakes[83]. DO NOT attempt to dissect tonsils from underlying medulla. In cases with a significant syringomyelic cavity, a syringo-subarachnoid shunt is placed[82].

Tracheostomy (usually temporary) is recommended if stridor and abductor laryngeal palsy were present pre-op. Close post-op respiratory monitoring is needed for obstruction and reduced ventilatory drive (mechanical ventilation is indicated for hypoxia or hypercarbia).

OUTCOME

68% had complete or near complete resolution of symptoms, 12% had mild

to moderate residual deficits, and 20% had no improvement (in general, neonates fared worse than older children)[82].

Respiratory arrest is the most common cause of mortality (8 of 17 patients who died), with the rest due to meningitis/ventriculitis (6 patients), aspiration (2 patients), and biliary atresia (1 patient)[83].

In follow-up ranging 7 mos-6 yrs, 37.8% mortality in operated patients.

Pre-op status and the rapidity of neurologic deterioration were the most important prognosticators. Mortality rate is 71% in infants having cardiopulmonary arrest, vocal cord paralysis or arm weakness within 2 weeks of presentation; compared to 23% mortality in patients with a more gradual deterioration. Bilateral vocal cord paralysis was a particularly poor prognosticator for response to surgery[82].

OTHER CHIARI MALFORMATIONS

CHIARI TYPE 3

Rare. The most severe form. Displacement of posterior fossa structures, with cerebellum herniated through foramen magnum into cervical canal, often with a high cervical or suboccipital encephalomeningocele. Usually incompatible with life.

CHIARI TYPE 4

Cerebellar hypoplasia without cerebellar herniation.

8.7. Dandy Walker malformation

Definition: an enlarged posterior fossa with complete or partial agenesis of the cerebellar vermis and cystic dilatation of the fourth ventricle which is distorted and encased in a membrane. The anomaly was first described by Dandy & Blackfan in 1914, and was named Dandy Walker malformation forty years later by Benda to acknowledge Taggart and Walker's contributions in 1942[88].

Differential diagnosis

Disorders with posterior fossa CSF collections include[148]:

1. Dandy Walker malformation **(DWM)**

2. Dandy Walker variant **(DWV)**: vermian hypoplasia and cystic dilatation of the fourth ventricle, without enlargement of the posterior fossa
3. persistent Blake's pouch cyst **(BPC)**: tetraventricular hydrocephalus, communicating 4th ventricle and posterior fossa cyst, with or without hypoplasia of both the cerebellar vermis and the medial aspects of the cerebellar hemispheres
4. retrocerebellar arachnoid cyst: anteriorly displaces the 4th ventricle and cerebellum, which can produce significant mass effect
5. Joubert's syndrome: absence or underdevelopment of the cerebellar vermis
6. mega cisterna magna: enlarged posterior fossa secondary to an enlarged cisterna magna with a normal vermis and fourth ventricle)

Differentiating features: DWM and DWV are difficult to distinguish, and may represent a continuum of developmental anomalies that are grouped together as **Dandy Walker complex**[89].

Retrocerebellar arachnoid cysts and BPCs may mimic DWM, but these do not have vermian agenesis and the cyst does not open into the 4th ventricle. The position of the choroid plexus of the fourth ventricle is normal in arachnoid cysts, absent in Dandy Walker malformations, and displaced into the superior cyst wall in BPC. An intrathecal enhanced CT scan (performed after instilling iodinated contrast into a ventricular catheter) would identify a mega cisterna magna which communicates with the ventricles, while DWM and most but not all arachnoid cysts do not.

Pathophysiology

The etiology of DWM is unknown. Multiple unsatisfactory theories have been abandoned. DWM is likely due to dysembryogenesis, secondary to insults of varying severity to the cerebellum and 4th ventricle. This results in agenesis of the cerebellar vermis with a large posterior fossa cyst communicating with an enlarged 4th ventricle[88, 89].

Hydrocephalus occurs in 70-90% of cases, and Dandy Walker malformation is present in 2-4% of all cases of hydrocephalus.

Risk factors and epidemiology

Gestational exposure to rubella, CMV, toxoplasmosis, warfarin, alcohol, and isotretinoin are thought to be predisposing factors. Autosomal recessive inheritance has been identified in a few cases, but a genetic basis is lacking in

most. Incidence: 1 per 25,000-35,000 live births[88]. Male:female=1:3.

Associated abnormalities

CNS abnormalities include agenesis of the corpus callosum in 17%[90], and occipital encephalocele in 7%. Other findings include heterotopias, spina bifida, syringomyelia, microcephaly, dermoid cysts, porencephaly, and Klippel-Feil deformity. Most have an enlarged posterior fossa with elevation of the torcular herophili. Atresia of the foramina of Magendie and Luschka may occur[91].

Systemic abnormalities include[90]: facial abnormalities (e.g. angiomas, cleft palates, macroglossia, facial dysmorphia), ocular abnormalities (e.g. coloboma, retinal dysgenesis, microphthalmia), and cardiovascular anomalies (e.g. septal defects, patent ductus arteriosus, aortic coarctation, dextrocardia). Note: be aware of the possibility of a cardiac abnormality when considering surgery on these patients.

Treatment

Early decompression of ventriculomegaly is recommended to achieve maximum cognitive development. In the absence of hydrocephalus, DWM may be followed. When treatment is necessary, the posterior fossa cyst must be shunted. Shunting the lateral ventricles alone is contraindicated because of the risk of upward herniation[92]. However, it is important to confirm patency of the cerebral aqueduct, otherwise the supratentorial ventricles need to be shunted concomitantly. Varying reports exist regarding rates of associated aqueductal stenosis, although it is widely believed to be rare.

Another option once used commonly is excision of the obstructing membrane. This has fallen out of favor due to its associated risks of morbidity and mortality. However, it remains an option for patients with frequent shunt malfunctions.

Newer treatments include endoscopic third ventriculostomy in cases where the aqueduct is patent, however further study is necessary[93, 94].

Prognosis

Prognosis ranges widely as there are various levels of severity of the malformation. Some pediatric neurosurgical literature quotes 12-50% mortality rates, although this is improving with modern shunting techniques. Only 50% have normal IQ. Ataxia, spasticity, and poor fine motor control are common.

Seizures occur in 15%.

8.8. Aqueductal stenosis

Aqueductal stenosis **(AqS)** produces what is sometimes called **triventricular hydrocephalus**, characterized by a normal sized 4th ventricle and enlarged third and lateral ventricles on MRI or CT. Most cases occur in children, however some present for the first time in adulthood.

Etiologies

1. a congenital malformation: may be associated with Chiari malformation or neurofibromatosis
2. acquired
   A. due to inflammation (following hemorrhage or infection, e.g. syphilis, T.B.)
   B. neoplasm: especially brainstem astrocytomas (including tectal gliomas, *see page 608*), lipomas
   C. quadrigeminal plate arachnoid cysts

In infancy

AqS is a frequent cause of congenital hydrocephalus **(HCP)** (up to 70% of cases[60]), but occasionally may be the <u>result</u> of HCP. Patients with congenital AqS usually have HCP at birth or develop it within ≈ 2-3 mos. Congenital AqS may be due to an X-linked recessive gene[61]. Four types of congenital AqS described by Russell (summarized[95]):

1. forking: multiple channels (often narrowed) with normal epithelial lining that do not meet, separated by normal nervous tissue. Usually associated with other congenital abnormalities (spina bifida, myelomeningocele)
2. periaqueductal gliosis: luminal narrowing due to subependymal astrocytic proliferation
3. true stenosis: aqueduct histologically normal
4. septum

In adulthood

AqS may be an overlooked cause of “normal pressure hydrocephalus” in the

adult[96]. It is unknown why some cases of AqS would remain occult, and manifest only in adult-hood. In one series of 55 cases[97], 35% had duration of symptoms < 1 year, 47% for 1-5 years; the longest was 40 yrs. Although most follow this longstanding benign course, there are reports of elevated ICP and sudden death.

Symptoms

See *Table 8-13*. Headache was the most common symptom, and had characteristics of H/A associated with elevated ICP. Visual changes were next, and usually consisted of blurring or loss of acuity. Endocrine changes included menstrual irregularities, hypothyroidism, and hirsutism.

Signs

Papilledema was the most common finding (53%). Visual fields were normal in 78%, the remainder having reduced peripheral vision, increased blind spots, quadrantic or hemianopic field cuts, or scotomata. Intellectual impairment was present in at least 36%. Other signs included: ataxia (29%), "pyramidal tract signs" in 44% (mild hemi- or paraparesis (22%), spasticity (22%), or Babinski's (20%)), anosmia (9%).

EVALUATION

MRI is the test of choice. MRI will show the absence of the normal flow void in the Sylvian aqueduct. Contrast should be given to rule-out tumor.

Table 8-13 Symptoms of aqueductal stenosis presenting in adulthood (55 patients > 16 years age[97])

Symptom	No.	%
H/A	32	58%
visual disturbances	22	40%
mental deterioration	17	31%
gait disturbance	16	29%
frequent falling	13	24%
endocrine disturbance	10	18%
nausea/vomiting	9	16%
seizures	8	15%
incontinence	7	13%

vertigo	6	11%
LE weakness	4	7%
hemiparesis or hemianesthesia	4	7%
diplopia	3	5%
dysarthria	1	
deafness	1	

TREATMENT *(OF NON-TUMORAL AQS)*

Although treatments of the primary lesion have been attempted (e.g. lysis of aqueductal septum), this has fallen into disfavor with the improved efficacy of CSF shunting. CSF is usually shunted to the peritoneum or the vascular system, however shunting to subarachnoid space is also feasible (once obstruction at the level of the arachnoid granulations has been ruled out). A Torkildsen shunt may work in adult cases[95], however pediatric patients with obstructive hydrocephalus may not have an adequately developed subarachnoid space for this to function properly.

Follow-up of at least two years to rule-out tumor is recommended.

8.9. Neural tube defects

CLASSIFICATION

Various classification systems exist, this one is adapted from Lemire[98].

1. neurulation defects: non-closure of the neural tube results in open lesions
   A. craniorachischisis: total dysraphism. Many die as spontaneous abortion
   B. **anencephaly**: AKA exencephaly. Due to failure of fusion of the anterior neuropore. Neither cranial vault nor scalp covers the partially destroyed brain. Uniformly fatal. Risk of recurrence in future pregnancies: 3%
   C. meningomyelocele: most common in lumbar region
      1. myelomeningocele **(MM)**: *see page 248*
      2. myelocele
2. postneurulation defects: produces skin-covered (AKA closed) lesions (some may also be considered “migration abnormalities”, *see below*)
   A. cranial

1. microcephaly: *see below*
2. **hydranencephaly**: loss of most of cerebral hemispheres, replaced by CSF (*see below*). Must R/O maximal hydrocephalus (*see below*)
3. holoprosencephaly: *see below*
4. **lissencephaly**: *see below*
5. porencephaly: *see below* to distinguish from schizencephaly
6. agenesis of corpus callosum: *see below*
7. cerebellar hypoplasia/Dandy Walker syndrome: *see page 240*
8. macroencephaly AKA megalencephaly: *see below*

B. spinal
1. diastematomyelia, diplomyelia: see *Split cord malformation*, page 256
2. hydromyelia/syringomyelia: *see page 510*

Migration abnormalities

A slightly different classification scheme defines the following as abnormalities of neuronal migration (some are considered postneurulation defects, *see above*):

1. **lissencephaly**: The most severe neuronal migration abnormality. Maldevelopment of cerebral convolutions (probably an arrest of cortical development at an early fetal age). Infants are severely retarded and usually don't survive > 2 yrs
   A. **agyria**: completely smooth surface
   B. **pachygyria**: few broad & flat gyri with shallow sulci
   C. **polymicrogyria**: small gyri with shallow sulci. May be difficult to diagnose by CT/MRI, and may be confused with pachygyria
2. **heterotopia**: abnormal foci of (nonenhancing) gray matter which may be located anywhere from the subcortical white matter to (most commonly) the subependymal lining of the ventricles. May manifest as nodules or as a band of cortex. An early migration defect that results from arrest of radial migration. Almost always presents with seizures
3. cortical dysplasia: a cleft that does <u>not</u> communicate with the ventricle. Heterotopias are common. A migration abnormality not quite as severe as schizencephaly
4. **schizencephaly**:
   A. sine qua non: cleft that communicates with the ventricle (communication may be confirmed with CT cisternogram if necessary)

B. cleft lined with cortical grey matter (often abnormal, may have polymicrogyria). This distinguishes it from **porencephaly**, a cystic lesion lined with connective or glial tissue that may communicate with the ventricular system, often caused by vascular infarcts or following intracerebral hemorrhage or penetrating trauma (including repeated ventricular punctures)

C. two forms:
   1. open lipped: large cleft to ventricle. Very severe forms may mimic hydranencephaly (*see below*)
   2. close lipped (walls fused): ★ look for a dimple in the lateral wall of the lateral ventricle immediately under the cortical cleft (the appearance of which may mimic an enlarged sulcus)

D. may be unilateral or bilateral

E. pia and arachnoid fuse

F. there may be an "abnormal" vein that represents a cortical vein that now looks medullary because it follows the cortex into the cleft)

G. absence of septum pellucidum in 80-90%

H. presentation may range from seizures to hemiparesis depending on size and location

Hydranencephaly

A post-neurulation defect. Total or near-total absence of the cerebrum (small bands of cerebrum may be consistent with the diagnosis[99]), with intact cranial vault and meninges, the intracranial cavity being filled with CSF. There is usually progressive macrocrania, but head size may be normal (especially at birth), and, occasionally, microcephaly may occur. Facial dysmorphism is rare.

May be due to a variety of causes, the most commonly cited is bilateral ICA infarcts (which results in absence of brain tissue supplied by the anterior and middle cerebral arteries with preservation in the distribution of the PCA). May also be due to infection (congenital or neonatal herpes, toxoplasmosis, equine virus).

Less affected infants may appear normal at birth, but are often hyperirritable and retain primitive reflexes (Moro, grasp, and stepping reflex) beyond 6 mo. They rarely progress beyond spontaneous vowel production and social smiling. Seizures are common.

Differentiation from hydrocephalus: Progressive enlargement of CSF spaces may occur which can mimic severe ("maximal") hydrocephalus **(HCP)**. It is

critical to differentiate the two since true HCP may be treated by shunting which may produce some re-expansion of the cortical mantle. Many means to distinguish hydranencephaly and HCP have been described, including:

1. **EEG**: shows no cortical activity in hydranencephaly (maximal HCP typically produces an abnormal EEG, but background activity will be present throughout the brain[99]) and is one of the best ways to differentiate the two
2. **CT**[99, 100], **MRI** or **ultrasound**: majority of intracranial space is occupied by CSF. Usually do not see frontal lobes or frontal horns of lateral ventricles (there may be remnants of temporal, occipital or subfrontal cortex). A structure consisting of **brainstem nodule** (rounded thalamic masses, hypothalamus) and medial occipital lobes sitting on the tentorium occupies a midline position surrounded by CSF. Posterior fossa structures are grossly intact. The falx is usually intact (unlike alobar holoprosencephaly), and is not thickened, but may be displaced laterally. In HCP, some cortical mantle is usually identifiable
3. **transillumination** of the skull: in a darkened room, a bright light is placed against the surface of the skull. To transilluminate, the patient must be < 9 mos old and the cortical mantle under the light source must be **< 1 cm thick**[61 (p 215)], can also occur if fluid displaces the cortex inward (e.g. subdural effusions). Too insensitive to be very helpful
4. **angiography**: in "classic" cases resulting from bilateral ICA occlusion, no flow through supraclinoid carotids and a normal posterior circulation is expected

Treatment: Shunting may be performed to control head size, but unlike the case with maximal hydrocephalus, there is no restitution of the cerebral mantle.

Holoprosencephaly

AKA **arhinencephaly**. Failure of the telencephalic vesicle to cleave into two cerebral hemispheres. The degree of cleavage failure ranges from the severe alobar (single ventricle, no interhemispheric fissure) to semilobar and lobar (less severe malformations). The olfactory bulbs are usually small and the cingulate gyrus remains fused. Median faciocerebral dysplasia is common, and the degree of severity parallels the extent of the cleavage failure (*see Table 8-14*). 80% are associated with trisomy (primarily trisomy 13, and to a lesser extent trisomy 18). Survival beyond infancy is uncommon, most survivors are severely retarded, a minority are able to function in society. Some develop shunt dependent

hydrocephalus. The risk of holoprosencephaly is increased in subsequent pregnancies of the same couple.

Table 8-14 The five facies of severe holoprosencephaly[101]

Type of face	Facial features	Cranium and brain findings
cyclopia	single eye or partially divided eye in single orbit; arhinia with proboscis	microcephaly; alobar holoprosencephaly
ethmocephaly	extreme orbital hypotelorism; separate orbits; arhinia with proboscis	microcephaly; alobar holoprosencephaly
cebocephaly	orbital hypotelorism; proboscis-like nose; no median cleft lip	microcephaly; usually has alobar holoprosencephaly
with median cleft lip	orbital hypotelorism; flat nose	microcephaly; sometimes has trigonocephaly; usually has alobar holoprosencephaly
with median philtrum-premaxilla anlage	orbital hypotelorism; bilateral lateral cleft lip with median process representing philtrumpremaxillary anlage; flat nose	microcephaly; sometimes has trigonocephaly; semilobar or lobar holoprosencephaly

Microcephaly

Definition: head circumference more than 2 standard deviations below the mean for sex and gestational age. Terms that are sometimes used synonymously: microcrania, microcephalus. Not a single entity, many of the conditions in *Table 8-14* may be associated with microcephaly. It may also result from maternal cocaine abuse[102]. It is important to differentiate microcephaly from a small skull resulting from craniosynostosis in which surgical treatment may provide opportunity for improved cerebral development.

Macroencephaly[60] (PP 109)

AKA macrencephaly, AKA megalencephaly (not to be confused with *macrocephaly*, which is enlargement of the skull (*see page 1206*)). Not a single pathologic entity. An enlarged brain which may be due to: hypertrophy of gray matter alone, gray and white matter, presence of additional structures (glial overgrowth, diffuse gliomas, heterotopias, metabolic storage diseases…). May be seen in neurocutaneous syndromes (especially neurofibromatosis).

Brains may weigh up to 1600-2850 grams. IQ may be normal, but developmental delay, retardation, spasticity and hypotonia may occur. Head

circumference is 4-7 cm above mean. The usual signs of hydrocephalus (frontal bossing, bulging fontanelle, "setting sun" sign, scalp vein engorgement) are absent. Imaging studies (CT or MRI) show normal sized ventricles and can be used to rule out extra-axial fluid collections.

RISK FACTORS

1. early administration of folic acid[103-105] (0.4 mg/d if no history of neural tube defects) reduces the incidence of neural tube defects **(NTDs)** (confirm that vitamin B_{12} levels are normal, *see page 1187*)
2. folate antagonists (e.g. carbamazepine) doubles the incidence of MM
3. mothers with 5, 10-methylenetetrahydrofolate reductase (MTHFR) gene poly-morphism → reduced levels of tissue folate[106]
4. use of valproic acid (Depakene®) during pregnancy is associated with a 1-2% risk of NTD[107]
5. maternal heat exposure in the form of hottubs, saunas or fever (but not electric blankets) in the first trimester was associated with an increased risk of NTDs[108]
6. obesity (before and during pregnancy) increases the risk of NTD[109, 110]
7. maternal cocaine abuse may increase the risk of microcephaly, disorders of neuronal migration, neuronal differentiation and myelination[102]

PRENATAL DETECTION OF NEURAL TUBE DEFECTS

Serum alpha-fetoprotein (AFP)

(See *Alpha-fetoprotein* on page 721 for background). A high maternal serum AFP (≥ 2 multiples of the median for the appropriate week of gestation) between 15-20 weeks gestation carries a relative risk of 224 for neural tube defects, and an abnormal value (high or low) was associated with 34% of all major congenital defects[111]. The sensitivity of maternal serum AFP for spina bifida was 91% (10 of 11 cases), it was 100% for 9 cases of anencephaly. However, other series show a lower sensitivity. Closed lumbosacral spine defects, accounting for ≈ 20% of spina bifida patients[112], will probably be missed by serum AFP screening, and may also be missed on ultrasound. Since maternal serum AFP rises during normal pregnancy, an overestimate of gestational age may cause an elevated AFP to be interpreted as normal, and an underestimate may cause a normal level to be interpreted as elevated[113].

Ultrasound

Prenatal ultrasound will detect 90-95% of cases of spina bifida, and thus in cases of elevated AFP, it can help differentiate NTDs from non-neurologic causes of elevated AFP (e.g. omphalocele), and can help to more accurately estimate gestational age.

Amniocentesis

For pregnancies subsequent to a MM, if prenatal ultrasound does not show spinal dysraphism, then amniocentesis is recommended (even if abortion is not considered, it may allow for optimal post-partum care if MM is diagnosed). Amniotic fluid AFP levels are elevated with open neural tube defects, with a peak between weeks 13-15 of pregnancy. Amniocentesis also carries a ≈ 6% risk of fetal loss in this population.

8.9.1. Agenesis of the corpus callosum

A failure of commissuration occurring ≈ 2 weeks after conception. Results in expansion of the third ventricle and separation of the lateral ventricles (which develop dilated occipital horns and atria, and concave medial borders).

The corpus callosum **(CC)** forms from rostrum (genu) to splenium[114], ∴ in agenesis there may be an anterior portion with absence of the posterior segment (the converse occurs infrequently). Absence of the anterior CC with presence of some posterior CC is indicative of some form of holoprosencephaly.

Incidence

1 in 2,000-3,000 neuroradiological examinations.

Associated neuropathologic findings[14]

- porencephaly
- microgyria
- interhemispheric lipomas and lipomas of the corpus callosum (*see page 225*)
- arhinencephaly
- optic atrophy

- colobomas
- hypoplasia of the limbic system
- bundles of Probst: aborted beginnings of corpus callosum, bulge into lateral ventricles
- loss of horizontal orientation of cingulate gyrus
- schizencephaly (*see page 243*)
- anterior and hippocampal commissures may be totally or partially absent[115]
- hydrocephalus
- cysts in the region of the corpus callosum
- spina bifida with or without myelomeningocele
- absence of the septum pellucidum: *see page 247*

Possible presentation

- hydrocephalus
- microcephaly
- seizures (rare)
- precocious puberty
- disconnection syndrome: more likely with acquired CC defect than in congenital

May be an incidental finding, and by itself may have no clinical significance. How-ever, may be occur as part of a more complex clinical syndrome or chromosomal abnormality (e.g. Aicardi syndrome: agenesis of CC, seizures, retardation, patches of retinal pigmentation).

8.10. Absence of the septum pellucidum

Etiologies[81] (p 178)

1. holoprosencephaly: *see page 244*
2. schizencephaly: *see page 243*
3. agenesis of the corpus callosum: *see page 246*
4. Chiari type 2 malformation: *see page 238*
5. basal encephalocele
6. porencephaly/hydranencephaly

7. may occur in severe hydrocephalus: thought to be due to necrosis with resorption
8. septo-optic dysplasia: *see below*

Septo-optic dysplasia[81] (p 175-8), [116]

AKA de Morsier syndrome. Incomplete early morphogenesis of anterior midline structures produces hypoplasia of the optic nerves and possibly optic chiasm (affected patients are blind) and pituitary infundibulum. The septum pellucidum is absent in about half the cases. About half the cases also have schizencephaly (*see page 243*).

Presentation may be due to secondary hypopituitarism manifesting as dwarfism, isolated growth hormone deficiency, or panhypopituitarism. Occasionally hypersecretion of growth hormone, corticotropin or prolactin may occur, and precocious puberty may occur. Most patients are of normal intelligence although retardation may occur. Septo-optic dysplasia may be a less severe form of holoprosencephaly, and occasionally may occur as part of this anomaly (with its attendant poorer prognosis for function or survival, *see page 244*). The ventricles may be normal or dilated. May be seen by the neurosurgeon because of concerns of possible hydrocephalus.

8.11. Spinal dysraphism (spina bifida)

DEFINITIONS[61]

spina bifida occulta	Congenital absence of a spinous process and variable amounts of lamina. No visible exposure of meninges or neural tissue (*see below*).

The following two entities are grouped together under the term **spina bifida aperta** (*aperta* from the Latin for “open”) or **spina bifida cystica**.

meningocele	Congenital defect in vertebral arches with cystic distension of meninges, but no abnormality of neural tissue. One third have some neurologic deficit.
myelomeningocele	Congenital defect in vertebral arches with cystic dilatation of meninges and structural or functional abnormality of spinal cord or cauda equina (*see below*).

SPINA BIFIDA OCCULTA (SBO)

Reported prevalence range of SBO: 5-30% of North Americans (5-10% is probably more realistic). The defect may be palpable, and there may be overlying cutaneous manifestations (see *cutaneous stigmata of dysraphism* in *Table 8-17*, page 255).

Often an incidental finding, usually of no clinical importance when it occurs alone. Numerous reviews have shown no statistical association of SBO with nonspecific LBP[117, 118]. An increased incidence of disc herniation was shown in one study[119].

SBO may occasionally be associated with diastematomyelia, tethered cord, lipoma, or dermoid tumor. When symptomatic from one of these associated conditions, the presentation is usually that of tethered cord (gait disturbance, leg weakness and atrophy, urinary disturbance, foot deformities…, see *Tethered cord syndrome*, page 254).

MYELOMENINGOCELE

EMBRYOLOGY

The anterior neuropore closes at gestation day 25. The caudal neuropore closes at day 28.

EPIDEMIOLOGY/GENETICS

Incidence of spina bifida with meningocele or myelomeningocele **(MM)** is 1-2/1000 live births (0.1-0.2%). Risk increases to 2-3% if there is one previous birth with MM, and 6-8% after two affected children. The risk is also increased in families where close relatives (e.g. siblings) have given birth to MM children, especially when on the mother's side of the family. Incidence may increase in times of war, famine or economic disasters, but it may be gradually declining overall[120]. Transmission follows non-Mendelian genetics, and is probably multifactorial. Prenatal folate (in the form of folic acid) lowers the incidence of MM (*see page 245*).

Hydrocephalus in myelomeningocele

Hydrocephalus **(HCP)** develops in 65-85% of patients with MM, and 5-10% of MM patients have clinically overt HCP at birth[121]. Over 80% of MM patients who will develop HCP do so before age 6 mos. Most MM patients will have an associated Chiari type 2 malformation (see *Type 2 (Arnold)-Chiari malformation*, page 238). Closure of the MM defect may convert a latent HCP to

active HCP by eliminating a route of egress of CSF.

Latex allergy in myelomeningocele

Up to 73% of MM patients are allergic to proteins present in latex (the milky sap from the rubber tree Hevea brasiliensis), found only in naturally occurring rubber products (and which are not present in synthetics such as: silicone, vinyl, plastic, neoprene, nitrile…). The allergy is thought to arise from early and frequent exposure to latex products during medical care for these patients, and there is a suggestion that latex-free surgery on these infants may reduce the risk of the development of latex allergy[122].

PRENATAL DIAGNOSIS

See *Prenatal detection of neural tube defects* on page 245.

MANAGEMENT

Intrauterine closure of MM defect

Controversial. Does reduce incidence of Chiari II defect, but it has not been determined if this is clinically significant. Argued whether this reduces incidence of hydrocephalus. Does not improve distal neurologic function.

ADMISSION

1. assessment and management of lesion:
   - A. measure size of defect
   - B. assess whether lesion is ruptured or unruptured
     1. ruptured: start antibiotics (e.g. nafcillin and gentamicin; D/C 6 hrs after MM closure, or continue if shunt anticipated in next 5 or 6 days)
     2. unruptured: no antibiotics necessary
   - C. cover lesion with telfa, then sponges soaked in lactated ringers or normal saline (form a sterile gauze ring around the lesion if it is cystic and protruding) to prevent desiccation
   - D. Trendelenburg position, patient on stomach (keeps pressure off lesion)
   - E. perform surgical closure within 36 hrs unless there is a contraindication to surgery (simultaneous shunt is not usually done except if overt hydrocephalus **(HCP)** at birth): see *Timing of MM*

closure below

2. neurological assessment and management:
   A. items related to spinal lesion
      1. watch for spontaneous movement of the LEs (good spontaneous movement correlates with better later functional outcome[123])
      2. assess lowest level of neurologic function (*see Table 8-15*) by checking response of LEs to painful stimulus: although some infants will have a clear demarcation between normal and abnormal levels, at least 50% show some mixture of normal, reflex, and autonomous activity (arising from uninhibited anterior horn motor neurons)[123]
         a. differentiating reflex movement from voluntary may be difficult. In general, voluntary movement is not stereotyped with repetitive stimulus and reflex movement usually only persists as long as the noxious stimulus is applied

Table 8-15 Findings in various levels of MM lesion[124]

Paralysis below	Findings
T12	complete paralysis of all muscles in LEs
L1	weak to moderate hip flexion, palpable contraction in sartorius
L2	strong hip flexion and moderate hip adduction
L3	normal hip adduction & almost normal knee extension
L4	normal hip adduction, knee extension & dorsiflexion/inversion of foot; some hip abduction in flexion
L5	normal adduction, flexion & lateral rotation of hip; moderate abduction; normal knee extension, moderate flexion; normal foot dorsiflexion; hip extension absent; • produces dorsiflexed foot and flexed thigh
S1	normal hip flexion & abduction/adduction, moderate extension and lateral rotation; strong knee flexion & inversion/eversion of foot; moderate plantarflexion of foot; extension of all toes, but flexion only of terminal phalanx of great toe; normal medial & lateral hip rotation; complete paralysis of foot intrinsic (except abductor and flexor hallucis brevis); • produces clawing of toes and flattening of sole of foot
S2	difficult to detect abnormality clinically; • with growth this produces clawing of the toes due to weakness of intrinsic muscles of sole of foot (innervated by S3)

   B. items related to the commonly associated Chiari type 2 malformation:
      1. measure OFC: risk of developing hydrocephalus (*see above*). Use

OFC graphs (*see* *page 312*), and also look for abnormal rate of growth (e.g. > 1 cm/day)
    2. head U/S within ≈ 24 hrs
    3. check for inspiratory stridor, apneic episodes
3. ancillary assessment and management:
    A. evaluation by neonatologist to assess for other abnormalities, especially those that may preclude surgery (e.g. pulmonary immaturity). There is an average incidence of 2-2.5 additional anomalies in MM patients
    B. bladder: start patient on regular urinary catheterizations, obtain urological consultation (non-emergent)
    C. AP & lat spine films: assess scoliosis (baseline)
    D. orthopedic consultation for severe kyphotic or scoliotic spine deformities and for hip or knee deformities

SURGICAL CONSIDERATIONS

TIMING OF MM CLOSURE

Early closure of MM defect is not associated with improvement of neurologic function, but evidence supports lower infection rate with early closure. MM should be closed within 24 hrs whether or not membrane is intact (after ≈ 36 hrs the back lesion is colonized and there is increased risk of postoperative infection).

Simultaneous MM defect closure and VP shunting

In patients without hydrocephalus, most surgeons wait at least ≈ 3 days after MM repair before shunting. In MM patients with clinically overt HCP at birth (ventriculomegaly with enlarged OFC and/or symptoms), MM repair and shunting may be performed in the same sitting without increased incidence of infection, and with shorter hospitalization[125, 126]. It may also reduce the risk of MM repair breakdown previously seen during the interval before shunting. Patient is positioned prone, head turned to right (to expose the right occiput), right knee and thigh flexed to expose right flank (consider using left flank to prevent confusion with appendectomy scar later in life).

TECHNIQUE

Key concepts of surgical treatment:

- critical goals: 1) free placode from dura (to avoid tethering), 2) water-tight dural closure, 3) skin closure (can be accomplished in essentially all cases). Closure does not restore any neurologic function
- timing goal: surgical closure with latex-free setup ideally ≤ 36 hours after birth
- helpful tips: start at normal dura, open as wide as the defect, trim placode if necessary to close dura, undermine skin to achieve closure (avoid trapping skin -> dermoid tumor)
- post-op CSF leak usually means a shunt is required

General principles[127]: keep the exposed neural tissue moist; prevent desiccation. Use latex-free environment (may reduce development of latex allergy, and reduces maternal antibodies may also cross placenta). Do not allow scrubs or chemical antimicrobials to contact neural placode. Do not use monopolar cautery. At every point during the closure, avoid placing tension on the neural placode.

Multiple layer closure is advocated, 5 layers should be attempted, although occasionally only 2 or so layers may be closed. There is no evidence that multiple layer closure either improves neurologic function or prevents later tethering, but there is a suggestion that when tethering does occur, it may be easier to release when a previous multilayered closure was performed. Silastic does not prevent adherence in series with long follow-up (> 6 yrs), and may even render untethering procedures more difficult.

Begin by dividing the abnormal epithelial covering from the normal skin. The piaarachnoid may be separated from the neural tissue. The placode is folded into a tube and the piaarachnoid is then approximated around it with 7-0 suture (absorbable suture, e.g. PDS, may make future re-operation easier). It often helps to start with normal dura above, and then work down. The dura can then be isolated around the periphery and followed deep to the spinal canal superiorly. The dura is then also formed into a tube and approximated in a water-tight closure. If the dura cannot be closed, the placode may be judiciously trimmed. The filum terminale should be divided if it can be located. The skin is then mobilized and closed. Dermoid tumors may result from retained skin during the closure, but alternatively dermoids may also be present congenitally[128].

If there is a kyphotic deformity, it is repaired at the same sitting as the MM defect closure. The kyphotic bone is rongeured, and 2-0 Vicryl is used to suture the adjacent bones. Some surgeons use a brace post-op, some do not.

POST-OP MANAGEMENT OF MM REPAIR

1. keep patient off all incisions
2. bladder catheterization regimen
3. daily OFC measurements
4. avoid narcotics (midbrain malformation renders these patient more sensitive to respiratory depression from narcotics)
5. if not shunted
   A. regular head U/S (twice weekly to weekly)
   B. keep patient flat to ↓ CSF pressure on incision
6. if a kyphectomy was done, use of a brace is optional (surgeon preference)

LATE PROBLEMS/ISSUES

Include:

1. hydrocephalus: may mimic ≈ anything listed below. ALWAYS RULE OUT SHUNT MALFUNCTION when a MM patient deteriorates
2. syringomyelia (and/or syringobulbia): *see page 510*
3. tethered cord (see *Tethered cord syndrome*, page 254): as many as 70% of MM patients have a tethered cord radiographically (some quote 10-20%), but only a minority are symptomatic. Unfortunately there is no good test to check for symptomatic retethering (SSEPs may deteriorate[129], myelography may help)
   A. scoliosis: early untethering of cord may improve scoliosis (see *Scoliosis in tethered cord*, page 255)
   B. symptomatic tethering may manifest as delayed neurological deterioration[130]
4. dermoid tumor at the MM site[131]: incidence ≈ 16% (*see page 729*)
5. medullary compression at foramen magnum (symptomatic Chiari II malformation, *see page 238*)
6. use of growth hormone to increase stature is controversial

OUTCOME

Without any treatment, only 14-30% of MM infants survive infancy; these usually represent the least severely involved; 70% will have normal IQ's. 50% are ambulatory.

With modern treatment, ≈ 85% of MM infants survive. The most common cause of early mortality are complications from the Chiari malformation (respiratory arrest, aspiration…), where late mortality is usually due to shunt

malfunction. 80% will have normal IQ. Mental retardation is most closely linked to shunt infection. 40-85% are ambulatory with bracing, however, most choose to use wheelchairs for ease. 3-10% have normal urinary continence, but most may be able to remain dry with intermittent catheterization.

LIPOMYELOSCHISIS

Dorsal spinal dysraphism with lipoma. Six forms are described[132], the following 3 are clinically important as possible causes of progressive neurologic dysfunction via tethering (see *Tethered cord syndrome*, page 254) and/or compression:

1. (intra)dural lipoma
2. lipomyelomeningocele (*see below*)
3. fibrolipoma of the filum terminale

LIPOMYELOMENINGOCELE

A subcutaneous lipoma that passes through a midline defect in the lumbodorsal fascia, vertebral neural arch, and dura, and merges with an abnormally low tethered cord[132]. These may be terminal, dorsal, or transitional (between the two).

The intradural fatty tumor may also be known as **lipoma of the cauda equina**. In addition to being abnormally low, the conus medullaris is split in the midline dorsally usually at the same level as the bifid spine, and this dorsal myeloschisis may extend superiorly under intact spinal arches[133]. There is a thick fibrovascular band that joins the lamina of the most cephalic vertebrae with the bifid lamina. This band constricts the meningocele sac and neural tissue, causing a kink in the superior surface of the meningocele. Asymptomatic lipomas of the filum terminale occur in 0.2-4%[134, 135] of MRIs.

The dura is dehiscent at the level of the dorsal myeloschisis, and reflects onto the placode. The lipoma passes through this dehiscence to become attached to the dorsal surface of the placode, and may continue cephalad under intact arches with the possibility of extension into the central canal superiorly to levels without dorsal myeloschisis. The lipoma is distinct from the normal epidural fat which is looser and more areolar. The subarachnoid space typically bulges to the side contralateral to the lipoma. These lipomas account for 20% of covered lumbosacral masses.

PRESENTATION

In a pediatric series, 56% presented with a back mass, 32% with bladder problems, and 10% because of foot deformities, paralysis or leg pain[136].

Physical examination

Almost all patients have cutaneous stigmata of the associated spina bifida: fatty subcutaneous pads (located over the midline and usually extends asymmetrically to one side) with or without dimples, port-wine stains, abnormal hair, dermal sinus opening, or skin appendages[137]. Clubbing of the feet (talipes equinovarus) may occur.

The neurologic exam may be normal in up to 50% of patients (most presenting with skin lesion only). The most common neurologic abnormality was sensory loss in the sacral dermatomes.

Evaluation

Plain LS spine x-rays will show spina bifida in most cases (present in almost all by definition, but some may have segmentation anomalies instead such as butterfly vertebra (*see page 138*)). Abnormalities of fusion and sacral defects may also be seen.

The abnormally low conus can be demonstrated on myelogram/CT or on MRI. MRI also demonstrates the lipomatous mass (high signal on T1WI, low signal on T2WI).

All patients should have pre-op urological evaluation to document any deficit.

Treatment

Since symptoms are due to (1) tethering of the spinal cord, especially during growth spurts, and (2) compression due to progressive deposition of fat, especially during periods of rapid weight gain; the goals of surgery are to release the tethering and reduce the bulk of fatty tumor. Simple cosmetic treatment of the subcutaneous fat pad does not prevent neurologic deficit, and may make later definitive repair more difficult or impossible.

Surgical treatment is indicated when the patient reaches 2 months of age, or at the time of diagnosis if the patient presents later in life. Adjuncts to surgical treatment include evoked potential monitoring and laser. Overall, with surgery, 19% will improve, 75% will be unchanged, and 6% will worsen. Foot deformities often progress regardless.

Surgical technique (modified[133])

1. mobilize the subcutaneous mass, it funnels down through the deep fascia
2. open last intact vertebral arch (work from normal dura)
3. identify the fibrovascular band that crosses the most cephalic widely bifid lamina
4. sectioning the fibrovascular band frees the dural tube and releases the sharp kink in the superior surface of the meningocele
5. taking care to preserve dorsal nerve roots, the dura is incised anterior to the duralipoma junction
6. similar procedure is carried out with arachnoid membrane
7. dural/arachnoid incisions are continued around entire extent of tethered conus
8. cord and placode are untethered (monitoring techniques described in *Tethered cord syndrome* on page 254 are an option)
9. ★ subtotal removal of lipoma: lipoma is then trimmed as completely as possible, intentionally leaving some fat behind to avoid injury to dorsal surface of placode. Superior extension along dorsal surface of cord or into central canal is debulked as much as is safely possible
10. the placode is reformed into a closed neural tube
11. close the pial margins
12. the dura is closed (primarily if possible, or using fascia lata graft if too much tension is placed on folded placode)

DERMAL SINUS

A tract beginning at the skin surface, lined with epithelium. Usually located at either end of neural tube: cephalic or caudal. Most common location is lumbosacral. Probably results from failure of the cutaneous ectoderm to separate from the neuro-ectoderm at the time of closure of the neural groove[61].

SPINAL DERMAL SINUS

May appear as a dimple or as a sinus, with or without hairs, usually very close to midline, with an opening of only 1-2 mm. Surrounding skin may be normal, pigmented ("port wine" discoloration), or distorted by an underlying mass.

The sinus may terminate superficially, may connect with the coccyx, or may traverse between normal vertebrae or through bifid spines to the dural tube. It

may widen at any point along its path to form a cyst; called an **epidermoid cyst** if lined with stratified squamous epithelium and containing only keratin from desquamated epithelium, or called a **dermoid cyst** if also lined with dermis (containing skin appendages, such as hair follicles and sebaceous glands) and also containing sebum and hair.

Although innocuous in appearance, they are a potential pathway for intradural infection which may result in meningitis (sometimes recurrent) and/or intrathecal abscess. Less serious, a local infection may occur. The lining dermis contains normal skin appendages which may result in hair, sebum, desquamated epithelium and cholesterol, within the tract. As a result, the contents of the sinus tract are irritating and can cause a sterile (chemical) meningitis with possible delayed arachnoiditis if it enters the dural space.

Incidence of a presumed sacral sinus (a dimple whose bottom could not be seen on skin retraction): 1.2% of neonates[138].

Dermal sinuses are similar but distinct from **pilonidal cysts** which may also be congenital (although some authors say they are acquired), contain hair, are located superficial to the postsacral fascia, and may become infected.

If the tract expands intrathecally to form a cyst, the mass may present as a tethered cord or as an intradural tumor. Bladder dysfunction is usually the first manifestation.

The tract from a spinal dermal sinus always courses cephalad as it dives inward from the surface. An occipital sinus may penetrate the skull and can communicate with dermoid cysts as deep as the cerebellum or fourth ventricle.

Evaluation

These tracts are NOT to be probed or injected with contrast as this can precipitate infection or sterile meningitis.

Exam is directed towards detecting abnormalities in sphincter function (anal and urinary), lumbosacral reflexes, and lower extremity sensation and function.

Radiologic evaluation

When seen at birth, ultrasound is the best means to evaluate for spina bifida and a possible mass inside the canal.

If seen initially following birth, an MRI should be obtained. Sagittal images may demonstrate the tract and its point of attachment. MRI also optimally demonstrates masses (lipomas, epidermoids…) within the canal.

Plain x-rays and CT are unable to demonstrate the fine tract which may exist between the skin and the dura.

Plain x-rays must be done when embarking on surgery as part of operative planning, as preparation for the possibility of a complete laminectomy.

TREATMENT

Sinuses above the lumbosacral region should be surgically removed. More caudally located sinuses are slightly controversial. Although ≈ 25% of presumed sacral sinuses seen at birth will regress to a deep dimple on follow-up (time not specified), it is recommended that all dermal sinuses should be surgically explored and fully excised prior to the development of neurologic deficit or signs of infection. The results following intradural infection are never as good as when undertaken prior to infection. Surgery within the week of diagnosis is appropriate. Sinuses that terminate on the tip of the coccyx rarely penetrate the dura, and may not need to be treated unless local infection occurs.

Surgical technique

An ellipse is cut around the opening, and the sinus is followed deep until the termination of the tract is encountered. Careful insertion of a lacrimal duct probe under direct vision may facilitate excision without violating the tract. If the tracts penetrates the spine, laminectomy must be performed and the tract followed to its full extent (even if necessary to extend the laminectomy to T12). An extradural cyst may be present. If the tract enters the dura, it usually does so in the midline, and in these cases the dura should be opened and inspected. Extreme care is taken to prevent spilling the contents into the subdural space.

CRANIAL DERMAL SINUS

Stalk begins with a dimple in the occipital or nasal region. Cutaneous stigmata of hemangioma, subcutaneous dermoid cyst, or abnormal hair formation may occur. Occipital sinuses extend caudally, and if they enter the skull, they do so caudal to the torcular herophili. Presentation may include recurrent bacterial (usually *S. aureus*) or aseptic meningitis. Evaluation should include MRI to look for intracranial extension and associated anomalies, including an intracranial dermoid cyst.

Treatment

When operating on a cranial dermal sinus, use a sagittally based incision to permit deep exploration. The tract must be followed completely. Be prepared to enter the posterior fossa.

8.11. Klippel-Feil syndrome

Congenital fusion of two or more cervical vertebrae. Ranges from fusion of only the bodies (congenital **block vertebrae**) to fusion of the entire vertebrae (including posterior elements). Results from failure of normal segmentation of cervical somites between 3-8 weeks gestation. Involved vertebral bodies are often flattened and associated disc spaces are absent or hypoplastic. Hemivertebrae may also occur. Neural foramina are smaller than normal and oval. Cervical stenosis is rare. Complete absence of the posterior elements with an enlarged foramen magnum and fixed hyperextension posture is called **iniencephaly** and is rare. Incidence of Klippel-Feil is unknown due to its rarity and the fact that it is frequently asymptomatic.

Classic clinical triad (all 3 are present in < 50%): low posterior hairline, shortened neck (**brevicollis**), and limitation of neck motion (may not be evident if < 3 vertebrae are fused, if fusion is limited only to the lower cervical levels[139], or if hypermobility of non-fused segments compensates). Limitation of movement is more common in rotation than flexion-extension or lateral bending.

May occur in conjunction with other congenital cervical spine anomalies such as basilar impression and atlanto-occipital fusion. Other clinical associations include scoliosis in 60%, facial asymmetry, torticollis, webbing of the neck (called **pterygium colli** when severe), **Sprengel's deformity** in 25-35% (raised scapula due to failure of the scapula to properly descend from its region of formation high in the neck to its normal position about the same time as the Klippel-Feil lesion occurs), **synkinesis** (mirror motions, primarily of hands but occasionally arms also) and less commonly facial nerve palsy, ptosis, cleft or high arched palate. Systemic congenital abnormalities may also occur including: genitourinary (the most frequent being unilateral absence of a kidney), cardiopulmonary, CNS, and in ≈ 30% deafness[140] (due to defective development of the osseous inner ear).

No symptoms have ever been directly attributed to the fused vertebrae, however symptoms may occur from nonfused segments (less common in short-segment fusions) which may be hypermobile possibly leading to instability or degenerative arthritic changes.

Treatment

Usually directed at detecting and managing the associated systemic anomalies. Patients should have cardiac evaluation (EKG), CXR, and a renal

ultrasound. Serial examinations with lateral flexion-extension lateral C-spine x-rays to monitor for instability. Occasionally, judicious fusion of an unstable nonfused segment may be needed at the risk of further loss of mobility. Also *see page 981*, for recommendations regarding athletic competition.

8.12. Tethered cord syndrome

Abnormally low conus medullaris. Usually associated with a short, thickened filum terminale, or with an intradural lipoma (other lesions, e.g. lipoma extending through dura, or diastematomyelia are considered as separate entities). Most common in myelomeningocele **(MM)**. Diagnosis must be made clinically in MM, as almost all of these patients will have tethering radiographically.

Table 8-16 Presenting signs and symptoms of tethered cord[141] (p 1331-2)

Finding	%
cutaneous findings	54%
hypertrichosis	22%
sub-Q lipoma (no intraspinal extension)	15%
miscellaneous (hemangiomatous discoloration, dermal sinus, multiple manifestations)	17%
gait difficulty with LE weakness	93%
visible muscle atrophy, short limb, or ankle deformity	63%
sensory deficit	70%
bladder dysfunction	40%
bladder dysfunction as only deficit	4%
pain in back, leg, or foot arches	37%
scoliosis or kyphosis*	29%
posterior spina bifida (lumbar or sacral)	98%

* high incidence of scoliosis and kyphosis due to inclusion of series by Hoffman

PRESENTATION

Presenting signs and symptoms in patients with tethered cord are shown in *Table 8-16*.

Myelomeningocele patients

If a MM patient has increasing scoliosis, increasing spasticity, worsening gait (in those previously ambulatory), or deteriorating urodynamics[142]:

- always make sure that there is a working shunt with normal ICP
- if painful, should be considered tethered cord until proven otherwise
- if painless, should be considered syringomyelia until proven otherwise
- may be due to brainstem compression (symptomatic Chiari II malformation, *see page 238*) requiring posterior fossa decompression

Scoliosis in tethered cord

Progressive scoliosis may be seen in conjunction with tethered cord; early untethering of the cord may result in improvement of scoliosis, however, untethering must be done when the scoliosis is mild. When cases of ≤ 10° scoliosis were untethered, 68% had neurologic improvement and the remaining 32% were stabilized, whereas when scoliosis is severe (≥ 50°) ≈ 16% deteriorated.

Tethered cord in adults

Although most cases of tethered cord present in childhood, cases of adult tethered cord have been reported (≈ 50 published cases as of 1982). For comparison of adult and childhood forms, *see Table 8-17*.

Table 8-17 Comparison of childhood and adult tethered cord syndrome[143]
(from J Neurosurg, D. Pang and J.E. Wilberger, Vol. 57, pp. 40, 1982, with permission)

Finding	Childhood tethered cord	Adult tethered cord
pain	uncommon; usually in back and legs, not peri-anal nor perineal	present in 86%, often peri-anal & perineal; diffuse & bilateral; occasionally shock-like
foot deformities	common early; usually progressive cavovarus deformity (club foot)	not seen
progressive spinal deformity	common; usually progressive scoliosis	uncommon (< 5%)
motor deficits	common; usually gait abnormalities & regression of gait training	usually presents as leg weakness
urological symptoms	common; usually continuous urinary dribbling, delayed toilet training, recurrent UTIs, enuresis	common; usually urinary frequency, urgency, sensation of incomplete emptying, stress incontinence, overflow incontinence

trophic ulcerations	relatively common in LEs	rare
cutaneous stigmata of dysraphism	present in 80-100% (tuft of hair, dimple, capillary angioma (**naevus flammeus**)	present in < 50%
aggravating factors	growth spurts	trauma, maneuvers associated with stretching conus, lumbar spondylosis, disc herniation, spinal stenosis

EVALUATION

Radiographically: low conus medullaris (below L2) and thickened filum terminale (definition of thickened filum: normal diameter < 1 mm; diameters > 2 mm are pathological). NB: apparent filum diameter on CT-myelogram may vary with concentration of contrast material.

It is difficult to differentiate a tethered cord from a congenitally low lying conus (filum diameter is generally normal in the latter).

Pre-op evaluation

Pre-operative cystometrogram is strongly recommended, especially if the patient seems continent (postoperative changes in bladder function are not uncommon, possibly due to stretching of the lower fibers of the cauda equina).

TREATMENT

If the only abnormality is a thickened, shortened filum, then a limited lumbosacral laminectomy may suffice, with division of the filum once identified.

If a lipoma is found, it may be removed with the filum if it separates easily from neural tissues.

Distinguishing features of the filum terminale intraoperatively

The filum is differentiated from nerve roots by presence of characteristic squiggly vessel on surface of filum. Also, under the microscope, the filum has a distinctively whiter appearance than the nerve roots, and ligamentous-like strands can be seen running through it. NB: intra-op electrical stimulation and recording of anal sphincter EMG are more definitive.

OUTCOME

In MM, it is usually impossible to permanently untether a cord, however, in a growing MM child, it may be that after 2-4 untetherings that the child will be finished growing and tethering may cease to be a problem. Cases that are untethered early in childhood may recur later, especially during the adolescent growth-spurt. Incidence of post-op CSF leak: 15%.

Adult form: surgical release is usually good for pain relief. However, it is poor for return of bladder function.

8.13. Split cord malformation

There is no uniformly accepted nomenclature for malformations characterized by duplicate or split spinal cords. Pang et al.[144] have proposed the following.

The term split cord malformation **(SCM)** should be used for all double spinal cords, all of which appear to have a common embryologic etiology.

Type I SCM

Defined as two hemicords, each with its own central canal and surrounding pia, each within a separate dural tube separated by a dural-sheathed rigid osseocartilaginous (bony) median septum. This has often (but not consistently) been referred to as **diastematomyelia**. There are abnormalities of the spine at the level of the split (absent disc, dorsal hypertrophic bone where the median "spike" attaches)[145]. Two-thirds have overlying skin abnormalities including: nevi, hypertrichosis (tuft of hair), lipomas, dimples or hemangiomas. These patients often have and an orthopedic foot deformity (neurogenic high arches).

Treatment: symptoms are most commonly due to tethering of the cord; and are usually improved by untethering. In addition to untethering, the bony septum must be removed and the dura reconstituted as a single tube (these spines are often very distorted and rotated, therefore start at normal anatomy and work towards defect). ✖ DO NOT cut the tethered filum until after the median septum is removed to avoid having the cord retract up against septum.

Type II SCM

Consists of two hemicords within a single dural tube, separated by a nonrigid fibrous median septum. This has sometimes been referred to as **diplomyelia**.

Each hemicord has nerve roots arising from it. There is usually no spine abnormality at the level of the split, but there is usually spina bifida occulta in the lumbosacral region.

Treatment: consists of untethering the cord at the level of the spina bifida occulta, and occasionally at the level of the split[145].

8.14. Lumbosacral nerve root anomalies

Congenital anomalies of nerve roots are rare. Should be considered in cases of failed back surgery for herniated disc.

Classification system of Cannon et al.[146].

Type 1 anomalies: include **conjoined nerve root** (2 nerve roots arise from a common dural sheath). They separate at various distances from the thecal sac, and exit through the same or separate neural foramina. Neurosurgeons need to be aware of this anomaly to avoid inadvertent injury e.g. during surgery for herniated disc

Type 2 anomalies: 2 nerve roots exit through one foramen. Variants[147]:

A. leaves an unoccupied neural foramen

B. all foramina occupied, but one foramen has 2 nerve roots

Type 3 anomalies: adjacent nerve roots are connected by an anastomosis

NOTES

9. Neuroendovascular intervention

Neuroendovascular surgery (AKA endovascular neurosurgery), which overlaps with interventional neuroradiology, employs techniques of catheter-based diagnosis and treatments. This chapter addresses some general aspects of importance to the management of these patients that are not covered in other sections. For endovascular issues related to specific entities (e.g. aneurysms), see the chapter on that subject (listed below).

CONDITIONS TREATED

Conditions that are sometimes amenable to endovascular techniques include:

1. aneurysms: coiling, stent assisted coiling (*see page 1059*)
2. arteriovenous malformations **(AVMs)**: embolization
   A. pial AVMs: *see page 1098*
   B. dural AVMs (considered to be fistulas by some): *see page 1109*
   C. spinal AVMs: *see page 507*
3. arteriovenous fistulas: CCFs (*see page 1113*)
4. acute embolic stroke: intraarterial clot lysis (*see page 1018*) or mechanical clot disruption/removal (*see page 1018*)
5. cerebrovascular arterial dissections: *see page 1160*
6. internal carotid artery stenosis: angioplasty/stenting in high-risk patients (*see page 1151*)
7. tumors: embolization. Primarily used before surgery as an adjunct to decrease vascularity, e.g. with some meningiomas, hemangioblastomas…
8. intracranial atherosclerosis
9. inferior petrosal sinus/cavernous sinus sampling for localizing pituitary microadenomas: *see page 646*

PHARMACOLOGIC AGENTS

Some drugs that are used almost exclusively in endovascular procedures are shown below. Other drugs (e.g. heparin, Plavix®…) are covered in other sections (*see index*).

Platelet glycoprotein IIb/IIIa receptor binding drugs: All are parenteral

eptifibatide (Integrilin®) DRUG INFO

Rx: bolus 180 mcg/kg IV (up to a max of 22.6 mg) over 1-2 minutes followed by infusion of 2 mcg/kg/min (duration of therapy depends on indication - for some up to 96 hrs).

abciximab (ReoPro®) DRUG INFO

Made from the Fab fragment of a monoclonal antibody. Platelet inhibition lasts up to 48 hours.

Rx: bolus with 0.25 mg/kg IV 10-60 minutes prior to procedure (e.g. stenting) followed by infusion of 0.125 mcg/kg/min.

tirofiban (Aggrastat®) DRUG INFO

A synthetic nonpeptide antiplatelet drug. Platelet inhibition lasts 4-8 hours.

Rx: bolus with 0.4 mcg/kg/min IV **x** 30 minutes, followed by infusion of 0.1 mcg/kg/min.

9.1. Neuroendovascular procedure basics

The femoral artery is punctured just below the inguinal ligament (which lies on the line connecting the anterior superior iliac spine and the anterior superior pelvic tubercle) to avoid bleeding at a non-compressible location (which can lead to significant retroperitoneal hematoma). An 18-19 gauge needle is usually employed.

The Seldinger technique is then used to place a wire in the artery with removal of the percutaneous needle and the introduction of the sheath[1].

A guiding catheter is usually used to access the target vessel (carotid or vertebral artery). A microcatheter is inserted co-axially within the guiding catheter to access the lesion (aneurysm, AVM nidus…)

Sheaths and catheters are all kept under pressurized heparinized saline flush. An arterial line flush system may be used.

Systemic anticoagulation with heparin is frequently used during the

procedure and reversal is not always performed.

Femoral Sheath Management

Except as indicated below, the sheath is removed at the end of the procedure. If the patient has not had systemic anticoagulation during the procedure, then manual compression should be performed for 10-20 minutes to achieve hemostasis. This minimizes the risk of local and embolic complications.

If the sheath is to remain in place for an intraoperative examination or a subsequent interventional procedure, then it should remain on heparinized flush. Remove the sheath only when the aPTT has returned to normal (< 36 secs) or when the ACT is < 170.

There are a number of femoral arterial closure devices, including: Starclose, Perclose, Angioseal, Minx…

Stenting

Indications for stent placement:

1. to assist in the coiling of wide necked aneurysms where there is risk of coil herniation into the parent artery. ✖ Stent-assisted coiling is not recommended for ruptured aneurysms because of the need for dual antiplatelet therapy and the increased risk of hemorrhage if EVD placement is required on this regimen[2]
2. treatment of intracranial stenosis due to atherosclerosis
3. cerebrovascular arterial dissections

Initially, only cardiac stents were available, however, they are being replaced by stents which are FDA approved for CNS use and are more suitable[3]. Currently available stents approved for CNS use:

- **Wingspan**: (Boston Scientific, Natick, MA) self-expanding nitinol microstent used for intracranial atherosclerosis, exerts greater outward radial force than stents used for aneurysm coiling
- **Neuroform**: (Boston Scientific, Natick, MA) self-expanding flexible stent used for stent-assisted coiling of wide necked saccular aneurysms
- **Enterprise**: (Cordis Neurovascular, Miami, FL) self-expanding nitinol stent used for stent-assisted coiling of wide necked intracranial aneurysms
- **Pipeline**: (ev[3], Plymouth, MN) self-expanding flow directed bimetallic microstent with braided tubular design that will exclude aneurysms. May also be useful for arterial dissections[4]. Currently awaiting FDA approval

Post stenting medical management

Aspirin is usually recommended indefinitely following stent placement to prevent stent thrombosis. Plavix® is prescribed for at least 6 weeks following stent placement to allow for endothelialization of the stent.

NOTES

10. Electrodiagnostics

10.1. Electroencephalogram (EEG)

Common EEG rhythms are shown in *Table 10-1*. The primary use of EEG is in the diagnosis and management of seizure disorders. Non-convulsive use of EEG is essentially limited to monitoring for burst suppression (*see below*) (e.g. during carotid endarterectomy) or for differential diagnosis of diffuse encephalopathy, including:

1. differentiating psychogenic unresponsiveness from organic: a normal EEG indicates either psychiatric unresponsiveness or locked-in syndrome
2. non-convulsive status epilepticus (seizures): absence or complex partial status
3. subclinical focal abnormalities: e.g. PLEDs (*see below*), focal slowing…
4. specific patterns diagnostic for certain pathologies: e.g.:
   A. **periodic lateralizing epileptiform discharges (PLEDs)**: may occur with any acute focal cerebral insult (e.g. herpes simplex encephalitis **(HSE)**, abscess, tumor, embolic infarct): seen in 85% of cases of HSE (onset 2-5 d after presentation), if bilateral is ≈ diagnostic of HSE
   B. subacute sclerosing panencephalitis **(SSPE)** (pathognomonic pattern): periodic high voltage with 4-15 secs separation with accompanying body jerks, no change with painful stimulation (differential diagnosis includes PCP overdose)
   C. Creutzfeldt-Jakob disease (*see page 361*): myoclonic jerks. EEG → bilateral sharp wave 1.5-2 per second (early → slowing; later → triphasic). May resemble PLEDs, but are reactive to painful stimulation (most PLEDs are not)
   D. triphasic waves: not really specific. May be seen in hepatic encephalopathy, post-anoxia, and hyponatremia
5. objective measure of severity of encephalopathy: usually used for anoxic encephalopathy (e.g. periodic spikes with seizures indicates < 5% chance of normal neurologic outcome, with high mortality). Alpha coma, burst suppression, and electrocerebral silence are all poor prognosticators

6. differentiating hydranencephaly from severe hydrocephalus (see *Hydranencephaly*, page 244)
7. as a clinical confirmatory test in the determination of brain death (*see page 291*)

Table 10-1 Common EEG rhythms

Rhythm	Symbol	Frequency
delta	Δ	0-3 Hz
theta	θ	4-7 Hz
alpha	α	8-13 Hz
beta	ß	> 13 Hz

BURST SUPPRESSION

Isoelectric intervals interrupted by bursts of 8-12 Hz electrical activity that diminish to 1-4 Hz prior to electrical silence[1]. Often used as an endpoint for titrating neuroprotective drugs such as barbiturates, propofol… (e.g. *see page 1064*).

10.2. Evoked potentials

Evoked potentials are averaged EEG waveforms recorded following repetitive stimulation. The EEGs are then averaged to null-out activity that is not time locked to the stimulus. Resultant waveforms contain peaks that are named N (negative - upward deflection) or P (positive - downward deflection) followed by the latency in milliseconds to the onset of the peak.

Sensory evoked potentials (SEP)

May use electrical stimulation of peripheral nerves (somatosensory or **(SSEP)**), auditory clicks through earphones (auditory or AEP AKA BAER (brainstem auditory evoked response)) or flashing lights through goggles (visual EP or VEP).

Clinical indications for evoked potentials **(EPs)**.

1. diagnosis: (MRI has largely replaced EPs for these 3 indications)

A. vestibular schwannoma
B. subclinical lesions of multiple sclerosis
C. brainstem lesions
2. SSEP (especially from median nerve stimulation) has prognostic significance in cervical spondylotic myelopathy[2]
3. intraoperative use (*see below*)

Brainstem auditory evoked responses (BAER)

AKA auditory brainstem response **(ABR)**, AKA auditory evoked potential **(AEP)**. Auditory clicks are delivered to the patient by earphones. Peaks (*see Table 10-2*).

INTRA-OPERATIVE EVOKED POTENTIALS

For anesthetic requirements for intraoperative SSEP monitoring *see page 4*.

EPs may be used for intraoperative monitoring (e.g. monitoring hearing during resection of vestibular schwannomas, or monitoring SSEPs during some spine surgery), however, their delayed nature often makes them of limited usefulness in avoiding acute intraoperative injury. A 10% increased latency of a major EP peak, or a drop in amplitude ≥ 50% is significant and should cause the surgeon to assess all variables (retractors, instruments, blood pressure…). Intraoperative SSEPs may also be used to localize primary sensory cortex in anesthetized patients (as opposed to using brain mapping techniques in awake patients) by looking for phase reversal potentials across the central sulcus[3, 4] (*see page 150*). For anesthesia requirements for EPs, *see page 4*.

EP monitoring during spine surgery

SSEPs: Typical stimulus sites: median, ulnar, and tibial nerves. Impulses ascend in the ipsilateral posterior column. UE SSEPs travel primarily in the dorsal columns, but LE SSEPs are carried mostly in the dorsolateral fasciculus (*see page 92*) which is supplied by the anterior spinal artery. Thus, UE and LE SSEPs are sensitive to direct mechanical effects primarily on the posterior spinal cord (sensory) and may remain unchanged with some injuries to the anterior cord (motor), LE SSEPs can detect ischemic effects on the anterior cord by virtue of involvement of the anterior spinal artery. Paralytics actually help SSEPs by reducing muscle artifact, but will abolish the visible twitch that confirms that the stimulus is being received.

Criteria for EP changes to trigger notification of surgeon:

1. decrease in peak amplitude > 50%
2. increase in peak latency > 10%
3. complete loss of a waveform

In a personal series of 809 patients[5], 17 had SSEP degradation, 14 of these (82%) responded to intra-op interventions (*see below*), and in 13 of these 14 (93%) there were no new deficits. In the 3 that did not respond, 2 had significant new neurologic deficits.

Transcranial motor evoked potentials (TCMEPs): AKA **motor evoked potentials (MEP):** transcranial electrical or magnetic stimulation of motor cortex and descending motor axons with recording of motor potentials from distal spinal cord or muscle groups. Using direct electrical stimulation is limited in awake patients by local pain. Due to the large potentials, the acquisition time is shorter and feedback to the surgeon is almost immediate. However, due to patient movement from the muscle contractions, continuous recording is usually not possible (except with monitoring the response over the spinal cord). Useful for surgery involving the spinal cord (cervical or thoracic), no utility for lumbar spine. In addition to EP anesthetic requirements, neuromuscular blockade must be minimized to permit ≥ 2 out of 4 twitches. Seizures occur rarely, usually in patients with increased seizure risk and with high-rate stimulation frequency. Contraindications to MEP:

1. history of epilepsy/seizures
2. past surgical skull defects
3. metal in head or neck
4. use special care with implanted electronic devices

Descending evoked potentials (DEP): (Formerly referred to by the misleading term “neurogenic motor evoked potentials”). Rostral stimulation of the spinal cord with recording of a caudal neurogenic response from the spinal cord or peripheral nerve, or a myogenic response from a distal muscle. DEPs can be mediated primarily by sensory nerves and therefore do not represent true motor potentials. However, shown to be sensitive to spinal cord changes and may be useful when TCMEPs cannot be obtained.

Interventions for SSEP deterioration during surgery (options/suggestions):

1. check technical factors:
   A. rule-out 60 Hz. interference from other equipment (O.R. table, C-arm, microscope, anything with a plug)

    B. verify stimulating electrodes are making good contact
    C. check anesthetic technical factors: no paralytics, no acidemia
2. rule-out hypotension or anemia (could contribute to cord ischemia)
3. get an x-ray to rule out change in position
4. release retractors
5. consider repositioning patient, reduce traction, remove shoulder tape…
6. consider giving steroids: some use the methylprednisolone protocol (*see page 936*)
7. remove any hardware that might have caused the change
8. consider "wake up test" (AKA Miami wake-up test): discontinue anesthesia when patient is stable enough to do so and verify if they can move
9. truncate surgery

ABBREVIATIONS

Abbreviations used below: **BAER** = brain stem auditory evoked response; **UE/LE SSEP** = upper/lower extremity somatosensory evoked potential; **PR VER** = pattern reversal visual evoked response which requires patient cooperation and visual attention as opposed to flash VER which may even be done through closed eyelids. See also references[6, 7].

Table 10-2 Evoked potential waveforms
(note: values may differ from lab to lab)

Test	Figure	Possible generators
BAER		CM cochlear microphonic P_1 distal VIII nerve, P_2 proximal VIII or cochlear nucleus, P_3 lower pons (? superior olivary complex), P_4 mid-upper pons, **P_5** upper pons or inferior colliculus
UE SSEP		N_9 (on F_Z-E_P where E_P is Erb's point) AKA EP: entry of volley into distal brachial plexus, N_{11} (on C_{V7}-F_{PZ}): root entry zone (cervical region), N_{13} cervicomedullary junction (recorded from C2), **N_{19}** primary sensory cortex, P_{22} (early) motor cortex, P_{22} (late) IPSP "reaction" to N_{18}
LE SSEP		P_{22} (on L_5-T_{12}): lumbo-sacral plexus, P_{40} (on C_Z-F_{PZ}): sensory cortex (analogous to N18 in UE SSEP, reversed in polarity for ? reason), N_{27} (on C_{V7}-F_{PZ}): ? dorsal column nucleus **N_{30}**
PR VER		P_{100} striate & pre-striate occipital cortex, with contributions from thalamocortical volleys

Table 10-3 Normal values for evoked potentials*
(note: values may differ from lab to lab)

Test	Parameters measured	– – Normal values – –		Comment
		Mean	+2.5 std dev	
BAER	I-V peak latency	4.01 mS	**4.63 mS**	
	I-III peak latency	2.15 mS	**2.66 mS**	prolongation suggests lesion between pons & colliculus, often **vestibular schwannoma**
	V absolute latency	5.7 mS	**6.27 mS**	
	III-V peak latency			prolongation suggests lesion between lower pons & midbrain, may be seen in M.S.
UE SSEP	N_9-N_{18} peak latency	9.38 mS	**11.35 mS**	
LE SSEP	P_{22}-P_{40} peak latency	15.62 mS	**20.82 mS**	
	P_{40} absolute latency	37.20 mS	**44.16 mS**	
PR VER	P_{100} absolute latency		+ 3 S.D.	
	P_{100} inter-eye difference	8-10 mS		Inter-eye difference is more sensitive with full field stimulation. Monocular defect suggests conduction defect in that optic nerve anterior to chiasm (e.g. M.S., glaucoma, compression retinal degeneration). Bilateral defect does not localize.

* normal values in boldface are critical values used as cutoff for abnormal results

10.3. NCS/EMG

Electrodiagnostic studies of peripheral nerves consist of two parts:

1. conduction measurements: typically referred to as "NCV" (nerve conduction velocity) but technically should be called NCS (nerve conduction *studies*) since amplitude, latency and duration of motor & sensory nerves are also evaluated
2. electromyogram **(EMG)** AKA "needle exam" (*see below*)

ELECTROMYOGRAPHY

3 phases of EMG exam:

1. insertional activity: the electric response of the muscle to mechanical irritation caused by small movements of the needle
2. spontaneous activity: in muscle at rest
   A. normal: silent with stationary needle once insertional activity has subsided
   B. **spontaneous activity**: independently produced electrical activity. Usually abnormal (although sometimes seen in normal volunteers).
      1. after <u>denervation</u> (secondary to a nerve injury) or muscle injury:

a. positive sharp waves **(PSW)**

b. **fibrillation potentials** (AKA fibrillations or fibs): action potentials arising from single muscle fibers. Detectable on EMG; not visible to the naked eye (c.f. fasciculations, *see page 787*). Earliest onset 7-10 days after denervation, sometimes not for 3-4 weeks. If the nerve recovers, it may reinnervate the muscle, but with larger motor units resulting in longer duration and decreased numbers

2. myotonic discharges ("dive bomber" sound on speaker monitor)
3. complex repetitive discharge **(CRD)**: ephaptic conduction of groups of adjacent muscle fibers. Occurs in neuropathic or myopathic disorders
4. fasciculation potentials: nonspecific, but typically associated with motor neuron disease (ALS) (*see page 65*)
5. other less common spontaneous activity includes: myokymic, neuromytonic and cramp discharges

3. volitional activity: evaluated with minimal volitional effort and maximal effort

A. motor unit action potential **(MUAP)** analysis: includes evaluation of motor unit amplitude, duration, polyphasia and stability. Generally increase amplitude and duration suggest a disorder of the LMN, and reduction of amplitude and duration suggests a primary myopathic disorder

B. with minimal volitional effort. Two possible abnormal findings

1. reduced recruitment (or fast firing) is always indicative of a neuropathic process
2. early or increased recruitment: indicative of a myopathic process

C. with maximal effort

Definitions

SNAP: sensory nerve action potential. Key concept: since the ganglion of the sensory nerves lies within the neural foramen, preganglionic lesions (injury to the nerve root proximal to the neural foramen, e.g. root compression by herniated disc or root avulsion) does not affect the cell body, and therefore the distal SNAP is unaffected[8]. Postganglionic lesions (distal to the neural foramen, e.g. peripheral nerve injury) reduces SNAP amplitudes and/or slows the sensory conduction velocity.

F-wave: stimulation of a nerve causes orthodromic and antidromic

conduction. Some anterior horn cells that are stimulated antidromically will fire orthodromically producing the F-wave. F-wave latency may be prolonged in multilevel radiculopathy (not sensitive). Most helpful in evaluating proximal root slowing (e.g. GBS - *see page 66*)

H-reflex: practical ≈ only in S1 nerve root, similar information to the ankle jerk. Stimulation of Ia afferent fibers passes through a monosynaptic connection causing an orthodromic alpha-motor action potential that can be measured in the triceps surae.

Volitional activity: the motor unit action potential **(MUAP)** can be assessed only with voluntary muscle contraction by the patient. Components of the MUAP measured include: amplitude, rise time, duration, and number of phases (crossings of the baseline).

Polyphasic potentials: MUAPs with > 4 phases. Normally comprise < 15% of MUAPs. Following a nerve injury, abnormally increased polyphasic potentials can be seen 6-8 weeks after reinnervation begins, gradually increase over several months, and then begin to wane (as firing becomes more synchronous).

Radiculopathy

EMG for evaluating radiculopathy is low yield if the strength exam is normal. ∴ EMG is best reserved for cases with documented weakness where additional localizing/prognostic information is needed, or when the patient's strength cannot be reliably assessed (inability to cooperate, functional overlay…).

EMG is not extremely sensitive for radiculopathy (e.g irritative radiculopathy might not be picked up), this is true in the cervical region more so than in the lumbar region. However, when abnormal, EMG is very specific. If there is no weakness on exam, it is less likely that an EMG will be positive. Findings include spontaneous activity (fibs & PSWs, *see above*) and the earliest possible finding (within 2-3 d) is reduced recruitment with volitional activity, but this occurs only with significant compression of motor fibers.

EMG is useful if there is a concern about possible overlapping peripheral neuropathy (e.g carpal tunnel syndrome vs. C6 radiculopathy).

EMG criteria for radiculopathy

1. fibrillations and/or positive sharp waves in at least 2 muscles innervated

by a single nerve root in question, but by 2 different peripheral nerves
2. abnormal paraspinals: this supports the diagnosis, but is not required since paraspinals will be normal in ≈ 50%

Lumbar radiculopathy from herniated disc

Also *see page 432*. With radiculopathy, SNAP is usually normal (*see above*). Paraspinal muscle fibrillations may occur. Accuracy in predicting level of involvement[9] is ≈ 84%.

Foot drop: the short head of the biceps femoris in the LE is the first muscle innervated by the peroneal division of the sciatic nerve at or just above the popliteal fossa just after the nerve splits off from the sciatic nerve. In cases e.g. of foot drop it is a good muscle to test to determine if there is a peroneal neuropathy vs. a more proximal lesion (i.e. above the popliteal fossa).

Findings with healing radiculopathy (e.g. following discectomy or spontaneous healing):

- motor potentials return first (if nerve injury were "complete", it would take a month to return)
- if lost, sensory potentials return last or may not return
- following laminectomy, paraspinal potentials may no longer be useful because when the muscles are cut during surgery it alters their electrical signals resulting in effective denervation due to muscle injury. Fibs and PSWs decrease in amplitude over time but may remain present indefinitely

Plexopathy

Reduction of SNAP with no paraspinal muscle fibrillations (the dorsal rami exit proximally to innervate the paraspinals, and are involved ≈ only with root lesions).

Nerve root avulsion

Produces muscles weakness and sensory loss with normal SNAP.

NOTES

11. Neurotoxicology

Also *see* *page 998* for plumbism (lead poisoning) from retained bullets.

11.1. Ethanol

The acute and chronic effects of ethyl alcohol (ethanol, **EtOH**) abuse on the nervous system are protean[1], and are beyond the scope of this text (not to mention the effects of EtOH on other organ systems). Neuromuscular effects include:

1. acute intoxication: *see below*
2. effects of chronic alcohol abuse
   A. **Wernicke's encephalopathy**: *see page 275*
   B. cerebellar degeneration: due to degeneration of Purkinje cells in the cerebellar cortex, predominantly in the anterior superior vermis
   C. central pontine myelinolysis: *see page 11*
   D. stroke: increased risk of
      1. intracerebral hemorrhage: *see page 1121*
      2. ischemic stroke[2]
      3. possibly aneurysmal SAH: *see page 1035*
   E. peripheral neuropathy: *see page 794*
   F. skeletal myopathy
3. effects of alcohol withdrawal: usually seen in habituated drinkers with cessation or reduction of ethanol intake
   A. alcohol withdrawal syndromes: *see below*
   B. seizures: up to 33% of patients have a generalized tonic-clonic seizure 7-30 hrs after cessation of drinking (see *Alcohol withdrawal seizures*, page 399)
   C. delerium tremens **(DTs)**: *see below*

ACUTE INTOXICATION

The primary effect of EtOH on the CNS is depression of neuronal

excitability, impulse conduction, and neurotransmitter release due to direct effects on the cell membranes. *Table 11-1* shows the clinical effects associated with specific EtOH concentrations. **Mellanby effect**: the severity of intoxication is greater when blood alcohol levels are rising than when falling.

In most jurisdictions, individuals with blood ethanol levels ≥ 21.7 mmol/l (100 mg/dl) are defined as legally intoxicated, and a number of states have changed this to 80 mg/dl. However, even levels of 10.2 mmol/l (47 mg/dl) are associated with increased risk of involvement in motor vehicle accidents. Chronic alcoholism leads to increased tolerance; in habituated individuals survival with levels exceeding 1000 mg/dl has been reported.

Table 11-1 Blood ethanol concentrations (in non-alcoholic patients)

[blood EtOH]		Clinical effect
mmol/liter	mg/dl	
5.4	25	mild intoxication: altered mood, impaired cognition, incoordination
> 21.7	100	vestibular and cerebellar dysfunction: increased nystagmus, diplopia, dysarthria, ataxia
> 108.5	500	usually fatal from respiratory depression

ALCOHOL WITHDRAWAL SYNDROME

Compensation for the CNS depressant effects of EtOH occurs in chronic alcoholism. Consequently, rebound CNS hyperactivity may result from falling EtOH levels. Clinical signs of EtOH withdrawal are classified as major or minor (the degree of autonomic hyperactivity and the presence/absence of DTs differentiates these), as well as early (24-48 hrs) or late (> 48 hrs).

Signs/symptoms include: tremulousness, hyperreflexia, insomnia, N/V, autonomic hyperactivity (tachycardia, systolic HTN), agitation, myalgias, mild confusion. If EtOH withdrawal seizures occur, they tend to be early (*see page 399*). Perceptual disturbances or frank **hallucinosis** may also occur early. Hallucinosis consists of visual and/or auditory hallucinations with an otherwise clear sensorium (which distinguishes this from the hallucinations of DTs). DTs can occur 3-4 days after cessation of drinking (*see below*).

Suppressed by benzodiazepines, resumption of drinking, ß-adrenergic antagonists, or α_2-agonists.

PREVENTION OF AND TREATMENT FOR ALCOHOL WITHDRAWAL SYNDROME[3]

Mild EtOH withdrawal is managed with a quiet, supportive environment, reorientation and one-to-one contact. If symptoms progress, institute

pharmacologic treatment.

Benzodiazepines

Benzodiazepines **(BDZs)** are the mainstay of treatment. They reduce autonomic hyperactivity, and may prevent seizures and/or DTs. All BDZs are effective. Initial doses are shown in *Table 11-2* and are higher than those used for treating anxiety. Symptom triggered dosing with repeated evaluation utilizing a standardized protocol (e.g. CIWA-Ar[5]) may be more efficacious than fixed-dose schedules[6]. Avoid IM administration (erratic absorption).

Table 11-2 BDZ doses for EtOH withdrawal*

Drug	Dose	
	Oral	IV
chlordiazepoxide (Librium®)	100 mg initially, then 25-50 mg PO TID-QID, gradually taper over ≈ 4 days). Additional doses may be needed for continuing agitation, up to 50 mg PO hourly[4]	–
lorazepam† (Ativan®)	4 mg initially, then 1-2 mg PO q 4 hrs	1-2 mg q 1-2 hrs
diazepam (Valium®)	20 mg PO initially, then 10 mg PO BID-QID	5-10 mg initially
midazolam (Versed®)		titrate drip to desired effect

* modify as appropriate based on patient response

Adjunctive medications

Associated conditions commonly seen in patients experiencing alcohol withdrawal syndrome include dehydration, fluid and electrolyte disturbances, infection, pancreatitis, and alcoholic ketoacidosis, and should be treated accordingly.

Other medications used for EtOH withdrawal itself include:

1. drugs useful for controlling HTN (caution: these agents should not be used alone because they do not prevent progression to more severe levels of withdrawal, and they may mask symptoms of withdrawal)
   A. ß-blockers: also treat most associated tachyarrhythmias

        1. atenolol (Tenormin®): reduces length of withdrawal and BDZ requirement
        2. ✖ avoid propranolol (psychotoxic reactions)
    B. α-agonists: do not use together with ß-blockers. Clonidine (*see page 21*) has been extensively studied, and can be given in patch form (takes ≈ 2 days)
2. phenobarbital: an alternative to BDZs. Long acting, and helps prophylax against seizures
3. baclofen: a small study[7] found 10 mg PO q d X 30 days resulted in rapid reduction of symptoms after the initial dose and continued abstinence
4. "supportive" medications
    A. thiamine: 100 mg IM q d **x** 3 d (can be given IV if needed, but there is risk of adverse reaction). Rationale: high-concentration glucose may precipitate acute Wernicke's encephalopathy in patients with thiamine deficiency
    B. folate 1 mg IM, IV or PO q d **x** 3 d
    C. $MgSO_4$ 1 gm **x** 1 on admission: helpful only if magnesium levels are low, reduces seizure risk. Be sure renal function is normal before administering
    D. vitamin B_{12} for macrocytic anemia: 100 μg IM (do not give before folate)
    E. multivitamins: of benefit *only* if patient is malnourished
5. seizures: *see page 399* for indications for treatment
    A. phenytoin (Dilantin®): load with 18 mg/kg = 1200 mg/70 kg (*see page 409*)
6. ethanol drip: not widely used. 5% EtOH in D5W, start at 20 cc/hr, and titrate to a blood level of 100-150 mg/dl

DELERIUM TREMENS (DTS)

When DTs occur, they usually begin within 4 days of the onset of EtOH withdrawal, and typically persist for 1-3 days.

Signs and symptoms include: profound disorientation, agitation, tremor, insomnia, hallucinations, severe autonomic instability (tachycardia, HTN, diaphoresis, hyperthermia)[8]. Mortality is 5-10% (higher in elderly), but can be reduced with treatment (including treating associated medical problems and treatment for seizures).

Haloperidol and phenothiazines may control hallucinations, but can lower

the seizure threshold. HTN and tachyarrhythmias should be treated as outline above under alcohol withdrawal syndrome.

WERNICKE'S ENCEPHALOPATHY (WE)

AKA Wernicke-Korsakoff encephalopathy. Classic triad: encephalopathy (consisting of global confusion), ophthalmoplegia, and ataxia (NB: all 3 are present in only 10-33% of cases).

Due to thiamine deficiency. Body stores of thiamine are adequate only for up to ≈ 18 days. May be seen in:

1. a certain susceptible subset of thiamine deficient alcoholics. Thiamine deficiency here is due to a combination of inadequate intake, reduced absorption, decreased hepatic storage, and impaired utilization
2. hyperemesis (as in some pregnancies)
3. starvation: including anorexia nervosa, rapid weight loss
4. gastroplication (bariatric surgery)
5. hemodialysis
6. cancers
7. AIDS
8. prolonged IV hyperalimentation

Oculomotor abnormalities occur in 96% and include: nystagmus (horizontal > vertical), lateral rectus palsy, conjugate-gaze palsies.

Gait ataxia is seen in 87%, and results from a combination of polyneuropathy, cerebellar dysfunction, and vestibular impairment.

Systemic symptoms may include: vomiting, fever.

MRI: May show high signal in T2WI and FLAIR images in the paraventricular (medial) thalamus, the floor of the 4th ventricle, and periaqueductal gray of the midbrain. These changes may resolve with treatment[9]. Atrophy of the mammillary bodies may also be seen. Normal MRI does not R/O the diagnosis.

Treatment

Wernicke's encephalopathy **(WE)** is a medical emergency. When WE is suspected, 100 mg thiamine should be given IM or IV (oral route is unreliable, *see above*) daily for 5 days. ✖ IV glucose can precipitate acute WE in thiamine deficient patients, ∴ give thiamine first.

Thiamine administration improves eye findings within hours to days; ataxia

and confusion improve in days to weeks. Many patients that survive are left with horizontal nystagmus, ataxia, and 80% have **Korsakoff's syndrome** (AKA Korsakoff's psychosis), a disabling memory disturbance involving retrograde and anterograde amnesia.

11.2. Opioids

Includes heroin (which is usually injected IV, but the powder can be snorted or smoked) as well as prescription drugs. Opioids produce small pupils (miosis).

Overdose produces:

1. respiratory depression
2. pulmonary edema
3. coma
4. hypotension and bradycardia
5. seizures may occur with: propoxyphene, meperidine (Demerol®) which may also cause delerium, and the street drug combination of "T's and blues" (*see* *page 397*)
6. fatal overdose may occur with any agent, but is more likely with synthetic opioids such as fentanyl (Sublimaze®) among users unfamiliar with their high potency

Reversal of intoxication[10]

A test dose of naloxone (Narcan®) 0.2 mg IV avoids sudden complete reversal of all opioid effects. If no significant reaction occurs, an additional 1.8 mg (for a total dose of 2 mg) will reverse the toxicity of most opioids. If needed, the dose may be repeated q 2-3 minutes up to a total of 10 mg, although even larger doses may be needed with propoxyphene, pentazocine or buprenorphine (Buprenex®). Naloxone may precipitate narcotic withdrawal symptoms in opioid dependent patients, with anxiety or agitation, piloerection, yawning, sneezing, rhinorrhea, nausea, vomiting, diarrhea, abdominal cramps, muscle spasms… which are uncomfortable but not life threatening. Clonidine (Catapres®) may be helpful for some narcotic withdrawal symptoms.

With longer acting opioids, especially methadone (Dolophine®), repeat doses of naloxone may be obviated by the use of nalmefene (Revex®), a long-acting narcotic antagonist which is not appropriate for the initial treatment of

opioid overdosage.

11.3. Cocaine

The increasing use of cocaine in its various forms (including crack) is resulting in a rise in the incidence and recognition of its deleterious effects on the CNS. Effects on other body systems (tachycardia, acute myocardial infarction, arrhythmias, rupture of ascending aorta (aortic dissection), abruptio placenta, hyperthermia, intestinal ischemia, sudden death…) are well documented elsewhere, and are not further discussed here.

Cocaine is extracted from *Erythroxylon coca* leaves (and other *Erythroxylon* species) and is thus unrelated to opioids. It blocks the re-uptake of nor-epinephrine by presynaptic adrenergic nerve terminals. It is available in 2 forms: cocaine hydrochloride (heat labile and water soluble, it is usually taken PO, IV or by nasal insufflation) and as the highly purified cocaine alkaloid (free base or crack cocaine, which is heat stable but insoluble in water and is usually smoked).

Peak toxicity occurs 60-90 minutes after ingestion (except for “body packers”), 30-60 minutes after snorting, and minutes after IV injection or smoking (freebase or crack)[10].

Acute pharmacologic effects of cocaine

Acute pharmacologic effects pertinent to the nervous system include:

1. mental status: initial CNS stimulation that first manifests as a sense of well-being and euphoria. Sometimes dysphoric agitation results, occasionally with delerium. Stimulation is followed by depression. Paranoia and toxic psychosis may occur with overdosage or chronic use. Addiction may occur
2. pupillary dilatation (mydriasis)
3. hypertension: from adrenergic stimulation

Non-pharmacologic effects related to the nervous system

1. pituitary degeneration: from chronic intranasal use
2. cerebral vasculitis: less common than with amphetamines

3. seizures: possibly related to the local anesthetic properties of cocaine
4. cerebrovascular accident (CVA, stroke)[11]
    A. intracerebral hemorrhage: see *Intracerebral hemorrhage*, *Etiologies* on page 1119
    B. subarachnoid hemorrhage[12, 13]: possibly as a result of HTN in the presence of aneurysms or AVMs, however, sometimes no lesion is demonstrated on angiography[14]. May possibly be due to cerebral vasculitis
    C. ischemic stroke[15]: may result from vasoconstriction
    D. thrombotic stroke[10]
    E. TIA[16]
5. anterior spinal artery syndrome[16]
6. effects of maternal cocaine use on the fetal nervous system include[17]: microcephaly, disorders of neuronal migration, neuronal differentiation and myelination, cerebral infarction, subarachnoid and intracerebral hemorrhage, and sudden infant death syndrome (SIDS) in the postnatal period

Treatment of toxicity

Most cocaine toxicity is too short-lived to be treated. Anxiety, agitation or seizures may be treated with IV benzodiazepines (e.g. lorazepam, *see page 405*). Refractory HTN may be treated with nitroprusside (*see page 19*) or phentolamine (Regitine®, *see page 681*). IV lidocaine used to treat cardiac arrhythmias may cause seizures[10].

11.4. Amphetamines

Toxicity is similar to that of cocaine (*see above*), but longer in duration (may last up to several hours). Cerebral vasculitis may occur with prolonged abuse (*see page 79*) which may lead to cerebral infarction (*see page 1024*).

Elimination of amphetamines requires adequate urine output. Antipsychotic drugs such as haloperidol (Haldol®) should not be used because of risk of seizures.

11.5. Carbon monoxide

Carbon monoxide **(CO)** is the largest source of death from poisoning in the U.S.A.

Normal cellular function requires ≈ 5 ml O_2/100 ml blood. Blood normally contains ≈ 20 ml O_2/100 ml.

CO binds to hemoglobin **(Hb)** with an affinity ≈ 250 times that of O_2, and it causes a left shift of the Hb/O_2 dissociation curve. It also binds to intracellular myoglobin.

Only ≈ 6% of patients show the classic "cherry-red" color of blood.

Clinical findings

Related to CO-Hb level as shown in *Table 11-3*.

Diagnostic studies

EKG changes are common, usually non-specific ST-T wave changes.

In cases of severe intoxication, CT may show symmetrical low attenuation in the globus pallidus (*see page 1229* for differential diagnosis).

Outcome

Prognosticators

1. outcome is more closely correlated with hypotension than with actual CO-Hb level
2. coma
3. metabolic acidosis
4. EEG
5. CT/MRI changes: in one study, the presence of MRI lesions after 1 month did not accurately predict subsequent outcome
6. CO-Hb level
7. other factors probably have an effect, including: age, severity of exposure

Table 11-3 Levels of CO-Hb

CO-Hb level(%)	Signs/symptoms*
0-10	none

10-20*	mild H/A, mild DOE
20-30	throbbing H/A
30-40	severe H/A, dizziness, dimming of vision, impaired judgement
40-50	confusion, tachypnea, tachycardia, possible syncope
50-60	syncope, seizures, coma
60-70	coma, hypotension, respiratory failure, death
> 70	rapidly fatal

* NB: smokers may have CO-Hb levels of 15% without signs or symptoms

Approximately 40% of patients exposed to significant levels of CO die. 30-40% have transient symptoms but make a full recovery. 10-30% have persistent neurological sequelae including CO-encephalopathy (may be delayed in onset) - impaired memory, irritability, parietal lobe symptoms including various agnosias.

Brain lesions

1. white matter lesions:
    - A. multifocal small necrotic lesions in deep hemispheres
    - B. extensive necrotic zones along lateral ventricles
    - C. Grinker's myelinopathy (not necrosis)
2. grey matter lesions
    - A. bilateral necrosis of globus pallidus
    - B. lesions of hippocampal formation and focal cortical necrosis

NOTES

12. Coma

12.1. General information

Consciousness has two components: arousal and content. Impairment of arousal can vary from mild (drowsiness or somnolence), to obtundation, to stupor to coma. **Coma** is the severest impairment of arousal, and is defined as the inability to obey commands, speak, or open the eyes to pain.

The Glasgow Coma Scale **(GCS)** is shown in *Table 12-1* (note: the scale is used to assess level of consciousness and is not designed for following neurologic deficits). Some centers record a “T” next to the total score for patients whose verbal axis cannot be assessed because of intubation[2]. 90% of patients with GCS ≤ 8 and none with GCS ≥ 9 meet the above definition of coma. Thus, **GCS ≤ 8** is a generally accepted operational definition of coma.

A scale for use in children is shown in *Table 12-2*[3].

Table 12-1 Glasgow coma* scale[1]
(recommended for age ≥ 4 yrs)

Points†	Best eye opening	Best verbal	Best motor
6	–	–	obeys
5	–	oriented	localizes pain
4	spontaneous	confused	withdraws to pain
3	to speech	inappropriate	flexion (decorticate)
2	to pain‡	incomprehensible	extensor (decerebrate)
1	none	none	none§

* technically, this is a scale of *impaired* consciousness, whereas “coma” implies unresponsiveness

† range of total points: 3 (worst) to 15 (normal)

‡ when testing eye opening to pain, use peripheral stimulus (the grimace associated with central pain may cause eye closure)

§ if no motor response, important to exclude spinal cord transection

Table 12-2 Children's coma scale* (for age < 4 yrs)

Points†	Best eye	Best verbal		Best motor
6	–	–		obeys
5	–	smiles, oriented to sound, follows objects, interacts		localizes pain
		Crying	**Interaction**	
4	spontaneous	consolable	inappropriate	withdraws to pain
3	to speech	inconsistently consolable	moaning	flexion (decorticate)
2	to pain	inconsolable	restless	extensor (decerebrate)
1	none	none	none	none

* same as adult Glasgow coma scale except for verbal response[3]

† range of total points: 3 (worst) to 15 (normal)

Coma results from one or more of the following:

- dysfunction of high brainstem (central upper pons) or midbrain
- bilateral diencephalic dysfunction
- diffuse lesions in both cerebral hemispheres (cortical or subcortical white matter)

Posturing

The following terms are inaccurate in the implication of the location of the lesion. Decorticate posturing implies a more rostral lesion and prognosis may be better.

Decorticate posturing: Classically attributed to disinhibition by removal of corticospinal pathways above the midbrain.

Overview: abnormal flexion in UE and extension in LE.

Detail: slow flexion of arm, wrist and fingers with adduction in the UE. Extension, internal rotation, plantarflexion in LE.

Decerebrate posturing: Classically attributed to disinhibition of vestibulospinal tract (more caudal) and pontine reticular formation **(RF)** by removing inhibition of medullary RF (transection at intercollicular level, between vestibular and red nuclei).

Overview: abnormal extension in UE and LE.

Detail: opisthotonos (head and trunk extended), teeth clenched, arms extended, adducted and hyperpronated (internally rotated), wrists flexed, fingers flexed. Legs extended and internally rotated, feet plantarflexed and inverted, toes plantarflexed.

ETIOLOGIES OF COMA

TOXIC/METABOLIC CAUSES OF COMA

1. electrolyte imbalance: especially hypo- or hypernatremia, hypercalcemia, renal failure with elevated BUN & creatinine, liver failure with elevated ammonia
2. endocrine: hypoglycemia, nonketotic hyperosmolar state, DKA (diabetic ketoacidosis, AKA diabetic coma), myxedema coma, Addisonian crisis (hypoadrenalism)
3. vascular: vasculitis, DIC, hypertensive encephalopathy (*see page 73*)
4. toxic: EtOH, drug overdose (including narcotics, iatrogenic polypharmacy, barbiturates), lead intoxication, carbon monoxide (CO) poisoning, cyclosporine (causes an encephalopathy that shows white-matter changes on MRI that is often reversible with discontinuation of the drug)
5. infectious/inflammatory: meningitis, encephalitis, sepsis, lupus cerebritis, neurosarcoidosis (*see page 71*), toxic-shock syndrome
6. neoplastic: leptomeningeal carcinomatosis, rupture of neoplastic cyst
7. nutritional: Wernicke's encephalopathy, vitamin B_{12} deficiency
8. inherited metabolic disorders: porphyria, lactic acidosis
9. organ failure: uremia, hypoxemia, hepatic encephalopathy, Reye's syndrome, anoxic encephalopathy (e.g. post-resuscitation from cardiac arrest), CO_2 narcosis
10. epileptic: status epilepticus (including non-convulsive status), post-ictal state (especially with unobserved seizure)

STRUCTURAL CAUSES OF COMA

1. vascular:
   A. bilateral cortical or subcortical infarcts (e.g. with cardioembolism due to SBE, mitral stenosis, A-fib, mural thrombus…)
   B. occlusion of vessel supplying both cerebral hemispheres (e.g. severe bilateral carotid stenosis)
   C. bilateral diencephalic infarcts: well described syndrome. May be due to occlusion of a thalamo-perforator supplying both medial thalamic areas or with "top-of-the-basilar" occlusion. Initially resembles metabolic coma (including diffuse slowing on EEG), patient eventually arouses with apathy, memory loss, vertical gaze paresis
2. infectious: abscess with significant mass effect, subdural empyema, herpes simplex encephalitis
3. trauma: hemorrhagic contusions, edema, hematoma (*see below*)

4. neoplastic: primary or metastatic
5. herniation from mass effect: presumably brainstem compression causes dysfunction of reticular activating system or mass in one hemisphere causing compression of the other results in bilateral hemisphere dysfunction
6. increased intracranial pressure: reduces CBF
7. acute lateral shift (midline shift) of the brain: e.g. due hematoma (subdural or epidural): *see Table 12-3*

Table 12-3 Effect of lateral shift on level of consciousness[4]

Amount of midline shift	Level of consciousness
0-3 mm	alert
3-4 mm	drowsy
6-8.5 mm	stuporous
8-13 mm	comatose

PSEUDOCOMA

Differential diagnosis:

1. locked-in syndrome: ventral pontine infarction
2. psychiatric: catatonia, conversion reaction
3. neuromuscular weakness: myasthenia gravis, Guillain-Barré

12.2. Approach to the comatose patient

The following covers nontraumatic coma (see *Head trauma*, page 850 for that topic).

Initial evaluation: includes measures to protect brain (by providing CBF, O_2, and glucose), assesses upper brainstem (Cr. N. VIII), and rapidly identifies surgical emergencies. Keep "pseudocoma" as a possible etiology in back of mind.

APPROACH TO COMATOSE PATIENT, OUTLINE

1. cardiovascular stabilization: establish airway, check circulation (heartbeat,

BP, carotid pulse), CPR if necessary

2. obtain blood for tests
   A. STAT: electrolytes (especially Na, glucose, BUN), CBC + diff, ABG
   B. others as appropriate: toxicology screen (serum & urine), calcium, ammonia, antiepileptic drug **(AED)** levels (if patient is taking AEDs)
3. administer emergency supportive medications
   A. glucose: at least 25 ml of D_{50} IVP. Due to potentially harmful effect of glucose in global ischemia, if possible check fingerstick glucose first, otherwise glucose is given without exception, unless it is known with certainty that serum glucose is normal
   B. naloxone (Narcan®): in case of narcotic overdose. 1 amp (0.4 mg) IVP
   C. flumazenil (Romazicon®): in case of benzodiazepine overdose (*see page 52*). Start with 0.2 mg IV over 30 seconds, wait 30 secs, then give 0.3 mg over 30 secs at 1 minute intervals up to 3 mg or until patient arouses
   D. thiamine: 50-100 mg IVP (3% of Wernicke's present with coma)
4. core neuro exam (assesses midbrain/upper pons, allows emergency measures to be instituted rapidly, more thorough evaluation possible once stabilized): → (see *Core neuro exam* below)
5. if herniation syndrome or signs of expanding p-fossa lesion with brainstem compression (*see Table 12-4*): initiate measures to lower ICP (see *Treatment measures for elevated ICP*, page 876), then get a CT scan if patient begins improving, otherwise emergency surgery (*see page 1021*). ✖ Do <u>NOT</u> do LP

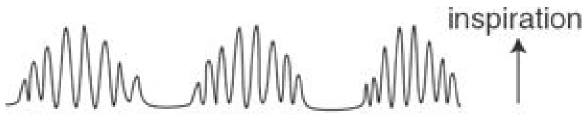
Table 12-4 Signs of herniation syndrome or posterior fossa lesion

HERNIATION SYNDROMES	SIGNS OF P-FOSSA LESION
(also see *Herniation syndromes*, page 284)	(also see *Posterior fossa (infratentorial) tumors*, page 590)
• unilateral sensory or motor deficit • progressive obtundation → coma • unilateral 3rd nerve palsy • decorticate or decerebrate posturing (especially if unilateral)	• initial symptoms of diplopia, vertigo, bilateral limb weakness, ataxia, occipital H/A • rapid onset of deterioration/coma • bilateral motor signs at onset • miosis • absent calorics to horizontal movement, possibly with preserved vertical movements • ocular bobbing • ophthalmoplegia • multiple cranial nerve abnormalities with long tract signs • apneustic, cluster or ataxic respirations

6. if meningitis suspected (altered mental status + fever, meningeal signs…)
   A. if no indication of herniation, p-fossa mass (*see* *Table 12-4*), focal deficit indicating mass effect or papilledema: perform LP, start antibiotics immediately (do not wait for CSF results) (see *Meningitis*, page 343)
   B. if evidence of possible mass effect, coagulopathy or herniation, CT to R/O mass. If significant delay anticipated, consider empiric antibiotics or careful LP with small gauge needle (≤ 22 Ga.), measure opening pressure **(OP)**, remove only a small amount of CSF if OP high, replace CSF if patient deteriorates (LP in this setting may be risky, see *Lumbar puncture*, page 201).
7. treat generalized seizures if present. If status epilepticus is suspected, treat as indicated on page 404 (obtain emergency EEG if available)
8. treat metabolic abnormalities
   A. restore acid-base balance
   B. restore electrolyte imbalance
   C. maintain body temperature
9. obtain as complete history as possible once stabilized
10. administer specific therapies

CORE NEURO EXAM (FOR COMA)

A. **respiratory** rate and pattern: the most common disorder in impaired consciousness
   1. **Cheyne-Stokes**: breathing gradually crescendos in amplitude and then trails off, followed by an expiratory pause, and then the pattern repeats. Hyperpneic phase is usually longer than apneic. Usually seen with diencephalic lesions or bilateral cerebral hemisphere dysfunction (non-specific), e.g. early increased ICP or metabolic abnormality. Results from an increased ventilatory response to CO_2

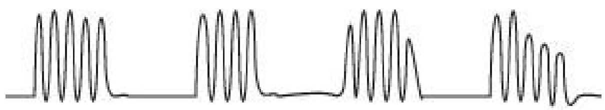


Cheyne-Stokes respiratory pattern

   2. **hyperventilation**: usually in response to hypoxemia, metabolic acidosis, aspiration, or pulmonary edema. True central neurogenic hyperventilation is rare, and usually results from dysfunction within the pons. If no other

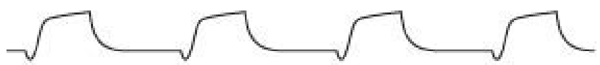
brainstem signs are present, may suggest psychiatric disorder

3. **cluster breathing**: periods of rapid irregular breathing separated by apneic spells, may appear similar to Cheyne-Stokes, may merge with various patterns of gasping respirations. High medulla or lower pons lesion. Often an ominous sign



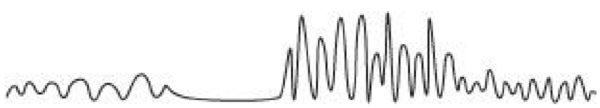
Cluster breathing

4. **apneustic** (rare): a pause at full inspiration. Indicates pontine lesion, e.g. with basilar artery occlusion



Apneustic respiratory pattern

5. **ataxic** (Biot's breathing): no pattern in rate or depth of respirations. Seen with medullary lesion. Usually preterminal



Ataxic respirations

⋆ B. **pupil** (size in mm) in ambient light, and in reaction to direct/consensual light

1. equal and reactive pupils indicates toxic/metabolic cause with few exceptions (*see below*) (may have hippus). The light reflex is the most useful sign in distinguishing metabolic from structural coma
   A. the <u>only</u> metabolic causes of fixed/dilated pupil: glutethimide toxicity, **anoxic encephalopathy**, anticholinergics (including topically applied atropine), occasionally with botulism toxin poisoning
   B. narcotics cause small pupils (<u>miosis</u>) with a small range of constriction and sluggish reaction to light (in severe overdose, the pupils may be so small that a magnifying glass may be needed to see reaction)
2. unequal (note: an afferent pupillary defect does <u>not</u> produce anisocoria (see *Alterations in pupillary diameter*, page 831)):
   A. fixed and dilated pupil: usually due to oculomotor palsy. Possible

herniation, especially if larger pupil associated with ipsilateral 3rd nerve EOM palsy (eye deviated "down and out")

B. possible Horner's syndrome: consider carotid occlusion/dissection

3. bilateral pupil abnormalities

A. pinpoint with minute reaction that can be detected with magnifying glass[5]: pontine lesion (sympathetic input is lost; parasympathetics emerge at Edinger-Westphal nucleus and are unopposed)

B. bilateral fixed and dilated (7-10 mm): subtotal damage to medulla or immeinspiration diate post-anoxia or hypothermia (core temperature < 90° F (32.2° C))

C. midposition (4-6 mm) and fixed: more extensive midbrain lesion, presumably due to interruption of sympathetics and parasympathetics

C. extraocular muscle function

1. deviations of ocular axes at rest

A. bilateral conjugate deviation:

1. frontal lobe lesion (frontal center for contralateral gaze): looks toward side of destructive lesion (away from hemiparesis). Looks away from side of seizure focus (looks at jerking side), may be status epilepticus. Reflex eye movements (*see below*) are normal
2. pontine lesion: eyes look away from lesion and towards hemiparesis; calorics impaired on side of lesion
3. "wrong way gaze": medial thalamic hemorrhage. Eyes look away from lesion and towards hemiparesis (an exception to the axiom that the eyes look towards a destructive supratentorial lesion)[5]
4. downward deviation: may be associated with unreactive pupils (**Parinaud's syndrome**, *see page 114*). Etiologies: thalamic or mid-brain pretectal lesions, metabolic coma (especially barbiturates), may follow a seizure

B. unilateral outward deviation on side of larger pupil (III palsy): uncal herniation

C. unilateral inward deviation: VI (abducens) nerve

D. skew deviation

1. III or IV nerve/nucleus lesion
2. infratentorial lesion (frequently dorsal midbrain)

2. spontaneous eye movements

A. "windshield wiper eyes": random roving conjugate eye movements. Non-localizing. Indicates an intact III nucleus and medial longitudinal fasciculus

B. periodic alternating gaze, AKA "ping-pong gaze": eyes deviate side to side with frequency of ≈ 3-5 per second (pausing 2-3 secs in each direction). Usually indicates bilateral cerebral dysfunction

C. <u>ocular bobbing</u>: repetitive rapid vertical deviation downward with slow return to neutral position. Pontine lesion (*see page 838*)

3. internuclear ophthalmoplegia **(INO)**: due to lesion in medial longitudinal fasciculus **(MLF)** (fibers crossing to contralateral III nucleus are interrupted). Eye ipsilateral to MLF lesion does not adduct on spontaneous eye movement or in response to reflex maneuvers (e.g. calorics) (*see page 834*)
4. reflex eye movements (maneuvers to test brainstem)

A. **oculovestibular reflex**[A], AKA **ice water calorics**: first rule-out TM perforation and occlusion of the EAC by cerumen. Elevate the HOB 30°[B], irrigate one ear with 60-100 ml of ice water[C]. NB: response is inhibited by neuromuscular blocking agents **(NMBA)**

1. a comatose patient with an <u>intact</u> brainstem will have tonic conjugate eye deviation to side of cold stimulus which may be delayed up to one minute or more. There will be no fast component (nystagmus) (the cortical component) even if the brainstem is intact (NB: **oculocephalic reflex**[D] (doll's eyes) provides similar information as oculovestibular reflex[E], but poses a greater risk to the spinal cord if C-spine not cleared)
2. **no response**: symmetrical, could be specific toxin (e.g. neuromuscular block or barbiturates), metabolic cause, brain death or possibly massive infratentorial lesion
3. asymmetric: infratentorial lesion, especially if response inconsistent with 3rd nerve palsy (herniation). Usually maintained in toxic/metabolic coma
4. nystagmus without tonic deviation (i.e. eyes remain in primary position) virtually diagnostic of psychogenic coma
5. contralateral eye fails to adduct: INO (MLF lesion)

B. **optokinetic nystagmus** presence strongly suggests psychogenic coma

D. motor: muscle tone and reflexes, response to pain, Babinski (note asymmetries)

1. appropriate: implies corticospinal tracts and cortex intact
2. asymmetric: supratentorial lesion (tone usually increased), unlikely in metabolic
3. inconsistent/variable: seizures, psychiatric

4. symmetric: metabolic (usually decreased). Asterixis, tremor, myoclonus may be present in metabolic coma
5. hyporeflexia: consider myxedema coma, especially in patient presenting weeks after transsphenoidal surgery
6. patterns
   A. decorticate posturing: arms flex, legs extend: large cortical or subcortical lesion
   B. decerebrate posturing: arms and legs extend: brainstem injury at or below lower midbrain
   C. arms flexed, legs flaccid: pontine tegmentum
   D. arms flaccid, legs appropriate ("man-in-the-barrel syndrome"): anoxic injury (poor prognosis)

E. **ciliospinal reflexes** (pupillary dilatation to noxious cutaneous stimuli): tests integrity of sympathetic pathways
1. bilaterally present: metabolic
2. unilaterally present: possible 3rd nerve lesion (herniation) if on side of larger pupil. Possible pre-existing Horner's syndrome if on side of smaller pupil
3. bilaterally absent: usually not helpful

A. **oculovestibular reflexes** (calorics): the anticipated response is commonly misunderstood. In a normal awake patient there is slow deviation towards the side of the cold stimulus with nystagmus (which is named for the rapid, cortical phase) in the *opposite* direction (hence the mnemonic "COWS" (cold-opposite, warm-same)). Nystagmus will be absent in the comatose patient

B. HOB at 30° places the horizontal semicircular canal **(SCC)** vertically for maximal response[6] (p 56)

C. cold water → downward endolymphatic currents, away from the ampulla of the horizontal SCC[6] (p 57)

D. **oculocephalic reflex** ("doll's eyes" or "doll's head"): do not perform if there is any uncertainty about cervical-spine stability. In an awake patient, the eyes will either move with the head, or, if the movement is slow enough and the patient is fixating on an object, there will be contraversive conjugate eye movement[7] (c.f. oculovestibular reflex which does not depend on patient's level of cooperation). In a comatose patient with an intact brainstem & cranial nerves, there will also be contraversive conjugate eye movement (a positive doll's eyes response)

E. oculovestibular reflexes are absent but oculocephalic are maintained only when vestibular inputs are interrupted, e.g. streptomycin toxicity of labyrinths or bilateral vestibular schwannomas

---

12.3. Herniation syndromes

Classic teaching has been that shifts in brain tissue (e.g. caused by masses or increased intracranial pressure) through rigid openings in the skull (herniation) compress other structures of the CNS producing the observed symptoms. This view has been challenged[8], with the hypothesis that herniation may be an epiphenomenon that occurs late in the process and is not actually the cause of the observations. However, herniation models still serve as useful approximations.

The five most common herniation syndromes are:

1. central (transtentorial) herniation (*see page 285*) } supratentorial herniation
2. uncal herniation (*see page 286*) } supratentorial herniation
3. cingulate herniation: cingulate gyrus herniates under falx (AKA subfalcine herniation). Usually asymptomatic unless ACA kinks and occludes causing bifrontal infarction. Usually warns of impending transtentorial herniation
4. upward cerebellar (*see below*) } infratentorial herniation
5. tonsillar herniation (*see below*) } infratentorial herniation

COMA FROM SUPRATENTORIAL MASS[6]

Central and uncal herniation each causes a different form of **rostral-caudal deterioration**. Central herniation results in sequential failure of: diencephalon, midbrain, pons, medulla (*see page 285*). For uncal herniation, *see page 286*. "Classic" signs of increased ICP (HTN, bradycardia, altered respiratory pattern) usually seen with p-fossa lesions may be absent in slowly developing supratentorial masses.

Distinction between central and uncal herniation is difficult when dysfunction reaches the midbrain level or below. Predicting the location of the lesion based on the herniation syndrome is unreliable.

Clinical characteristics differentiating uncal from central herniation

- decreased consciousness occurs early in central herniation, late in uncal
- uncal herniation syndrome rarely gives rise to decorticate posturing

Differential diagnosis of supratentorial etiologies

1. vascular: CVA, intracerebral hemorrhage, SAH
2. inflammatory: cerebral abscess, subdural empyema, herpes simplex encephalitis
3. neoplastic: primary or metastatic
4. traumatic: epidural or subdural hematoma, depressed skull fracture

COMA FROM INFRATENTORIAL MASS

NB: it is essential to identify patients with primary posterior fossa lesions (see *Table 12-4*, page 281) as they may require emergent surgical intervention (*see page 1021*).

Etiologies of infratentorial mass

1. vascular: brainstem infarction (including basilar artery occlusion), cerebellar infarction or hematoma
2. inflammatory: cerebellar abscess, central pontine myelinolysis, brainstem encephalitis
3. neoplasms: primary or metastatic
4. traumatic: epidural or subdural hematoma

HYDROCEPHALUS

Infratentorial masses can produce obstructive hydrocephalus by compressing the Sylvian aqueduct and/or 4th ventricle (*see page 586*).

UPWARD CEREBELLAR HERNIATION

Occasionally seen with p-fossa masses, may be exacerbated by ventriculostomy. Cerebellar vermis ascends above tentorium, compressing the midbrain, and possibly occluding SCAs → cerebellar infarction. May compress sylvian aqueduct → hydrocephalus.

TONSILLAR HERNIATION

Cerebellar tonsils “cone” through foramen magnum, compressing medulla → respiratory arrest. Usually rapidly fatal.

Occurs with either supra- or infratentorial masses or with elevated ICP. May be precipitated by LP. In many cases, there may simply be pressure on the brainstem without actual herniation[9]. There are also cases with significant cerebellar herniation through the foramen magnum with the patient remaining

alert[8].

12.3.1. Central herniation

AKA transtentorial herniation AKA tentorial herniation. Usually more chronic than uncal herniation, e.g. due to tumor, especially of frontal, parietal or occipital lobes.

The diencephalon is gradually forced through the tentorial incisura. The pituitary stalk may be sheared, resulting in diabetes insipidus. PCAs may be trapped along the open edge of the incisura, and may occlude producing cortical blindness (see *Blindness from hydrocephalus*, page 335). The brainstem suffers ischemia from compression and shearing of perforating arteries from basilar artery → hemorrhages within the brainstem (**Duret hemorrhages**).

CT or plain x-ray criteria

Downward displacement of the pineal gland may be demonstrated[10]. Perimesencephalic cisterns are compressed.

DIENCEPHALIC STAGE

Early. May be due to diffuse bilateral hemisphere dysfunction (e.g. from decreased blood flow from increased ICP) or (more likely) from bilateral diencephalic dysfunction due to downward displacement. This stage warns of impending (irreversible) midbrain damage but is frequently reversible if the cause is treated.

Consciousness	Altered alertness is first sign; usually lethargy, agitation in some. Later: stupor → coma.
Respiration	Sighs, yawns, occasional pauses. Later: Cheyne-Stokes.
Pupils	Small (1 - 3 mm), small range of contraction.
Oculomotor	Conjugate or slightly divergent roving eyes; if conjugate then brainstem intact. Usually positive DOLL’S EYES and conjugate ipsilateral response to cold water calorics (CWC). Impaired up-gaze due to compression of superior colliculi and diencephalic pretectum (Parinaud’s syndrome *see page 114*)
Motor	Early: appropriate response to noxious stimuli, bilateral Babinski, gegenhalten (paratonic resistance). If previously hemiparetic contralateral to lesion: may worsen. Later: motionlessness & grasp reflexes, then DECORTICATE (initially contralateral to lesion in most cases).

MIDBRAIN - UPPER PONS STAGE

When midbrain signs fully developed (in adults), prognosis is very poor (extreme ischemia of midbrain). Fewer than 5% of cases will have a good recovery if treatment is successfully undertaken at this stage.

Respiration	Cheyne-Stokes → sustained tachypnea.
Pupils	Moderately dilated midposition (3-5 mm), fixed*.
Oculomotor	Doll's eyes & CWC impaired, may be dysconjugate. MLF lesion → **internuclear ophthalmoplegia** (when doll's or CWC elicited and dysconjugate, medially moving eye moves less than laterally moving eye).
Motor	Decorticate → bilaterally DECEREBRATE (occasionally spontaneously).

* in pontine hemorrhage pinpoint pupils appear because the loss of sympathetics leaves the parasympathetics unopposed, whereas in herniation, the parasympathetics are usually lost, too (3rd nerve injury)

LOWER PONS - UPPER MEDULLARY STAGE

Respiration	Regular, shallow and rapid (20-40/min).
Pupils	Midposition (3-5 mm), fixed.
Oculomotor	Doll's eyes and CWC unelicitable.
Motor	Flaccid. Bilateral Babinski. Occasionally LE flexion to pain.

MEDULLARY STAGE (TERMINAL STAGE)

Respiration	Slow, irregular rate and depth, sighs/gasps. Occasionally hyperpnea alternating with apnea
Pupils	Dilate widely with hypoxia.

OUTCOME AFTER CENTRAL HERNIATION

In a series of 153 patients with signs of central herniation (altered level of consciousness, anisocoria or fixed pupils, abnormal motor findings) 9% had good recovery, 18% had functional outcome, 10% were severely disabled, and 60% died[11].

Factors associated with a better result were young age (especially age ≤ 17 yrs), anisocoria with deteriorating Glasgow Coma Score and nonflaccid motor function. Factors associated with poor outcome were bilaterally fixed pupils, with only 3.5% of these patients having a functional recovery.

12.3.2. Uncal herniation

Usually occurs in rapidly expanding traumatic hematomas, frequently in the lateral middle-fossa or temporal lobe pushing medial uncus and hippocampal gyrus over edge of tentorium, entrapping third nerve and directly compressing midbrain. PCA may be occluded (as with central herniation). For CT criteria *see below*.

Impaired consciousness is NOT a reliable early sign. Earliest consistent sign: unilaterally dilating pupil. However, it is unlikely that a patient undergoing early uncal herniation would be completely neurologically intact except for anisocoria (do not dismiss confusion, agitation, etc.). Once brainstem findings appear, deterioration may be rapid (deep coma may occur within hours).

CT criteria[12]

Tentorial incisura surrounds interpeduncular and pre-pontine cisterns and brainstem. There is great interpersonal variability in the amount of space in the incisura.

Impending uncal or hippocampal herniation may be indicated by encroachment on lateral aspect of suprasellar cistern → flattening of normal pentagonal shape. Once herniation occurs CT may show: brainstem displacement and flattening, compression of contralateral cerebral peduncle, midbrain rotation with slight increase of ipsilateral subarachnoid space. Also, contralateral hydrocephalus may occur[13].

Obliteration of parasellar and interpeduncular cisterns occurs as uncus and/or hippocampus are forced through hiatus. Brainstem compression → AP elongation. Since dural structures enhance with IV contrast, this may be used to help delineate tentorial margins when necessary.

EARLY THIRD NERVE STAGE

(NOT A BRAINSTEM FINDING, DUE TO 3RD NERVE COMPRESSION)

Pupils	Unilaterally dilating pupil (may be sluggish); 85% ipsilateral to lesion[14]
Oculomotor	Doll's = normal or dysconjugate. CWC = slow ipsilateral deviation, impaired nystagmus, may be dysconjugate if external oculomotor ophthalmoplegia **(EOO)**.
Respirations	Normal.
Motor	Appropriate response to nociceptive stimulus. Contralateral Babinski.

LATE THIRD NERVE STAGE

Midbrain dysfunction occurs almost immediately after symptoms extend beyond those due to focal cerebral lesion (i.e. may skip diencephalic stage, due to lateral pressure on midbrain). Treatment delays may result in irreversible damage.

Pupils	Pupil fully dilates.
Oculomotor	Once pupil blown, then external oculomotor ophthalmoplegia (EOO).
Consciousness	Once EOO, stuporous → comatose.
Respirations	Sustained hyperventilation, rarely Cheyne-Stokes.
Motor	Usually produces contralateral weakness. However, the contralateral cerebral peduncle may be compressed against the tentorial edge causing ipsilateral hemiplegia (Kernohan's phenomenon, a false localizing sign). Then bilateral decerebration (decortication unusual).

MIDBRAIN - UPPER PONS STAGE

Pupils	Contralateral pupil fixes in midposition or full dilation. Eventually, both midposition (5-6 mm) and fixed.
Oculomotor	Impaired or absent.
Respirations	Sustained hyperpnea.
Motor	Bilateral decerebrate rigidity.

From this point onward, the uncal syndrome is indistinguishable from central herniation (*see above*).

12.4. Hypoxic coma

Anoxic encephalopathy may be due to **anoxemic anoxia** (drop in pO_2) or **anemic anoxia** (following exsanguination or cardiac arrest). Myoclonus is common.

Vulnerable cells:

1. cerebral grey matter: lesions predominate in 3rd cortical layer (white matter is usually better preserved due to lower O_2 requirements)
2. Ammon's horn is also vulnerable

3. in the basal ganglia **(BG)**:

Table 12-5 Patients with BEST chance of regaining independence*

Time of exam	Finding
< 6 hrs from onset	(pupillary light reflex present) *AND* (GCS-motor > 1) *AND* (spontaneous EOM WNL, i.e. orienting or conjugate roving)
1 day	(GCS-motor > 3) *AND* (GCS-eye improved ≥ 2 from initial)
3 days	(GCS-motor > 3) *AND* (spontaneous EOM WNL)
1 week	GCS-motor = 6
2 weeks	oculocephalic WNL

A. anoxemic anoxia severely affects globus pallidus

B. anemic anoxia affects the caudate nucleus and putamen

4. in the cerebellum: Purkinje cells, dentate nuclei, and inferior olives are affected

Multivariate analysis yields out-come prognosticators shown in *Table 12-5* and *Table 12-6*. NB: this analysis applies only to hypoxic-ischemic coma[15]. More recent studies confirm the poor prognosis of unreactive pupils and lack of motor response to pain[16]; if either of these findings are seen within a few hours after cardiac arrest there is an 80% risk of death or permanent vegetative state, and if present at 3 days these this rate rose to 100%.

Glucocorticoids (steroids) have been shown to have no beneficial effect on survival rate or neurological recovery rate after cardiac arrest[17].

Table 12-6 Patients with virtually NO chance of regaining independence*

Time of exam	Finding
< 6 hrs	no pupillary light reflex
1 day	(GCS-motor < 4) *AND* (spontaneous eye movements not orienting nor conjugate roving)
3 days	GCS-motor < 4
1 week	(GCS-motor < 6) *AND* (at < 6 hrs spontaneous EOM not orienting nor conjugate roving) *AND* (at 3 d GCS-eye < 4)
2 week	(oculocephalic not WNL) *AND* (at 3 d GCS-motor < 6) *AND* (at 3 d GCS-eye < 4)

	AND (at 2 wk GCS-eye not improved at least 2 points from initial)

* abbreviations: WNL = within normal limits, GCS = Glasgow Coma Scale ("GCS-motor" refers to the motor score…); EOM = extraocular muscle;

13. Brain death

13.1. Brain death in adults

Most states accept some form of “brain death” as a valid determination of death. The President’s Commission provides the following guidelines[1]:

1. the diagnosis of death requires both cessation of function and irreversibility of cessation of either cardiopulmonary system or *entire* brain (including brainstem)
2. for age < 5 years, see *Brain death in children*, page 292
3. with no “complicating conditions” listed below, there are “…no cases of brain functions returning following a 6 hr cessation, documented by clinical examination and confirmatory EEG”[A]
4. with conditions such as massive intracerebral tumor with herniation or gunshot wound to the head, it is possible to pronounce death sooner with more certainty than, e.g. with post cardiac-arrest anoxia or following a coma of unknown etiology
5. when death results from criminal assault, or there is the possibility of litigation regarding the death, extra care must be taken and legal counsel may be advisable before making the determination of brain death

Table 13-1 Summary of findings in brain death (*see text* for details)

1. absence of brainstem reflexes
A. fixed pupils (no response to light)
B. absent corneal reflexes
C. absent oculovestibular reflex (calorics)
D. absent oculocephalic reflex (doll’s eyes)
E. absent gag & cough reflex
2. apnea with arterial $pCO_2 > 60$ mm Hg
3. no response to deep central pain
4. vital signs & general criteria
A. core temp > 32.2° C (90° F)
B. SBP ≥ 90 mm Hg
C. no drugs that could simulate brain death

BRAIN DEATH CRITERIA

Recommendations[1, 2] (*see Table 13-1* for summary):

A. absence of **brainstem reflexes**:

1. ocular examination:
   A. *fixed* pupils: no response to bright light (caution after resuscitation: *see below*). The size of the pupils is unimportant (they are usually midposition (4-6 mm) but may vary to dilated range[B] (9 mm))
   B. absent corneal reflexes[C]
   C. absent oculocephalic (doll's eyes) reflex (contraindicated if C-spine not cleared): *see page 283*
   D. absent **oculovestibular reflex** (cold water **calorics**): instill 60-100 ml ice water into one ear (do not do if TM perforated) with HOB at 30°. Brain death is excluded if <u>any</u> eye movement (*see page 283*). Wait at least 1 minute for response, and ≥ 5 min before testing the opposite side
2. absent oropharyngeal reflex (gag) to stimulation of posterior pharynx
3. no cough response to bronchial suctioning

B. **apnea test** AKA apnea challenge: no spontaneous respirations[D] after disconnection from ventilator (assesses function of medulla). Since elevating $PaCO_2$ increases ICP which could precipitate herniation and vasomotor instability, this test should be reserved for last and only used when the diagnosis of brain death is reasonably certain. Guidelines[4, 5]

1. apnea for > 2 minutes with $PaCO_2 > 60$ mm Hg or $PaCO_2 > 20$ mm Hg over base-line or pH < 7.3 (CO_2 is the most potent stimulus for respirations). If patient does not breathe by this point, they won't breathe at a higher $PaCO_2$. Not valid with severe COPD or CHF
2. to prevent hypoxemia during the test (with the danger of cardiac arrhythmia or myocardial infarction):
   - precede the test with 15 minutes of ventilation with 100% F_IO_2 (preoxygenation)
   - prior to the test, adjust the ventilator to bring the $PaCO_2 \approx 40$ mm Hg (to shorten the test time and thus reduce the risk of hypoxemia)
   - during the test, have passive O_2 flow administered at 6 L/min through either a pediatric oxygen cannula or a No. 14 French tracheal suction catheter (with the side port covered with adhesive tape) passed to the estimated level of the carina

3. starting from normocapnea, the average time to reach $PaCO_2 = 60$ mm Hg is **6 minutes** (classic teaching is that $PaCO_2$ rises 3 mm Hg/min, but in actuality this varies widely, with an average 3.7 ± 2.34; or 5.1 mm Hg/min if starting at normocarbia[5]). Sometimes as long as 12 minutes may be necessary
4. the test is aborted prematurely if:
   • the patient breathes: incompatible with brain death
   • significant hypotension occurs
   • if O_2 saturation drops below 80% (on pulse oximeter)
   • significant cardiac arrhythmias occur
5. if patient does not breathe, send ABG at regular intervals and at the completion of test regardless of reason for termination. If the patient does not breathe for at least 2 minutes after a $PaCO_2 > 60$ mm Hg is documented, then the test is valid and is compatible with brain death (if the patient is stable and ABGs results are available within a few minutes, the apnea challenge may be continued while waiting for results in case the $PaCO_2$ is < 60)
6. if $PaCO_2$ stabilizes below 60 mm Hg and the pO_2 remains adequate, try reducing the passive O_2 flow rate slightly (O_2 flow may be washing out CO_2)

C. no motor function
1. no response to deep central pain
2. true decerebrate or decorticate posturing or seizures are incompatible with the diagnosis of brain death
3. spinal cord mediated reflex movements (including flexor plantar reflexes, flexor withdrawal, muscle stretch reflexes[6], and even abdominal and cremasteric reflexes) can be compatible with brain death, and may occasionally consist of complex movements[7], including bringing one or both arms up to the face[8], or sitting up (the “Lazarus” sign[9]) especially with hypoxemia (thought to be due to spinal cord ischemia stimulating surviving motor neurons in the upper cervical cord). If complex integrated motor movements occur, it is recommended that confirmatory testing be performed prior to pronouncement of brain death[10]

D. absence of complicating conditions (that could simulate brain death on exam):
1. hypothermia: core temp should be > 32.2° C (90° F). Below this temp,

pupils may be fixed and dilated[11], respirations may be difficult to detect, and recovery is possible[12]

2. no evidence of remediable exogenous or endogenous intoxication, including drug or metabolic (barbiturates, benzodiazepines, meprobamate, methaqualone, trichloroethylene, paralytics, hepatic encephalopathy, hyperosmolar coma…). If there is doubt, depending on circumstances, lab tests including drug levels (serum and urine) may be sent. Pseudocholinesterase deficiency is present in 1/3000 patients which can cause succinycholine to last up to 8 hours (instead of 5 mins). A twitch monitor can rule-out NMB (place the electrodes immediately behind the eye or across the zygomatic arch)
3. shock (SBP should be ≥ 90 mm Hg) and anoxia. Loss of > 45% of circulating blood volume can produce lethargy
4. immediately post-resuscitation: shock or anoxia may cause fixed and dilated pupils. Atropine may cause slight dilatation but <u>not</u> unreactivity (*see page 292*). Neuromuscular blockage (e.g. for intubation) does not affect pupils because the iris lacks nicotinic receptors
5. patients coming out of pentobarbital coma (wait until level ≈ ≤ 10 mcg/ml)

E. confirmation of brain death by use of *Clinical confirmatory tests* (EEG, angiography, CRAG, BAER…, *see below*) is not required, but may be used as determined by judgement of attending or consulting physician

F. recommended <u>observation periods</u> during which time the patient fulfills criteria of clinical brain death before the patient may be pronounced dead:
1. in situation where <u>overwhelming</u> brain damage from an irreversible condition is well established (e.g. massive intracerebral hemorrhage), some experts will pronounce death following a single valid brain death exam in conjunction with a clinical confirmatory test
2. if an irreversible condition is well established, and clinical confirmatory tests are used: 6 hours
3. if an irreversible condition is well established and no clinical confirmatory tests are used: 12 hours
4. if diagnosis is uncertain and no clinical confirmatory tests: 12-24 hours
5. if anoxic injury is the cause of brain death: 24 hours (may be shortened if cessation of CBF is demonstrated)

A. note: EEG is <u>not</u> mandatory, see *recommended observation periods…*, page 291

B. cervical sympathetic pathways may remain intact

C. corneal reflex: eye closing to corneal (not scleral) stimulation
D. respirations are defined as abdominal or chest excursions that produce adequate tidal volumes; if there is any question, a spirometer may be connected to the patient[3]

CLINICAL CONFIRMATORY TESTS

CEREBRAL ANGIOGRAPHY

Criteria: absence of intracranial flow at the level of the carotid bifurcation or circle of Willis[2]). Filling of the superior sagittal sinus may occur in a delayed fashion. Interobserver validity has not been studied. Not routinely used in the diagnosis of brain death, but may be employed in difficult situations.

EEG

Can be done at bedside. Requires experienced interpreter. Does not detect brainstem activity, and electrocerebral silence **(ECS)** does not exclude the possibility of reversible coma. Thus, at least 6 hours observation is recommended in conjunction with ECS. Using ECS as a clinical confirmatory test should be done only in patients without drug intoxication, hypothermia, or shock.

Definition of **electrocerebral silence** on EEG: no electrical activity > 2 μV with the following requirements:

- recording from scalp or referential electrode pairs ≥ 10 cm apart
- 8 scalp electrodes and ear lobe reference electrodes
- inter-electrode resistance < 10,000 Ω (or impedance < 6,000 Ω) but over 100 Ω
- sensitivity of 2 μV/mm
- time constants 0.3-0.4 sec for part of recording
- no response to stimuli (pain, noise, light)
- record > 30 mins
- repeat EEG in doubtful cases
- qualified technologist and electroencephalographer with ICU EEG experience
- telephone transmission not permissible

CEREBRAL RADIONUCLIDE ANGIOGRAM (CRAG)

Can be performed at the bedside with a general purpose scintillation camera

with a low energy collimator[A]. May not detect minimal blood flow to the brain, especially brainstem, therefore 6 hours observation in conjunction with CRAG is recommended unless there is a clear etiology of overwhelming brain injury (e.g. massive hemorrhage or GSW).

A. portable scintillation cameras are becoming increasingly scarce

May be useful to confirm clinical brain death in the following settings:

1. where complicating conditions are present, e.g. hypothermia, hypotension (shock), drug intoxication
2. severe facial trauma where ocular findings may be difficult or confusing
3. in patients with severe COPD or CHF where apnea testing may not be valid
4. to shorten the observation period, especially when organ donation is a possibility

Technique

1. scintillation camera is positioned for an AP head and neck view
2. inject 20-30 mCi of ^{99m}Tc-labeled serum albumin or pertechnetate in a volume of 0.5-1.5 ml into a proximal IV port, or a central line, followed by a 30 ml NS flush
3. perform serial dynamic images at 2 second intervals for ≈ 60 seconds
4. then, obtain static images with 400,000 counts in AP and then lateral views at 5, 15 & 30 minutes after injection
5. if a study needs to be repeated because of a previous non-diagnostic study or a previous exam incompatible with brain death, a period of 12 hours should lapse

Findings

No uptake in brain parenchyma = "hollow skull phenomenon" (*see Figure 13-1*). Termination of carotid circulation at the skull base, and lack of uptake in the ACA and MCA distributions (absent "candelabra effect"). There may be delayed or faint visualization of dural venous sinuses even with brain death[13] due to connections between the extracranial circulation and the venous system.

Transcranial doppler[3]

1. small peaks in early systole without diastolic flow or reverberating flow (indicative of significantly increased ICP)
2. initial absence of doppler signals cannot be used as criteria for brain death since 10% of patients do not have temporal insonation windows

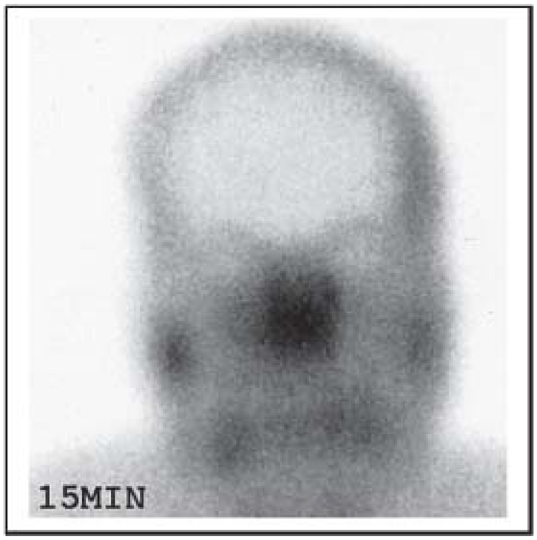

Figure 13-1 "Hollow-skull" sign on CRAG (static AP view taken[15] minutes after injection)

SSEPs

Bilateral absence of N20-P22 response with median nerve stimulation.

Atropine

In brain death, 1 amp of atropine (1 mg) IV should not affect the heart rate due to the absence of vagal tone (the normal response to atropine of increased heart rate rules out brain death, but absence of the response is not helpful since some conditions such as Guillain-Barre may blunt the response).

Systemic atropine in usual doses causes slight pupillary dilatation[14, 15], but does not eliminate reaction to light (therefore, to eliminate uncertainty, it is prudent to examine the pupils before giving the atropine).

13.2. Brain death in children

Criteria for death: irreversible loss of cardiopulmonary or entire brain

function (as in adult), but the (clinically unproven) assumption that a child's brain is more resilient results in more difficult determination of brain death. The following guidelines are proposed for patients < 5 yrs age[16]:

- these recommendations are not applicable for the premature infant
- determination of proximate cause of coma should be made to ensure absence of remediable conditions: especially toxic and metabolic disorders, sedatives, paralytics, hypothermia, hypotension (for age), and surgically treatable conditions
- criteria:
    A. coma and apnea must coexist: including complete loss of consciousness, vocalization and volitional activity
    B. absence of brainstem function
        1. midposition or fully dilated pupils, unresponsive to light (R/O drug effects)
        2. EOM: absence of spontaneous, doll's eyes and caloric movements of eyes
        3. absence of bulbar musculature movement: including oropharyngeal and facial muscles; absence of corneal, gag, cough, suck, and rooting reflex
        4. absence of respiratory movement (usually tested after other criteria met)
        5. flaccid tone and absence of spontaneous or induced movements (spinal myoclonus and spinal cord movements, e.g. reflex withdrawal are not included)
        6. examination results should remain consistent with brain death throughout observation period
- observation periods according to age:
    A. in newborns born at or after term (> 38 wks): 7 days
    B. age 7 days - 2 mos: 2 examinations and 2 EEGs 48 hrs apart (repeat exam unnecessary if cerebral radionuclide angiogram **(CRAG)** fails to visualize cerebral arteries)
    C. age 2-12 mos: 2 examinations and 2 EEGs 24 hrs apart (repeat exam unnecessary if CRAG negative)
    D. age > 12 mos: if irreversible condition exists, laboratory testing is not necessary, and 12 hrs observation is sufficient (unclear conditions, especially hypoxic-ischemic encephalopathy, are difficult to assess, and 24 hrs observation is suggested unless electrocerebral silence on EEG or a negative CRAG confirm diagnosis)

• confirmatory tests:
  A. EEG: standard requirement for 10 cm electrode distance (*see* *page 292*) may be decreased in proportion to size of head
  B. CRAG: applicability to patient < 2 mos age unproven

13.3. Organ and tissue donation

State and federal laws require families of individuals satisfying criteria for brain death to be approached about the possibility of organ donation. Facts that may be conveyed to family in order to help their understanding about organ procurement:

1. any or all suitable organs may be individually specified for donation or to be excluded from consideration for donation
2. organ procurement may be done in such a way as not to interfere with an open casket funeral (i.e. disfigurement can be avoided)
3. families can receive information as to the ultimate use of any recovered organs

13.3.1. Criteria for qualification for organ donation

General exclusionary criteria for organ donation (modified[17])

1. infection
   A. untreated septicemia
   B. the following infections or conditions: AIDS, viral hepatitis, viral encephalitis, Guillain-Barré syndrome
   C. current IV drug abuse
   D. active TB
2. malignancy: brain tumors represent possible exceptions (*see below*)
3. relative exclusions: chronic untreated HTN, hypotension (desired SBP > 100 with normal CVP)
4. disease of the organs considered for donation
5. anencephalic newborns: recent consensus is that the functioning brainstem in these infants (e.g. spontaneous respirations) disqualifies them from the diagnosis of brain death (furthermore, few such organs would likely benefit others)[18]

Guidelines for inclusion (some recommendations from reference[17] **included)**

These guidelines are constantly being revised, in part due to improved results with the use of cyclosporin in recipients. In general, consultation with a transplant coordinator is recommended to determine appropriateness of donation.

1. brain death or cardiac death[19]
2. organs:
   A. **kidneys**: age > 6 mos (because of size). Normal blood pressure, BUN, serum creatinine & U/A. No SLE (because of possible lupus nephritis)
   B. **heart** and **heart/lung**: age ideally < 40 years for males and < 45 for females (above these ages, a cardiac cath is usually performed) but up to 60 yrs may be used depending on condition of heart and potential recipients). Exam by cardiologist indicating no heart disease (cardiomyopathy, valve defect, reduced ejection fraction, severe ASHD, S/P CABG). No IDDM
   C. **liver**: age > 1 mos. Normal hepatic function (normal or acceptable AST, ALT, LDH, bilirubin (direct, indirect & total) and normal clotting studies) with no history of liver disease
   D. **pancreas**: age 15 - 40 yrs. No history of diabetes. Normal serum glucose and amylase
3. tissues:
   A. <u>corneas</u>: age ≥ 1 yr. Neither cancer nor sepsis disqualifies (rabies and Creutzfeldt-Jakob disease are contraindications)
   B. <u>skin</u>: age 15-65 yrs. Excluded if cancer
   C. <u>bone</u>: age 15-65 yrs. Excluded if cancer
   D. <u>bone marrow</u>: age ≤ 50 yrs
   E. <u>heart valves</u>: age ≤ 55 yrs

13.3.2. Organ donation in patients with brain tumors

Among patients with a brain tumor:

1. those that are <u>not</u> candidates for organ donation:
   A. metastatic tumors to the brain
   B. brain tumors that have been manipulated (biopsied or excised)
   C. patients with brain tumors who have been shunted
2. those that might be candidates, but considered *high-risk* donors[A] include

unmanipulated:

A. glioblastoma
B. anaplastic astrocytoma
C. medulloblastoma

3. unmanipulated tumors that might not be considered high risk
   A. hemangioblastoma
   B. meningioma

Optimally, if no metastases are seen on CT (chest, abdomen and pelvis) and no mets are found at time of organ procurement, a brain biopsy would be performed after the organs are procured at the same anesthetic and the organs would not be “released” until the biopsy proves which of the above categories applies.

13.3.3. Management after brain death for organ donation

Note: once brain death occurs, cardiovascular instability eventually ensues, generally within 3-5 days, and management with pressors is usually required. Fluid and electrolyte imbalances from loss of hypothalamic regulation must be normalized. In some instances a beating-heart cadaver can be maintained for months[20].

1. consent: must be obtained from donor’s legal guardian. NB: must also be obtained from medical examiner or coroner’s office for all cases under their jurisdiction (in most states, death resulting from accident, within 24 hrs of hospitalization, etc.)
2. signed note in chart stating date and time patient pronounced brain dead
3. contact transplant coordinator at earliest possible time
4. wean from vasopressors if possible. Control hypotension through volume expansion whenever possible (after brain death, ADH production ceases, producing diabetes insipidus with high urine output, thus copious fluid administration is anticipated (> 250-500 ml/hr is common). Most centers prefer AVOIDING exogenous ADH (vasopressin (Pitressin®)) if possible since the risk of renal shutdown increases in brain-death
   A. start with crystalloid (D5 1/4 NS + 20 mEq KCl/L is generally a good choice since it replaces free water), replace urine cc for cc plus 100 cc/hr maintenance

B. use colloid (FFP, albumin…) if unable to maintain BP by replacement

A. high-risk organs may be considered e.g. for liver transplants in patients who are very low on the list due to age or hepatocellular cancer

C. use vasopressors if still hypotensive. Start with low dose dopamine, increase up to ≈ 10 µg/kg/min, add dobutamine if still hypotensive at this dosage

D. if UO is still > 300 ml/hr after above measures, use ADH analog (aqueous vasopressin (Pitressin®) is preferred over DDAVP to avoid renal shutdown)

5. thyroglobulin given IV converts some cells from anaerobic to aerobic metabolism which may help stave off cardiovascular collapse

LABORATORY EVALUATION[17]

General initial labs

1. serology: VDRL or RPR, HBsAg, HIV, CMV, ABO blood group, HLA tissue type
2. chemistry: electrolytes, glucose, BUN, creatinine, calcium, phosphate, liver function tests, U/A (urine analysis)
3. hematology: CBC, PT/PTT
4. microbiology: blood, urine and sputum cultures; sputum Gram stain

Kidney donor

1. in addition to general labs (*see above*), check BUN & creatinine ≈ q day
2. check electrolytes ≈ q 12 hrs (modify as appropriate)

Liver donor

1. in addition to general labs (*see above*), check LDH, AST, ALT, bilirubin (direct, indirect, and total)

Heart donor

1. all require an echocardiogram prior to donation

13.3.4. Organ donation after cardiac death

Key concepts:

> • candidates: ventilator dependent patients (typically with brain or spinal cord injury) who are so near death that further care is futile
> • consent from legal next of kin for: organ donation, heparin, and femoral lines
> • clearance from medical examiner when applicable (usually unnatural death)
> • counsel the family that the procedure cannot be done in ≈ 20%. They are to be notified immediately if this happens and end-of-life care resumes
> • transplant team cannot participate in end-of-life care, declaration of death, and should not be in O.R. until after cardiad death is declared

Covered in this section because of relevance to organ donation.

Candidates for organ donation after cardiac death are typically ventilator dependent patients with brain or spinal cord injuries who are so near death that further treatment is futile, but who do not meet brain death criteria. Organs typically recovered in this manner: kidneys, liver, pancreas, lungs, and rarely the heart[19].

Ethical concerns related to this practice have been raised[21].

Cardiology consultation may help determine the likelihood that cardiac death will follow extubation in a timeframe consistent with organ procurement.

Consent

Consent for withdrawal of care and procurement of organs must be obtained from the legal next of kin (which may be a family member, designated health care representative or health care surrogate). Consent must also be obtained for any donation-related procedures prior to death (which typically includes heparin infusion to prolong organ viability[22] and the possibility of femoral catheters).

Clearance from the medical examiner must be obtained in applicable cases (including deaths due to accident, homicide, suicide…).

Procedure

Life sustaining measures are then discontinued (typically consisting of

extubation) usually in the operating room. Death is pronounced typically ≈ 2 minutes after cardiac activity becomes insufficient to generate a pulse, because limited data indicates that circulation will not spontaneously return[23] (NB: EKG activity does not need to cease). After declaration of death, cold perfusion of organs is performed and they are procured.

To avoid potential conflicts of interest, no member of the transplant team can participate in end-of-life care nor the declaration of death[19]. About 20% of the time, the progression to cardiac death does not occur in a timeframe that permits organ retrieval. In these cases, organ donation is cancelled, the family must be immediately notified, and end-of-life care continues.

14. Cerebrospinal fluid

14.1. General information

Cerebrospinal fluid **(CSF)** surrounds the brain and spinal cord, and may function as a shock absorber for the CNS. It may also serve an immunological function analogous to the lymphatic system[1]. It circulates within the subarachnoid space, between the arachnoid and the pial membranes.

CSF is normally a clear colorless fluid with a specific gravity of 1.007 and a pH of ≈ 7.33-7.35.

Production

80% of CSF is produced by the choroid plexuses, located in both lateral ventricles (accounts for ≈ 95% of CSF produced in the choroid plexuses) and in the 4th ventricle. Most of the rest of intracranial production occurs in the interstitial space[2]. A small amount may also be produced by the ependymal lining of the ventricles. In the spine, it is produced primarily in the dura of the nerve root sleeves. *Table 14-1* shows properties of CSF production, volumes and pressures.

Table 14-1 Normal CSF production, volumes, and pressure

Property	—— Peds ——		Adult
	Newborn	1-10 yrs	
total volume (ml)	5		150 (50% intracranial, 50% spinal)
formation rate	25 ml/d		≈ 0.3-0.35 ml/min (≈ 450-750 ml/d)
pressure* (cm of fluid)	9-12	mean: 10 normal: < 15	adult: 7-15 (> 18 usually abnormal) young adult: < 18-20

* as measured in the lumbar subarachnoid space, with the patient relaxed in the lateral decubitus position

Production rate: In the adult, CSF is produced at a rate of about 0.3 ml/min (*see Table 14-1*). In terms that are clinically relevant, this approximates 450 ml/24hrs, which means that in an adult, the CSF is “turned over” ≈ 3 times every day. The rate of formation is *independent* of the intracranial pressure[3] (except in the

limiting case when ICP becomes so high that cerebral blood flow is reduced[4]).

Absorption

CSF is absorbed primarily by arachnoid villi (granulations) that extend into the dural venous sinuses. Other sites of absorption include the choroid plexuses and lymphatics. The rate of absorption is pressure dependent[5].

14.2. CSF constituents

The composition of CSF differs slightly in the ventricles where the majority of it is produced compared to the lumbar subarachnoid space.

CELLULAR COMPONENT

In normal adult CSF, there are 0-5 lymphocytes or mononuclear cells per mm^3, and no polys (PMNs) or RBCs. In the absence of RBCs, 5-10 WBCs per mm^3 is suspicious, and > 10 WBCs per mm^3 is definitely abnormal.

TRAUMATIC TAP

Differentiating true leukocytosis from traumatic tap

When many RBCs and WBCs are present in the CSF due to a traumatic tap **(TT)**, it may be important to tell if the WBCs are elevated or if they are present in the same ratio as in the peripheral blood. In non-anemic patients, there should be ≈ 1-2 WBCs for every 1000 RBCs (as a correction[6 (p 176)]: subtract 1 WBC for every 700 RBCs[6 (p 176)]). In the presence of anemia or peripheral leukocytosis, use **Fishman's formula**[6 (p 176)] shown in *Eq 14-1* to estimate the original WBC count in the CSF before the TT,

$$WBC_{CSF\ ORIGINAL} = WBC_{CSF} - \frac{WBC_{BLOOD} \times RBC_{CSF}}{RBC_{BLOOD}} \qquad \textbf{Eq 14-1}$$

where WBC_{CSF} ORIGINAL = WBC count in the CSF before the TT, WBC_{CSF} & RBC_{CSF} = WBC & RBC counts measured in the CSF, and WBCBLOOD & RBCBLOOD = WBC & RBC per mm^3 in the peripheral blood.

Estimating true total CSF protein content with a traumatic tap

If the hemogram and peripheral protein are normal, then have the cell count and protein content run on the same tube, and the correction is[6 (p 176)]:

• subtract 1 mg per 100 ml of protein for every 1000 RBC per mm^3

Differentiating SAH from traumatic tap

For typical findings in SAH, *see page 1038*. Some features helpful in differentiating SAH from TT are shown in *Table 14-2*.

Table 14-2 Features distinguishing traumatic tap from SAH

Feature	Traumatic tap (TT)	SAH
RBC count (and gross appearance of bloodiness)	declines as CSF drains (compare first tube to last tube)	usually > 100,000 RBCs/mm^3, changes little as CSF drains
ratio of WBC:RBC	similar to the ratio in peripheral blood (see *Differentiating true leukocytosis from traumatic tap* above)	usually promotes a leukocytosis (elevated WBC count)
supernatant	clear	xanthochromic* (rarely in < 2 hrs, present in 70% by 6 hrs, and > 90% by 12 hrs after SAH)
clotting of fluid	usually clots if erythrocyte count > 200,000/mm^3	usually does not clot
protein concentration	fresh bleeding elevates CSF protein from normal by only ≈ 1 mg per 1000 RBC	blood breakdown products elevate this more than TT (measured protein exceeds the sum of normal protein + 1 mg protein/1000 RBC)
repeat LP at higher level	usually clear	remains bloody
opening pressure	usually normal	usually elevated

* NB: other conditions can cause xanthochromia

CSF CONSTITUENTS

Table 14-3 CSF solutes [6 (p 169), 7]

(for CEA, AFP, & hCG, see *Tumor markers*, page 720)

Data from Table 6-1 of "Cerebrospinal Fluid in Diseases of the Nervous System" by Robert A. Fishman, M.D., © 1980, W. B. Saunders Co., Philadelphia, PA, used with permission

Constituent	Units	CSF	Plasma	CSF:plasma ratio
osmolarity	mOsm/L	295	295	1.0
H_2O content		99%	93%	
sodium	mEq/L	138	138	1.0
potassium	mEq/L	2.8	4.5	0.6
chloride	mEq/L	119	102	1.2

lactate:pyruvate		26	17.6*	
total protein†	mg/dl	35	7000	0.005
albumin	mg/L	155	36600	0.004
IgG	mg/L	12.3	9870	0.001

* arterial plasma

† Note: CSF protein is lower in ventricular fluid than in lumbar subarachnoid space

Table 14-4 Variations with age

Age group	WBC /mm³	RBC /mm³	Protein (mg/dl)	Glucose (mg/dl)	Glucose ratio (CSF:plasma)
newborn					
preemie	10	many	150	20-65	0.5-1.6
term	7-8	mod	80	30-120	0.4-2.5
infants					
1-12 mos	5-6	0	15-80		
1-2 yrs	2-3	0	15		
young child	2-3	0	20		
child 5-15 yrs	2-3	0	25		
adolescent & adult	3	0	30	40-80	0.5
senile	5	0	40*		

* normal CSF protein rises ≈ 1 mg/dl per year of age in the adult

Table 14-5 CSF findings in various pathologic conditions (adult values)*

Condition	OP (cm H_2O)	Appearance	Cells (per mm^3)	Protein (mg%)	Glucose (% serum)	Miscellaneous
normal	7-18	clear colorless	0 PMN, 0 RBC 0-5 monos	15-45	50	
acute purulent meningitis	freq ↑	turbid	few-20K (WBCs mostly PMNs)	100-1000	< 20	few cells early or if treated
viral meningitis & encephalitis	nl	nl	few-350 WBCs (mostly monos)	40-100	nl	PMNs early
Guillain-Barré	nl	nl	nl	50-1000	nl	protein ↑, freq. IgG
polio	nl	nl	50-250 (monos)	40-100	nl	
TB meningitis†	freq ↑	opalescent, yellow, fibrin clot on standing	50-500 (lymphocytes and monocytes)	60-700	20-40	PMN early, (+) AFB culture, (+) Ziel-Neelson stain
fungal meningitis	freq ↑	opalescent	30-300 (monos)	100-700	< 30	(+) India ink prep with cryptococcus
amebic meningoencephalitis (*Naegleria*)	freq ↑	cloudy, may be hemorrhagic	↑ WBCs (400-26K), ↑ RBCs	↑	nl or ↓	negative Gram stain; wet mount → motile trophozoites (*see page 375*)
parameningeal infection	↑ if block	nl	WBCs nl or ↑ (0-800)	↑	nl	e.g. spinal epidural abscess
traumatic‡ (bloody) tap	nl	bloody; supernatant colorless	RBC:WBC ratio ≈ as in peripheral	slight ↑	nl	RBCs ↓ in successive tubes; no xanthochromia
SAH‡	↑	bloody; supernatant xanthochromic	early: ↑ RBCs	50-400	nl or ↓	RBCs disappear in 2 wks, xanthochromia may persist for weeks
			late: ↑ WBCs	100-800		
multiple sclerosis (MS)§	nl	nl	5-50 monos	nl-800	nl	usually ↑ gamma globulins (oligoclonal)

* abbreviations: OP = opening pressure; nl = normal; ↑ = increased; ↓ = decreased; freq = frequently

† the CSF findings in TB meningitis are almost pathognomonic when they occur in combination; 20-30% have acid-fast bacilli in their CSF sediment smears

‡ to differentiate traumatic tap from SAH, also see *Differentiating SAH from traumatic tap*, page 298

§ for more information on the CSF in MS, *see page 64*

14.3. Artificial CSF

A number of formulations of "artificial" CSF have been proposed over the years in order to more closely mimic the pH, osmolarity, CO_2, and membrane active ion concentration of CSF. In many instances, normal saline **(NS)** has been used in brain surgery, probably without consequence. However, renewed interest in the subject of artificial CSF has been brought about by the use of neuroendoscopy, with possible reactions to nonphysiologic solutions when large volumes of fluid are exchanged, as occurs during some of these procedures. An

actual reaction to NS, however, has never been proven.

In addition to simulating the constituents of CSF, it may also be well to insure a physiologic temperature of the solution[8].

Elliott's solution

AKA Solution B of Elliott and Jasper[9, 10]: an elaborate formulation that was widely used in the past.

14.4. CSF fistula (cranial)

Key concepts:

> • suspect in posttraumatic otorrhea/rhinorrhea or recurrent meningitis
> • management strategy: 1) confirm the fluid is CSF, 2) identify the site of origin of the leak, 3) determine etiology/mechanism
> • most bedside tests are unreliable and include: "reservoir sign", target/halo sign, qualitative glucose
> • most accurate confirmatory test is $ß_2$-transferrin
> • CT cisternography is the test of choice for localizing site of fistula

AKA CSF leak. Two major subgroups (omitting the ambiguous category of "spontaneous")[11]:

1. traumatic (or posttraumatic): may occur acutely or may be delayed
   A. post-procedure (iatrogenic). Including: post-transsphenoidal surgery and post skull base surgery
   B. posttraumatic (more common): 67-77% of cases
2. nontraumatic
   A. high pressure
      1. hydrocephalus
      2. tumor
   B. normal pressure
      1. congenital defects
      2. bony erosion from infection or necrosis
      3. focal atrophy (olfactory or sellar)

CSF fistula should be suspected in patients with otorrhea or rhinorrhea after

head trauma, or in patients with recurrent meningitis.

Possible routes of egress of CSF

1. mastoid air cells (especially after p-fossa surgery, e.g. for vestibular schwannoma **(VS)**, *see page 630*)
2. sphenoid air cells (especially post-transsphenoidal surgery)
3. cribriform plate/ethmoidal roof (floor of frontal fossa)
4. frontal air cells
5. herniation into empty sella and then into sphenoid air sinus
6. along path of internal carotid artery
7. Rosenmüller's fossa: located just inferior to cavernous sinus, may be exposed by drilling off anterior clinoids to allow access to ophthalmic artery aneurysms
8. site of the opening of the transient lateral craniopharyngeal canal
9. percutaneously through a surgical or traumatic wound
10. petrous ridge or internal auditory canal: following temporal bone fracture or vestibular schwannoma surgery (*see page 630*). Then either:
    A. **rhinorrhea**: through middle ear → eustachian tube → nasopharynx
    B. **otorrhea**: via perforated tympanic membrane → external auditory canal

TRAUMATIC FISTULA

Occur in 2-3% of all patients with head injury, 60% occur within days of trauma, 95% within 3 months[12]. 70% of cases of CSF rhinorrhea stop within 1 wk, and usually within 6 mos in the rest. Non-traumatic cases cease spontaneously in only 33%. Adult:child ratio is 10:1, rare before age 2 yrs. In children the incidence of CSF leaks is less than 1% of closed head injuries[13]. Anosmia is common in traumatic leaks (78%), rare in spontaneous[14]. Most (80-85%) CSF otorrhea ceases in 5-10 days.

CSF fistula occurred in 8.9% of 101 cases of penetrating trauma, and increases the infection rate over those penetrating injuries without fistula (50% vs. 4.6%)[15]. It is reported to occur post-op in up to 30% of cases of skull-base surgery[16].

NONTRAUMATIC CSF FISTULA

Nontraumatic leaks primarily occur in adults > 30 yrs. Often insidious. May

be mistaken for allergic rhinitis. Unlike traumatic leaks, these tend to be intermittent, the sense of smell is usually preserved, and pneumocephalus is uncommon[17].

Sometimes associated with the following[18]

1. agenesis of the floor of the anterior fossa (cribriform plate) or middle fossa
2. empty sella syndrome: primary or post transsphenoidal surgery (*see page 660*)
3. increased ICP and/or hydrocephalus
4. infection of the paranasal sinuses
5. tumor: including pituitary adenomas (*see page 634*), meningiomas
6. a persistent remnant of the craniopharyngeal canal[19]
7. AVM[17]
8. congenital anomalies: most involve dehiscence of bone
    A. dehiscence of the footplate of the stapes (a congenital abnormality) which can produce CSF rhinorrhea via the eustachian tube[17]
    B. dehiscence below foramen rotundum

Posterior fossa

1. pediatric: usually presents with either meningitis or hearing loss
    A. preserved labyrinthine function (hearing and balance): these usually present with meningitis. 3 usual routes of fistula:
        1. facial canal: can fistulize into middle ear
        2. petromastoid canal: along path of arterial supply to mucosa of mastoid air sinuses
        3. Hyrtl’s fissure (AKA tympanomeningeal fissure): links p-fossa to hypotympanum
    B. anomalies of labyrinth (hearing lost): one of several types of Mundini dysplasias, usually presenting with rounded labyrinth/cochlea that permits CSF to erode through oval or round window into auditory canal
2. adult: usually presents with conductive hearing loss with serous effusion, meningitis (often following an episode of otitis media), or cerebral abscess. Occurs most commonly through middle fossa. May be due to arachnoid granulations eroding into air sinus compartment

Spinal

Often presents with postural headache associated with neck stiffness and tenderness[20] (*see page 305*).

MENINGITIS IN CSF FISTULA

Incidence with posttraumatic CSF leak: 5-10%, increases as leak persists > 7 days. Meningitis is more common with spontaneous fistula. Risk may be higher in post-neurosurgical CSF fistula than in post-traumatic due to elevated ICP common in latter (forces CSF outward). If site of leak unidentified prior to attempted surgical treatment, 30% develop a recurrent leak post-op, with 5-15% of these developing meningitis before leak is stopped[21].

Meningitis may promote inflammatory changes at the site of the leak, with a resultant cessation of the leak.

Pneumococcal meningitis is the most common pathogen (83% of cases[22]), mortality is lower than in pneumococcal meningitis without underlying fistula (< 10% vs. 50%), possibly because the latter is frequently seen in elderly debilitated patients. Prognosis in children is worse[12].

EVALUATION

Determining if rhinorrhea or otorrhea is due to a CSF fistula

1. characteristics of the fluid suggesting the presence of CSF
   A. fluid is as clear as water (unless infected or admixed with blood)
   B. fluid does not cause excoriation within or outside the nose
   C. patients with rhinorrhea describe the taste as salty
2. confirmatory tests
   A. **β_2-transferrin**: present in CSF, but absent in tears, saliva, nasal exudates and serum (except for newborns and patients with liver disease)[23, 24]. The only other source is the vitreous fluid of the eye. detected by protein electrophoresis. ≈ 0.5 ml needs to be placed in a sterile container, packed in dry ice, and shipped to a lab that can perform this study. Very sensitive & specific
   B. collect fluid and obtain quantitative **glucose** (urine glucose detection strips may be positive even with excess mucus). Test the fluid shortly after collection to minimize fermentation. Normal CSF glucose is > 30

mg% (usually lower with meningitis) whereas lacrimal secretions and mucus are usually < 5 mg%. A negative test is more helpful since it rules out CSF (except in hypoglycorrhachia), but there is a 45-75% chance of false positive[25 (p 1638)]

C. "**ring sign**": when a CSF leak is suspected but the fluid is blood tinged, allow the fluid to drip onto linen (sheet or pillowcase). A ring of blood with a larger concentric ring of clear fluid (so called "double ring" or halo sign) suggests the presence of CSF. An old, but unreliable, sign

D. **reservoir sign**: a gush of fluid that occurs with a certain head position. Most commonly when first sitting up after a period of recumbency. Thought to indicate drainage of CSF pooled in the sphenoid sinus. Not reliable[26]

3. radiographic signs: pneumocephalus on CT or skull x-ray. Pneumocephalus occurs in ≈ 20% of patients with CSF leaks[27 (p 280)]
4. cisternogram: intrathecal injection of radionuclide tracer followed by scintigram or injection of radioopaque contrast followed by CT scan (*see below*)
5. anosmia is present in ≈ 5% of CSF leaks
6. following skull-base surgery (especially involving greater superficial petrosal nerve) there may be a **pseudo-CSF rhinorrhea** possibly due to nasal hypersecretion from imbalanced autonomic regulation of the nasal mucosa[16] ipsilateral to the surgery. Often accompanied by nasal stuffiness and absent ipsilateral lacrimation, and occasionally by facial flushing

To localize site of CSF fistula

90% of the time, localization does not require water-soluble contrast CT cisternography **(WS-CTC)** (*see below*).

1. CT: to detect pneumocephalus, fractures, skull base defects, hydrocephalus and obstructive neoplasms. Include thin <u>coronal</u> cuts or reconstructions through anterior fossa all the way back to the sella turcica
   A. non-contrast (optional): to demonstrate bony anatomy
   B. with IV contrast: leak site is usually associated with abnormal enhancement of adjacent brain parenchyma (possibly from inflammation)
2. water-soluble contrast CT cisternography (procedure of choice): *see below*
3. plain skull x-ray (helpful in only 21%)

4. MRI: may provide additional information for localization and can R/O p-fossa mass, tumor, and empty sella better than CT. Both CT and MRI can R/O hydrocephalus. T2WI fast spin-echo sequences with fat suppression and video image reversal have been used to visualize CSF flow (sensitivity and specificity are 0.87 and 0.57 respectively)[28]
5. older tests (abandoned in favor of above):
   A. **radionuclide cisternography (RNC)**: may be useful in leaks too slow or small to show up on WS-CTC. Various radioactive agents have been used, including: radioiodinated human serum albumin (RIHSA)[17, 29], and 500 µCi Indium^{111} DPTA. Cotton pledgets are packed intranasally (anterior nasal roof, posterior nasal roof, sphenoethmoidal recess, middle meatus, and posterior floor of the nose) and are marked so that their location is known. Radiotracer is then injected intrathecally usually by lumbar puncture. Scans are performed in lateral, AP and posterior view. A protocol using In^{111} DTPA is to obtain a scan shortly after injection. At 4 hours post-injection, the scan is repeated, and 0.5 ml of blood is drawn (to measure serum activity), and the pledgets are removed. The pledgets are then individually placed in a well-counter and a ratio is calculated for pledget radioactivity relative to serum. A ratio ≤ 1.3 is normal, and a ratio > 1.3 suggests leak. If no leak, the nose can be repacked and the study repeated the following morning.
      Leaks into frontal sinus will empty into nasopharynx anterior to the middle concha, unlike leaks through cribriform plate. RNC identifies the site in only 50%. May be misleading[14] with possible contamination after several hours from absorption of radioisotope into the bloodstream and accumulation in the mucosal glands of the turbinates. Patient positioning may also contaminate other pledgets
   B. intrathecal (visible) dye studies: some success with indigo carmine or fluorescein (*see page 144*) with little or no complications (✖ methylene blue is neurotoxic and should not be used, *see page 144*)

Water-soluble contrast CT cisternography

Procedure of choice. This test is performed if:

1. no site identified on plain CT (with coronals)
2. when patient is leaking clinically (the site is only sometimes identified in the absence of an active leak)
3. when multiple bony defects are identified, and it is essential to determine

which site is actively leaking

4. if a bony defect seen on plain CT does not have associated changes of abnormal enhancement of adjacent brain parenchyma

Technique[30]

Use iohexol (*see* *page 122*) 6-7 ml of 190-220 mg/ml) injected into lumbar subarachnoid space via 22 gauge spinal needle (or 5 ml via C1-2 puncture). Patient positioned in -70° Trendelenburg **x** 3 min prone with neck gently flexed, in CT they are kept prone with head hyperextended with 5 mm coronal cuts with 3 mm overlap (use 1.5 mm cuts if necessary). May need provocative maneuvers (coronal scans prone (brow up) or in position of leak, intrathecal saline infusion (requires Harvard pump)[21]…).

Look for accumulation of contrast in air sinuses. Apparent discontinuity of bone on CT without extravasation of contrast is probably not the site of leakage (bone discontinuities may be mimicked by partial volume averaging on CT).

TREATMENT

Acutely after trauma, observation is justified as most cases cease spontaneously.
Prophylactic antibiotics: Controversial. There was no difference in the incidence or morbidity of meningitis between treated and untreated patients[31]. Furthermore, the risk of selecting resistant strains appears real[12] and is therefore usually avoided.

FOR PERSISTENT POSTTRAUMATIC OR POST-OP LEAKS

Non-surgical treatment

1. measures to lower ICP:
   A. bed rest: although recumbency may ameliorate symptoms, there is no other benefit from bed rest[32]
   B. avoid straining (stool softeners) and avoid blowing nose
   C. acetazolamide (250 mg PO QID) to reduce CSF production
   D. modest fluid restriction (caution post-transsphenoidal because of possible DI (*see* *page 15*): 1500 ml/day in adults, 75% of maintenance/day in peds
2. if leak persists (caution: first R/O obstructive hydrocephalus with CT or MRI)

A. **LP**: q d to BID (lower pressure to near atmospheric or until H/A)
OR
B. continuous **lumbar drainage (CLD)**: via percutaneous catheter. Two (of many) management options:
   1. keep HOB elevated 10-15° and place drip chamber at shoulder level (lower the chamber if leak persists)
   2. allow 15-20 cc to drain, then clamp tubing. Repeat q 1 hour

- CLD may require ICU monitoring. If patient deteriorates with drain in place: immediately stop drainage, place patient flat in bed (or slight Trendelenburg), start 100% O_2, get CT or bedside cross-table skull x-ray (to R/O tension pneumocephalus due to drawing in of air)

3. surgical treatment in persistent cases (*see below*)

SURGICAL TREATMENT

Indications for surgical intervention

1. traumatic CSF leak that persists > 2 weeks in spite of non-surgical measures
2. spontaneous leaks and those of delayed onset following trauma or surgery: usually require surgery because of a high incidence of recurrence
3. leaks complicated by meningitis

Petrous bone

May present as otorrhea or as rhinorrhea (via the eustachian tube).

1. following posterior fossa surgery: *see page 630* for treatment following vestibular schwannoma surgery
2. following mastoid fractures: may be approached via extensive mastoidectomy[17]
3. due to dehiscence of the footplate of the stapes: may require obliteration of the middle ear and eustachian tube through a tympanomeatal flap[17]

Leaks through cribriform plate/ethmoidal roof

Extradural approach: Generally preferred by ENT surgeons[33]. If a frontal craniotomy is being performed, an intradural approach should be used since problems may arise in dissecting the dura off of the floor of the frontal fossa,

wherein the dura almost always tears and then it is difficult to know if an identified tear is the cause of the leak or if it is iatrogenic. Fluorescein dye mixed with CSF injected intrathecally may help demonstrate the leak intraoperatively (CAUTION: must be diluted to reduce risk of seizures, *see page 144*).

Intradural approach: Generally the procedure of choice[34]. If the fistula site is unidentified preoperatively, use a bifrontal bone flap.

General techniques of intradural approach:

Close bone defects with fat, muscle, cartilage, or bone.

Close dural defect with fascia lata, temporalis muscle fascia, or pericranium. Fibrin glue may be used to help hold tissue in place.

If the leak is unidentified pre-op and intra-op, then pack both cribriform plates and sphenoid sinus (incise dura over tuberculum sellae, drill through bone to reach sphenoid sinus, remove mucosa or pack it inferiorly, pack with fat).

Post op: lumbar drain after craniotomy is controversial. Some feel CSF pressure may help enhance the seal[35]. If used, place the drip chamber at the level of shoulder for 3-5 days (for precautions, *see above*).

Consider shunt (LP or VP) if elevated ICP or hydrocephalus is demonstrated.

Leaks into sphenoid sinus (including post-transsphenoidal surgery leak)

1. LP BID or CLD: as long as pressure > 150 mm H_2O or CSF xanthochromic
   A. if leak persists > 3 days: repack sphenoid sinus and pterygoid recesses with fat, muscle, cartilage and/or fascia lata (must reconstruct floor of sella, packing alone is inadequate). Some recommend against muscle since it putrefies and shrinks. Continue LP or CLD as above for 3-5 days post-op
   B. if leak persists > 5 days: lumboperitoneal shunt (first R/O obstructive hydrocephalus)
2. more difficult surgical approach: intracranial (intradural) approach to medial aspect of middle cranial fossa
3. consider transnasal sellar injection of fibrin glue under local anesthesia[36]

14.5. Intracranial hypotension

May be spontaneous (*see below*), post-traumatic (including iatrogenic, e.g. post-LP).

SPONTANEOUS INTRACRANIAL HYPOTENSION (SIH)

The syndrome of spontaneous intracranial hypotension is characterized by the following in the absence of antecedent trauma or LP (or epidural injection…)[37]:

1. orthostatic headache: dramatically worse when upright, improved in recumbency
2. low CSF pressure
3. diffuse pachymeningeal enhancement (cerebral and/or spinal) on MRI

In most cases, the underlying etiology is thought to be a spontaneous CSF leak from a spinal meningeal diverticulum or dural tear[20].

Clinical features

Most patients have orthostatic headache. Onset is often sudden, and may be associated with spinal pain in a specific location. Atypical patients have been described without H/A, or H/A that is non-positional, without pachymeningeal enhancement on MRI[38], with clinical signs of encephalopathy, cervical myelopathy, or parkinsonism[39]. Since some patients may have normal intracranial pressure, the term "CSF hypovolemia" has been suggested[40].

Evaluation

1. brain MRI. Findings:
   A. ★ diffuse pachymeningeal enhancement (cerebral and/or spinal) is common
   B. brain descent with low lying cerebellar tonsils occurred in 36%[39]
   C. reversible pituitary enlargement with a convex superior margin[41]
   D. subdural hematomas (in 20%) and nonhemorrhagic subdural fluid collections (in 23%) in one series of 40 patients with SIH[42]
   E. small ventricles and cisterns may be seen
2. spinal MRI: may show evidence of CSF leak. If there is focal spine pain, the leak will often be near this location
3. radioisotope cisternography: abnormal in 90%. Revealed the site of CSF leak in 40%[39].

Treatment

Treatment includes:

1. bed rest
2. analgesics
3. hydration
4. caffeine
5. epidural blood patch **(EBP)** for appropriate cases: *see page 59*

Subdural fluid collections occasionally require intervention (usually drainage of the subdural and blood patching of the spinal leak, if identified).

Outcome

Complete resolution of H/A was achieved in 70% (usually in days to weeks), and was higher in patients receiving EBP, and was lower with multiple sites of CSF leak[39].

15. Hydrocephalus

[EPIDEMIOLOGY

Estimated prevalence: 1-1.5%.

Incidence of congenital hydrocephalus is ≈ 0.9-1.8/1000 births (reported range from 0.2 to 3.5/1000 births[1]).

FUNCTIONAL CLASSIFICATION

Two main functional subdivisions of hydrocephalus (HCP)

1. **obstructive** (AKA non-communicating): block proximal to the arachnoid granulations **(AG)**. On CT or MRI: enlargement of ventricles proximal to block (e.g. obstruction of aqueduct of Sylvius → lateral and 3rd ventricular enlargement out of proportion to the 4th ventricle, sometimes referred to as triventricular hydrocephalus)
2. **communicating** (AKA non-obstructive): CSF circulation blocked at level of AG

SPECIAL FORMS OF HYDROCEPHALUS AND "PSEUDOHYDROCEPHALUS"

1. conditions that are not actually hydrocephalus "pseudohydrocephalus"
   A. **hydrocephalus ex vacuo**: enlargement of the ventricles due to loss of cerebral tissue (cerebral atrophy), usually as a function of normal aging, but accelerated or accentuated by certain disease processes (e.g. Alzheimer's disease, Creutzfeldt-Jakob disease, traumatic brain injury). For means of differentiating from true hydrocephalus, *see page 906*
   B. otitic hydrocephalus: obsolete term used to describe the increased intracranial pressure seen in patients with otitis media (see see *Idiopathic intracranial hypertension (IIH)*, page 713)
   C. external hydrocephalus: seen in infancy, enlarged subarachnoid space with increasing OFCs and normal or mildly dilated ventricles *see page*

307

D. hydranencephaly: a post-neurulation defect (*see page 243*). Total or near-total absence of the cerebrum most commonly due to bilateral ICA infarcts. It is critical to differentiate this from severe ("maximal") hydrocephalus **(HCP)** since shunting for true HCP may produce some re-expansion of the cortical mantle (*see page 244* for means to differentiate)

2. normal pressure hydrocephalus **(NPH)**: *see page 329*
3. entrapped fourth ventricle: *see page 309*
4. arrested hydrocephalus: *see page 309*

External hydrocephalus (AKA benign external hydrocephalus)

Key concepts:

> • enlarged subarachnoid spaces over the frontal poles in the first year of life
> • ventricles are normal or minimally enlarged
> • may be distinguished from subdural hematoma by the "cortical vein sign"
> • usually resolves spontaneously by 2 years of age

Enlarged subarachnoid space (usually over the cortical sulci of the frontal poles) seen in infancy (primarily in the first year of life) usually accompanied by abnormally increasing head circumference with normal or mildly dilated ventricles[2]. There are often enlarged basal cisterns and widening of the anterior interhemispheric fissure. No other symptoms or signs should be present (although there may be slight delay only in motor milestones due to the large head). Etiology is unclear, but a defect in CSF resorption is postulated. External hydrocephalus **(EH)** may be a variant of communicating hydrocephalus[3]. No predisposing factor may be found in some cases, although EH may be associated with some craniosynostoses[4] (especially plagiocephaly) or it may follow intraventricular hemorrhage or superior vena cava obstruction.

Differential diagnosis: EH is probably distinct from benign subdural collections (or extra-axial fluid) of infancy (*see page 904*). ★ EH must be distinguished from symptomatic chronic extra-axial fluid collections (or chronic subdural hematoma), which may be accompanied by seizures, vomiting, headache… (*see page 905*) and may be the result of child abuse. With EH, MRI or CT may demonstrate cortical veins extending from the surface of the brain to the inner table of the skull coursing through the fluid collection ("**cortical vein sign**"), whereas the collections in subdural hematomas compress the subarachnoid space

which apposes the veins to the surface to the brain[5, 6].

Treatment: EH usually compensates by 12-18 mos age without shunting[7]. Recommend: follow serial ultrasound and/or CT to rule out abnormal ventricular enlargement. Emphasize to parents that this does not represent cortical atrophy. Due to increased risk for positional molding, parents may need to periodically reposition the head while the child is sleeping[8].

A shunt may rarely be indicated when the collections are bloody (consider the possibility of child abuse) or for cosmetic reasons for severe macrocrania or frontal bossing.

X-LINKED HYDROCEPHALUS

Inherited hydrocephalus **(HCP)** with phenotypic expression in males passed on through carrier mothers who are phenotypically normal. Classical phenotypic expression will skip single generations.

Incidence: 1/25,000 to 1/60,000. Prevalence: ≈ 2 cases per 100 cases of hydrocephalus.

Gene located on Xq28[151-153].

Pathophysiology

L1CAM membrane bound receptor plays a significant role in CNS development for axonal migration to appropriate target locations through Integrin cell adhesion molecules and MAP Kinase signal cascade[151-153].

Abnormal gene expression results in poor differentiation and maturation of cortical neurons macroscopic anatomical abnormalities (bilateral absence of pyramidal tracts, see below)

Cytoplasmic domain loss of function mutations result in severe L1 syndrome, whereas mutations retaining expression of some functional protein (component imbedded in cell membrane) leads to mild L1 syndrome.

L1 syndromes

Classical syndromes include CRASH (corpus callosum hypoplasia, retardation, adducted thumbs (clasp thumbs), spastic paralysis, HCP), MSAS (mental handicap, aphasia, shuffling gate, adducted thumbs), HSAS (HCP with stenosis of the aqueduct of sylvius). Spectrum of disease also includes x-linked agenesis of the corpus callosum **(ACC)**, and spastic paraparesis type 1[151, 152].

Recent delineations[153]:

- mild L1 syndrome: adducted thumbs, spastic paralysis, hypoplasia of CC
- severe L1 syndrome: as in mild L1 syndrome plus anterior cerebellar vermis hypoplasia, large massa intermedia, enlarged quadrigeminal plate, rippled ventricular wall following VP shunt placement (pathognomonic for X-linked HCP). Profound mental retardation in virtually all cases

Radiographic findings likely present if severe L1152:

1. severe symmetric HCP with predominant posterior horn dilation
2. hypoplastic CC/ACC
3. hypoplastic anterior cerebellar vermis
4. large massa intermedia
5. large quadrigeminal plate
6. rippled ventricular wall following VP shunt placement (pathognomonic)

Treatment: no intervention demonstrates improvement in retardation status in observational papers.

1. VP shunt: main purpose is management of head size for improved care by care-giver. Does not improve neurologic outcome
2. there are no current genetic therapies for L1CAM protein abnormalities
3. prenatal U/S: early (≈ 20-24 weeks gestational age) with frequent repeat scan in known carrier mothers. May allow for medically indicated termination early on
4. male infants with HCP and ≥ 2 clinical/radiographic signs should undergo genetic testing for L1CAM mutation detection for future pregnancy counseling[151]

"Arrested hydrocephalus"

The exact definition of this term is not generally agreed upon, and some use the term **compensated hydrocephalus** interchangeably. Most clinicians use these terms to refer to a situation where there is no progression or deleterious sequelae due to hydrocephalus that would require the presence of a CSF shunt. Patients and families should be advised to seek medical attention if they develop symptoms of intracranial hypertension (decompensation): headaches, vomiting, ataxia or visual symptoms[8].

Arrested hydrocephalus satisfies the following criteria in the absence of a CSF shunt:

1. near normal ventricular size
2. normal head growth curve

3. continued psychomotor development

Shunt independence

The concept of becoming independent of a shunt is not universally accepted[9]. Some feel that shunt independence occurs more commonly when the HCP is due to a block at the level of the arachnoid granulations (communicating hydrocephalus)[10], but others have shown that it can occur regardless of the etiology[11]. These patients must be followed closely as there are reports of death as late as 5 years after apparent shunt independence, sometimes without warning[10].

When to remove a disconnected or non-functioning shunt?

Note: a disconnected shunt may continue to function by CSF flow through an endothelialized subcutaneous tract. Recommendations on whether or not to repair vs. remove a disconnected or non-functioning shunt:

1. when in doubt, shunt
2. indications for shunt repair (vs. removal)
   A. marginally functioning shunts
   B. the presence of any signs or symptoms of increased ICP (vomiting, upgaze palsy, sometimes H/A alone[12]…)
   C. changes in cognitive function, ↓ attention span, or emotional changes
   D. patients with aqueductal stenosis or spina bifida: most are shunt dependent
3. because of risks associated with shunt removal, surgery for this purpose alone should be performed only in the situation of a shunt infection[13]
4. patients with a nonfunctioning shunt should be followed closely with serial CTs, and possibly with serial neuropsychological evaluations

Entrapped fourth ventricle

AKA isolated fourth ventricle: 4th ventricle that neither communicates with the 3rd ventricle (through sylvian aqueduct) nor with the basal cisterns (through foramina of Luschka or Magendie). Usually seen with chronic shunting of the lateral ventricles, especially with post-infectious hydrocephalus (fungal, in particular) or in those with repeated shunt infections. Possibly as a result of

adhesions forming from prolonged apposition of the ependymal lining of the aqueduct due to the diversion of CSF through the shunt. Occurs in 2-3% of shunted patients[14]. May also occur in Dandy Walker malformation (*see page 240*) if the aqueduct is also obstructed. The choroid plexus of the 4th ventricle continues to produce CSF which enlarges the ventricle when there is 4th ventricular outlet obstruction or obstruction at the level of the arachnoid granulations.

Presentation may include:

1. headache
2. lower cranial nerve palsies: swallowing difficulties
3. pressure on the floor of the 4th ventricle may compress the facial colliculus (*see page 844*) → facial diplegia and bilateral abducens palsy
4. ataxia
5. reduced level of consciousness
6. nausea/vomiting
7. may also be an incidental finding (NB: some “atypical” findings, such as reduced attention span, may be related)

Treatment

Treatment of the entrapped 4th ventricle may alleviate associated slit ventricles[15]. Most surgeons advocate shunting the ventricle either with a separate VP shunt, or linking into an existing shunt. Options:

1. usual first choice: insertion from below the tonsils under direct vision. The catheter may be brought out at the dural suture line, and may be anchored here by use of an angle adapter sutured to the dura
2. passage through a cerebellar hemisphere: potential complications include delayed injury to the brainstem by the catheter tip as the brainstem moves into its normal position with drainage of the 4th ventricle. This may be avoided by bringing the catheter into the 4th ventricle at a slight angle through the cerebellar hemisphere
3. Torkildsen shunt (ventriculocisternal shunt) is an option for obstructive hydrocephalus if it is certain that the arachnoid granulations are functional (usually not the case with hydrocephalus of infantile onset)
4. an LP shunt may be considered when the 4th ventricle outlets are patent

Cranial nerve palsies may occur with shunting of the 4th ventricle usually as a result of penetration of the brainstem by the catheter either at the time of

catheter insertion, or in a delayed fashion as the 4th ventricle decreases in size[16], but also possibly as a result of overshunting causing traction on the lower cranial nerves as the brainstem shifts posteriorly[14].

CT/MRI CRITERIA OF HYDROCEPHALUS

Numerous methods have been devised to attempt to quantitatively define hydrocephalus **(HCP)** (most date back to the early CT experience). Some are presented here for completeness. For radiologic features of *chronic* HCP, *see page 312*.

Hydrocephalus (HCP)

HCP is suggested when either[17]:

A. the size of both temporal horns **(TH)** is ≥ 2 mm in width (*see Figure 15-1*) (in the absence of HCP, the temporal horns should be barely visible), and the sylvian & interhemispheric fissures and cerebral sulci are not visible

OR

B. both TH are ≥ 2 mm, <u>and</u> the ratio $\frac{FH}{ID} > 0.5$ (where **FH** is the largest width of the frontal horns, and ID is the internal diameter from inner-table to inner-table at this level) (*see Figure 15-1*)

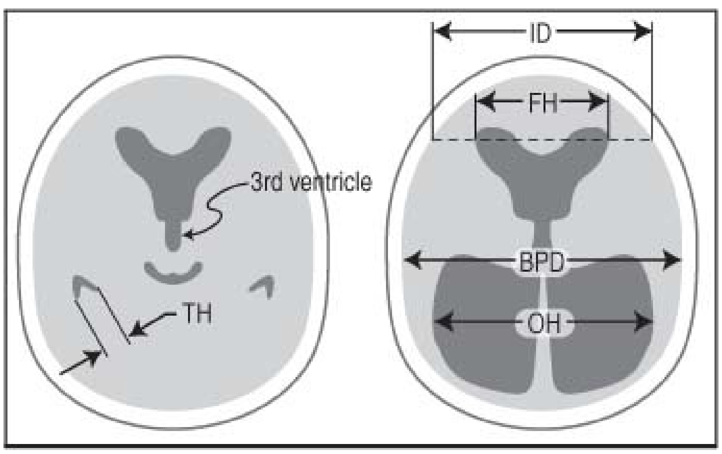

Figure 15-1 Linear ventricular measurement for CT, MRI or U/S Abbreviations: TH = temporal horns, FH = frontal horns, ID = internal diameter, BPD = biparietal diameter, OH = occipital horns

Other features suggestive of hydrocephalus (*see Figure 15-1* for measurements):

1. ballooning of frontal horns of lateral ventricles (“Mickey Mouse” ventricles) and/or 3rd ventricle (the 3rd ventricle should normally be slit-like)

2. periventricular low density on CT, or periventricular high intensity signal on T2WI on MRI suggesting **transependymal absorption**[A] of CSF
3. used alone, the ratio $\frac{FH}{ID} \begin{cases} < 40\% & \text{normal} \\ 40\text{-}50\% & \text{borderline} \\ > 50\% & \text{suggests hydrocephalus} \end{cases}$
4. **Evans ratio** 18 (or index)[B]: ratio of FH to <u>maximal</u> biparietal diameter **(BPD)** measured in the same CT slice: > 0.3 suggests hydrocephalus
5. sagittal MRI may show thinning and/or upward bowing of the corpus callosum

---

A. a misnomer: CSF does not actually penetrate the ependymal lining (proven with CSF labeling studies), probably represents stasis of fluid in brain adjacent to ventricles

B. NB: measurements that rely on the frontal horn diameter tend to underestimate hydrocephalus in pediatrics possibly because of disproportionate dilatation of the occipital horns in peds[19]

ETIOLOGIES OF HYDROCEPHALUS

HCP is either due to subnormal CSF reabsorption, or rarely to CSF overproduction (as with some choroid plexus papillomas; even here, reabsorption is probably defective in some as normal individuals could probably tolerate the slightly elevated CSF production rate of these tumors). The etiologies in one series of pediatric patients is shown in *Table 15-1*.

- congenital
  A. Chiari Type 2 malformation and/or myelomeningocele **(MM)** (usually occur together)
  B. Chiari Type 1 malformation: HCP may occur with 4th ventricle outlet obstruction
  C. primary aqueductal stenosis (usually presents in infancy, rarely in adult-hood)
  D. secondary aqueductal gliosis: due to intrauterine infection or germinal matrix hemorrhage[21]
  E. **Dandy Walker malformation**: atresia of foramina of Luschka & Magendie (*see page 240*). The incidence of this in patients with HCP is 2.4%
  F. X-linked inherited disorder: rare
- acquired

A. infectious (the most common cause of communicating HCP)
   1. post-meningitis (especially purulent and basal, including TB, cryptococcus (*see page 374*))
   2. cysticercosis
B. post-hemorrhagic (2nd most common cause of communicating HCP)
   1. post-SAH (*see page 1037*)
   2. post-intraventricular hemorrhage **(IVH)**: many will develop transient HCP. 20-50% of patients with large IVH develop permanent HCP
C. secondary to masses
   1. non neoplastic: e.g. vascular malformation
   2. neoplastic: most produce obstructive HCP by blocking CSF pathways, especially tumors around aqueduct, e.g. medulloblastoma. A colloid cyst can block CSF flow at the foramen of Monro. Pituitary tumor: suprasellar extension of tumor or expansion from pituitary apoplexy
D. post-op: 20% of pediatric patients develop permanent hydrocephalus (requiring shunt) following p-fossa tumor removal. May be delayed up to 1 yr
E. neurosarcoidosis: *see page 71*
F. "constitutional ventriculomegaly": asymptomatic. Needs no treatment
G. associated with spinal tumors[22]

Table 15-1 Etiologies of HCP in 170 pediatric patients with HCP[20]

congenital (without myelomeningocele)	38%
congenital (with MM)	29%
perinatal hemorrhage	11%
trauma/subarachnoid hemorrhage	4.7%
tumor	11%
previous infection	7.6%

DIFFERENTIAL DIAGNOSIS OF HYDROCEPHALUS

For etiologies of HCP, *see above*. Conditions that may mimic HCP but are not due to inadequate CSF absorption include:

1. atrophy: sometimes referred to as "hydrocephalus ex vacuo". Does not represent altered CSF hydrodynamics, but is rather loss of brain tissue (*see*

page 307)
2. hydranencephaly: *see page 243*
3. developmental anomalies where the ventricles appear enlarged:
   A. agenesis of the corpus callosum: *see page 246* (may occasionally be associated with HCP, but more often merely represents expansion of the third ventricle and separation of the lateral ventricles)
   B. septo-optic dysplasia: *see page 247*

SIGNS AND SYMPTOMS OF ACTIVE HCP

In young children

1. cranium enlarges at a rate > facial growth
2. irritability, poor head control, N/V
3. fontanelle full and bulging
4. enlargement and engorgement of scalp veins: due to reversal of flow from intracerebral sinuses due to increased intracranial pressure[23]
5. **Macewen's sign**: cracked pot sound on percussing over dilated ventricles
6. 6th nerve (abducens) palsy: the long intracranial course is postulated to render this nerve very sensitive to pressure
7. "setting sun sign" (upward gaze palsy): **Parinaud's syndrome** from pressure on region of suprapineal recess (*see page 114*)
8. hyperactive reflexes
9. irregular respirations with apneic spells
10. splaying of cranial sutures (seen on plain skull x-ray)

In older children/adults with rigid cranial vault

Symptoms of increased ICP, including: papilledema, H/A, N/V, gait changes, upgaze and/or abducens palsy. Slowly enlarging ventricles may initially be asymptomatic.

CHRONIC HCP

Features indicative of *chronic* hydrocephalus (as opposed to acute hydrocephalus):

1. beaten copper cranium (some refer to beaten silver appearance) on plain skull xray[24]. By itself, does not correlate with increased ICP, however when associated with #3 and #4 below, does suggest ↑ ICP. May be seen in

craniosynostosis (*see page 231* for description)
2. 3rd ventricle herniating into sella (seen on CT or MRI)
3. erosion of sella turcica (may be due to #2 above) which sometimes produces an **empty sella**, and erosion of the dorsum sella
4. the temporal horns may be less prominent on CT than in acute HCP
5. **macrocrania**: by convention, OFC greater than 98th percentile[25 (pp 203)]
6. atrophy of corpus callosum: best appreciated on sagittal MRI
7. in infants
   A. sutural diastasis
   B. delayed closure of fontanelles
   C. failure to thrive or developmental delay

OCCIPITAL-FRONTAL CIRCUMFERENCE

The occipital-frontal circumference **(OFC)** should be followed in every growing child (as part of a "well-baby" check-up, and especially in infants with documented or suspected hydrocephalus **(HCP)**). As a rule of thumb, the OFC of a normal infant should equal the distance from crown to rump[26] (rule #335). *See page 1206* for the DDx of macrocephaly.

Normal head growth: parallels normal curves as seen on the graphs on the inside front cover, or in *Figure 15-2* and *Figure 15-3* for preemies. Any of the following may signify treatable conditions such as active HCP, subdural hematoma, or subdural effusions, and should prompt an evaluation of the intracranial contents (e.g. CT, head U/S …):

1. upward deviations (crossing curves)
2. continued head growth of more than 1.25 cm/wk
3. OFC approaching 2 standard deviations **(SD)** above normal
4. head circumference out of proportion to body length or weight, even if within normal limits for age (*see Figure 15-3*)[27]

These conditions may also be seen in the "catch-up phase" of brain growth in premature infants after they recover from their acute medical illnesses, see *Catch-up phase of brain growth* page 1136). Deviations below the curves or head growth in the premature infant in the neonatal period of less than 0.5 cm/wk (excluding the first few weeks of life) may indicate microcephaly (*see page 245*).

Technique: measure circumference around forehead and occiput (excluding ears) three consecutive times, and use the largest value. OFC is then plotted on a

graph of average values as a function of age[28] and followed for each individual patient. Use the graphs on the inside front cover for most children and adolescents. The graph in *Figure 15-2* shows the OFC for premature infants as a function of gestational age up to term.

The graph in *Figure 15-3* shows the relationship of head circumference, weight and length for various gestational ages.

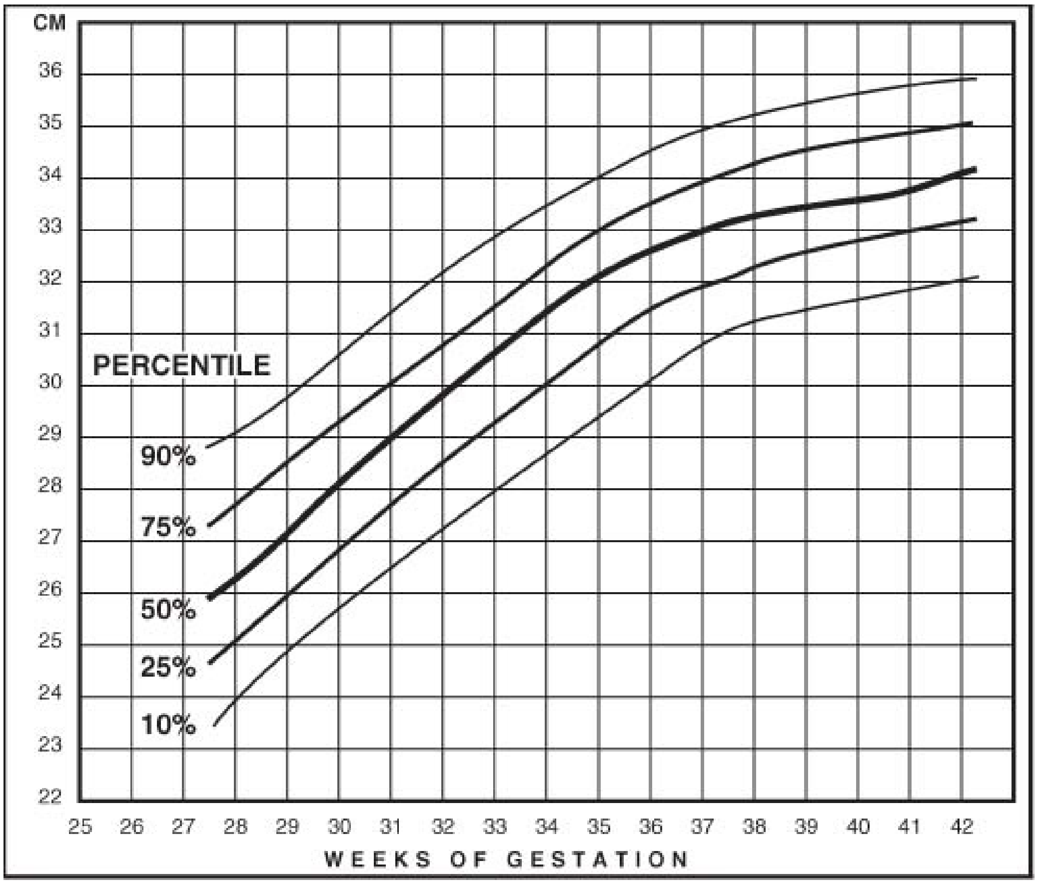

Figure 15-2 OFC for premature infants as a function of gestational age

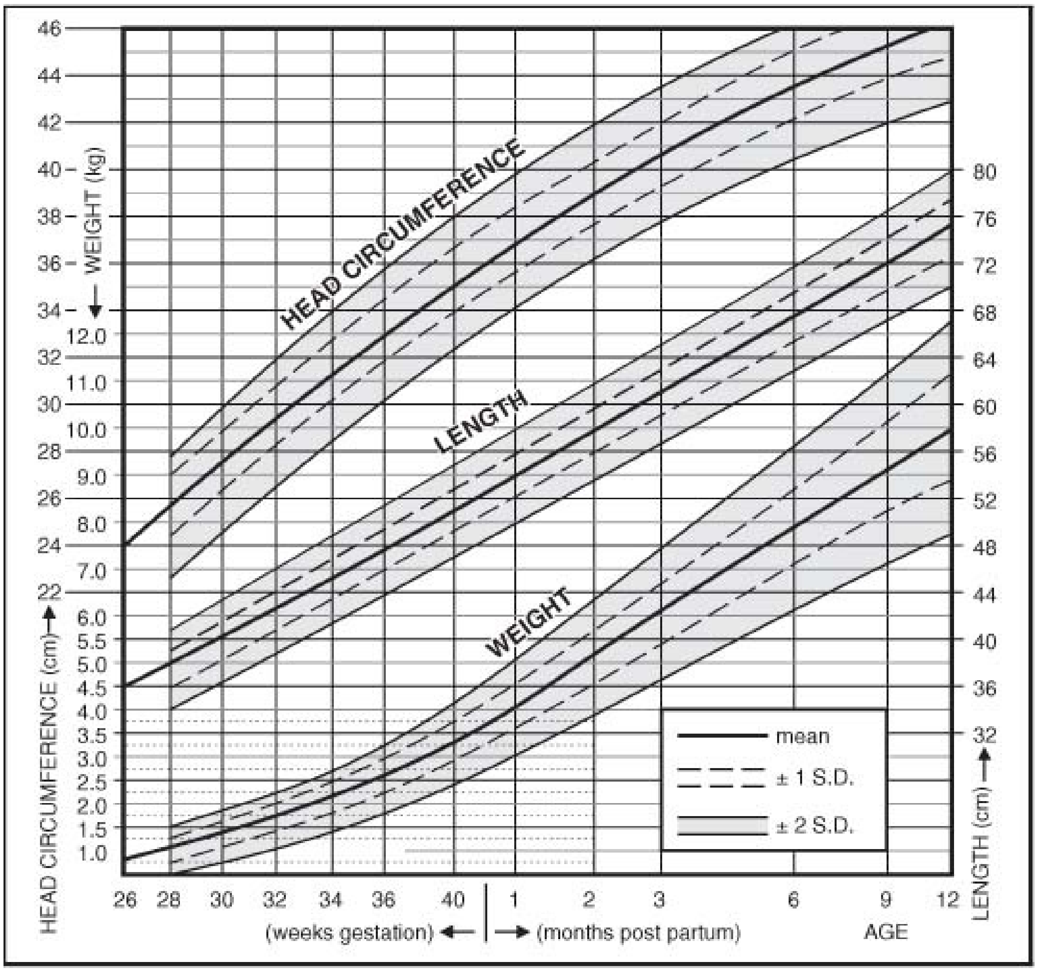

Figure 15-3 Head circumference, weight and length*

*(Redrawn from **Journal of Pediatrics**, "Growth Graphs for the Clinical Assessment of Infants of Varying Gestational Age", Babson S G, Benda G I, vol 89, pp 815, with permission)

15.1. Treatment of hydrocephalus

MEDICAL

HCP remains a surgically treated condition. Acetazolamide may be helpful for temporizing (*see below*).

Diuretic therapy

May be tried in premature infants with bloody CSF (as long as there is no evidence of active hydrocephalus) while waiting to see if there will be

resumption of normal CSF absorption. However, at best this should only be considered as an adjunct to definitive treatment or as a temporizing measure.

Satisfactory control of HCP was reported in ≈ 50% of patients of age < 1 year who had stable vital signs, normal renal function and no symptoms of elevated ICP (apnea, lethargy, vomiting) using the following[29]:

- **acetazolamide** (a carbonic anhydrase inhibitor): 25 mg/kg/day PO divided TID **x** 1 day, increase 25 mg/kg/day each day until 100 mg/kg/day is reached
- simultaneously start **furosemide**: 1 mg/kg/day PO divided TID
- to counteract acidosis:
  - ◆ tricitrate (Polycitra®) 4 ml/kg/day divided QID (each ml is equivalent to 2 mEq of bicarbonate, and contains 1 mEq K^+ and 1 mEq Na^+)
  - ◆ measure serial electrolytes, and adjust dosage to maintain serum HCO_3 > 18 mEq/L
  - ◆ change to Polycitra-K® (2 mEq K^+ per ml, no Na^+) if serum potassium becomes low, or to sodium bicarbonate if serum sodium becomes low
- watch for electrolyte imbalance and acetazolamide side effects: lethargy, tachypnea, diarrhea, paresthesias (e.g. tingling in the fingertips)
- perform weekly U/S or CT scan and insert ventricular shunt if progressive ventriculomegaly occurs. Otherwise, maintain therapy for a 6 month trial, then taper dosage over 2-4 weeks. Resume 3-4 mos of treatment if progressive HCP occurs

Spinal taps

HCP after intraventricular hemorrhage may be only transient Serial taps (ventricular or LP[30]) may temporize until resorption resumes (*see page 1135*) but LPs can only be performed for communicating HCP. If reabsorption does not resume when the protein content of the CSF is < 100 mg/dl, then it is unlikely that spontaneous resorption will occur (i.e. a shunt will usually be necessary).

Surgical

Goals of therapy:

Normal sized ventricles is not the goal of therapy. Goals are optimum neurologic function and a good cosmetic result.

Options include:

1. choroid plexectomy: described by Dandy in 1918 for communicating

hydrocephalus[31]. May reduce the rate but does not totally halt CSF production (only a portion of CSF is secreted by the choroid plexus, other sources include the ependymal lining of the ventricles and the dural sleeves of spinal nerve roots). Open surgery was associated with a high mortality rate (possibly due to replacement of CSF by air). Endoscopic choroid plexus coagulation was originally described in 1910 and was recently resurrected[32]

2. eliminating the obstruction: e.g. opening a stenosed sylvian aqueduct. Often higher morbidity and lower success rate than simple CSF diversion with shunts, except perhaps in the case of tumor
3. third ventriculostomy: (*see below*)
4. shunting: various shunts are described below. The techniques of shunt placement are covered on page 209 for VP shunts, page 210 for VA shunt, page 210 for ventriculopleural shunts, and page 213 for LP shunt

Third ventriculostomy

Endoscopic third ventriculostomy **(ETV)** has energized a renewed interest in third ventriculostomy (*see page 212* for technique).

Indications: ETV may be used in patients with obstructive HCP. May be an option in managing shunt infection (as a means to remove all hardware without subjecting the patient to increased ICP). ETV has also been proposed as an option for patients who developed subdural hematomas after shunting (the shunt is removed before the ETV is performed). ETV may also be indicated for slit ventricle syndrome (*see page 326*).

Contraindications: *Communicating* hydrocephalus has traditionally been considered a contraindication to ETV. However, it is used for NPH in some centers[33]. Relative contraindications to ETV would be the presence of any of the conditions associated with a low success rate (*see below*).

Complications:

1. hypothalamic injury
2. transient 3rd and 6th nerve palsies
3. uncontrollable bleeding
4. cardiac arrest[34]
5. traumatic basilar artery aneurysm[35]: possibly related to thermal injury from use of laser in performing ETV

Success rate: Overall success rate is ≈ 56% (range of 60-94% for nontumoral aqueductal stenosis[35] **(AqS)**). Highest maintained patency rate is with previously untreated acquired AqS. Success rate in infants may be poor because they may not have a normally developed subarachnoid space. There is a low success rate (only ≈ 20% of TVs will remain patent) if there is pre-existing pathology including:

1. tumor
2. previous shunt
3. previous SAH
4. previous whole brain radiation (success with focal stereotactic radiosurgery is not known)
5. significant adhesions visible when perforating through the floor of the third ventricle at the time of performance of ETV

In one series, clinical improvement after ETV was achieved in 76% (72 of 95 patients), including 6 patients requiring second ETVs (three of which had partially functioning shunts that were left in place at the time of ETV).

15.1.1. Shunts

For surgical insertion techniques, see *Ventricular shunts* on page 208.

TYPES OF SHUNTS

SHUNT TYPE BY CATEGORY

1. ventriculoperitoneal **(VP)** shunt:
   A. most commonly used shunt in modern era
   B. lateral ventricle is the usual proximal location
   C. intraperitoneal pressure: normal is near atmospheric
2. ventriculo-atrial **(VA)** shunt (“vascular shunt”):
   A. shunts ventricles through jugular vein to superior vena cava, so-called “ventriculo-atrial” shunt because it shunts the *cerebral ventricles* to the vascular system with the catheter tip in the region of the right *cardiac atrium*)
   B. treatment of choice when abdominal abnormalities are present (extensive abdominal surgery, peritonitis, morbid obesity, in preemies who have had NEC and may not tolerate VP shunt…)

C. shorter length of tubing results in lower distal pressure and less siphon effect than VP shunt, however pulsatile pressures may alter CSF hydrodynamics

3. Torkildsen shunt:
   A. shunts ventricle to cisternal space
   B. rarely used
   C. effective only in acquired obstructive HCP, as patients with congenital HCP frequently do not develop normal subarachnoid CSF pathways
4. miscellaneous: various distal projections used historically or in patients who have had significant problems with traditional shunt locations (e.g. peritonitis with VP shunt, SBE with vascular shunts):
   A. pleural space (**ventriculopleural shunt**): not a first choice, but a viable alternative if the peritoneum is not available[36]. To avoid symptomatic hydrothorax necessitating relocating distal end, it is recommended only for patients > 7 yrs age. Pressure in pleural space is less than atmospheric
   B. gall bladder
   C. ureter or bladder: causes electrolyte imbalances due to losses through urine
5. lumboperitoneal (LP) shunt (for insertion technique, *see page 213*):
   A. only for communicating HCP: primarily pseudotumor cerebri or CSF fistula[37]. Useful in situations with small ventricles
   B. over age 2 yrs, percutaneous insertion with Tuohy needle is preferred
6. cyst or subdural shunt: from arachnoid cyst or subdural hygroma cavity, usually to peritoneum

Disadvantages/complications of various shunts

1. those that may occur with any shunt:
   A. obstruction: the most common cause of shunt malfunction
      - proximal: ventricular catheter (the most common site)
      - valve mechanism
      - distal: reported incidence of 12-34%[38]. Occurs in peritoneal catheter in VP shunt (*see below*), in atrial catheter in VA shunt
   B. disconnection at a junction, or break at any point
   C. infection
   D. hardware erosion through skin, usually only in debilitated patients

(especially preemies with enlarged heads and thin scalp from chronic HCP, who lay on one side of head due to elongated cranium). May also indicate silicone allergy (*see below*)

E. <u>seizures</u> (ventricular shunts only): there is ≈ 5.5% risk of seizures in the first year after placement of a shunt which drops to ≈ 1.1% after the 3rd year[39] (NB: this does not mean that the shunt was the cause of all of these seizures). Seizure risk is questionably higher with frontal catheters than with parieto-occipital

F. act as a conduit for extraneural metastases of certain tumors (e.g. medulloblastoma). This is probably a relatively low risk[40]

G. silicone allergy[41]: rare (if it occurs at all). May resemble shunt infection with skin breakdown and fungating granulomas. CSF is initially sterile but later infections may occur. May require fabrication of a custom silicone-free device (e.g. polyurethane)

2. **VP** shunt:

A. 17% incidence inguinal hernia (many shunts are inserted while processus vaginalis is patent)[42]

B. need to lengthen catheter with growth: may be obviated by using long peritoneal catheter (*see page 209*)

C. obstruction of peritoneal catheter:

- may be more likely with distal slit openings ("slit valves") due to occlusion by omentum or by trapping debris from the shunt system[38]
- by peritoneal cyst (or pseudocyst)[43]: usually associated with infection, may also be due to reaction to talc from surgical gloves (the omentum tends to "wall off" a nidus of irritation). It may rarely be necessary to differentiate a CSF collection from a urine collection in patients with overdistended bladders that have ruptured (e.g. secondary to neurogenic bladder). Fluid can be aspirated percutaneously and analyzed for BUN and creatinine (which should be absent in CSF)
- severe peritoneal adhesions: reduce surface area for CSF resorption
- malposition of catheter tip:
    - at time of surgery: e.g. in preperitoneal fat
    - tubing may pull out of peritoneal cavity with growth

D. peritonitis from shunt infection

E. hydrocele

F. CSF ascites

G. tip migration

- into scrotum[44]
- perforation of a viscus[45]: stomach[46], bladder… More common with older spring-reinforced (Raimondi) shunt tubing
- through the diaphragm[47]

H. intestinal *obstruction* (as opposed to perforation): rare

I. volvulus[48]

J. intestinal strangulation: occurred only in patients in whom attempt was made to remove peritoneal tubing using traction on the catheter applied at the cephalad incision with subsequent breakage of the tubing leaving a residual intraabdominal segment (immediate peritoneal exploration is recommended under these circumstances)[49]

K. overshunting: more likely than with VA shunt. Some recommend LP shunt for *communicating* hydrocephalus (*see page 325*)

3. **VA** shunt:

A. requires repeated lengthening in growing child

B. higher risk of infection, septicemia

C. possible retrograde flow of blood into ventricles if valve malfunctions (rare)

D. shunt embolus

E. vascular complications: perforation, thrombophlebitis, pulmonary micro-emboli may cause pulmonary hypertension[50] (incidence ≈ 0.3%)

4. **LP** shunt:

A. if at all possible, should not be used in growing child unless ventricular access is unavailable (e.g. due to slit ventricles) because of:

- laminectomy in children causes scoliosis in 14%[51]
- risk of progressive cerebellar tonsillar herniation (Chiari I malformation)[52] in up to 70% of cases[53, 54]

B. overshunting harder to control when it occurs (a special horizontal-vertical **(H-V)** valve increases resistance when upright, *see below*)

C. difficult access to proximal end for revision or assessment of patency (see *Lumboperitoneal (LP) shunt evaluation*, page 214)

D. lumbar nerve root irritation (radiculopathy)

E. leakage of CSF around catheter

F. pressure regulation is difficult
G. bilateral 6th and even 7th cranial nerve dysfunction from overshunting
H. high incidence of arachnoiditis and adhesions

MISCELLANEOUS SHUNT HARDWARE

1. tumor filter: used to prevent peritoneal or vascular seeding in tumors that may metastasize through CSF (e.g. medulloblastoma[55], PNETs, ependymoma); may eventually become occluded by tumor cells and need replacement; may be able to radiate tumor filter to "sterilize" it. The risk of "shunt mets" appears to be low[40]
2. antisiphon device: prevents siphoning effect when patient is erect
3. "horizontal-vertical valve" (H-V valve) used with LP shunts to increase the valve resistance when the patient is vertical to prevent overshunting (*see page 321*)
4. there are a number of variable pressure valves on the market that may be externally programmed
5. on-off device: used to open or occlude shunt system by using external manipulation of shunt (e.g. Portnoy device)

Programmable shunt valves

3 externally programmable shunts are available in the U.S.: Strata by Medtronic (*page 319*), Polaris by Sophysa (*page 319*), and the Codman Hakim (*page 320*). All are programmed externally with a magnet, and can potentially be inadvertently reprogrammed by external magnetic fields including that encountered during an MRI (the Polaris valve may be less susceptible to inadvertent reprogramming *see page 319*).

★ Therefore, valve settings should be rechecked after an MRI scan performed for any reason, or if there is ever a concern about shunt function. The pressure setting on all of these valves can be checked on a plain x-ray taken perpendicular to the shunt valve (see the section in this book for each shunt for interpretation), the Strata and Polaris can also be checked using a special hand-held compass-like device provided by the manufacturer to most hospitals and clinics that deal with their valves.

In all 3 systems, increasing the programmed number results in higher valve pressures and therefore less CSF drainage at any given CSF pressure.

SHUNT TYPE BY MANUFACTURER

Numerous shunt systems are on the market. The following describes the salient features of some commonly used shunts. Diagrams are not to scale.

X-RAY APPEARANCE OF SOME SHUNTS

The following figure depicts idealized x-ray appearances of some common shunts.

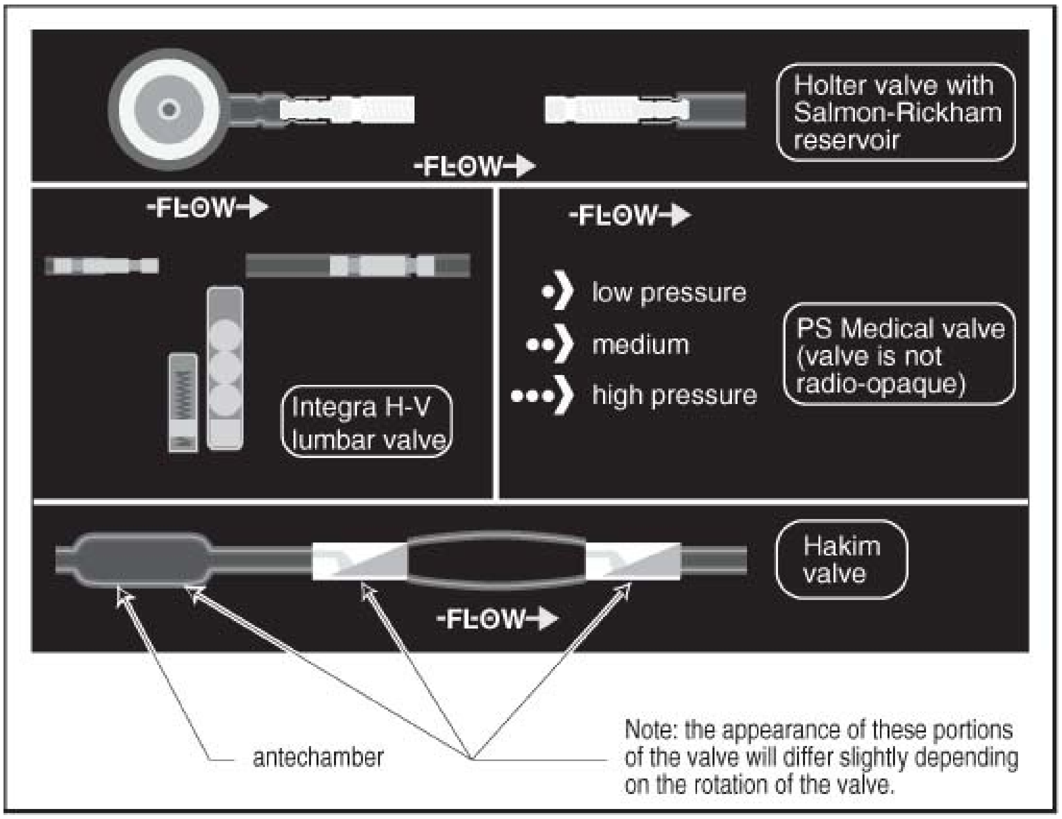

Figure 15-4 X-ray appearance of common shunts For x-ray appearance of programmable valves and the corresponding pressures, see the individual valve.

PS MEDICAL/MEDTRONIC

Medtronic
125 Cremona Dr.
Goleta, CA 93117 USA
(800) 826-5603
www.medtronic.com

Standard contoured valve

A single one-way membrane valve design. The radioopaque arrowhead points in the direction of flow (*see Figure 15-4*).

Pumping the valve

To pump the shunt in the "forward" direction, first occlude the inlet port (*see Figure 15-6*) with pressure from one finger on the "inlet occluder" (prevents back-flow into the ventricle during the next step). Then while maintaining this pressure, depress the reservoir dome with a second finger. Release both fingers, and repeat. The oneway valve regulates shunt pressure and prevents reflux of CSF during normal use and during the release phase of shunt pumping.

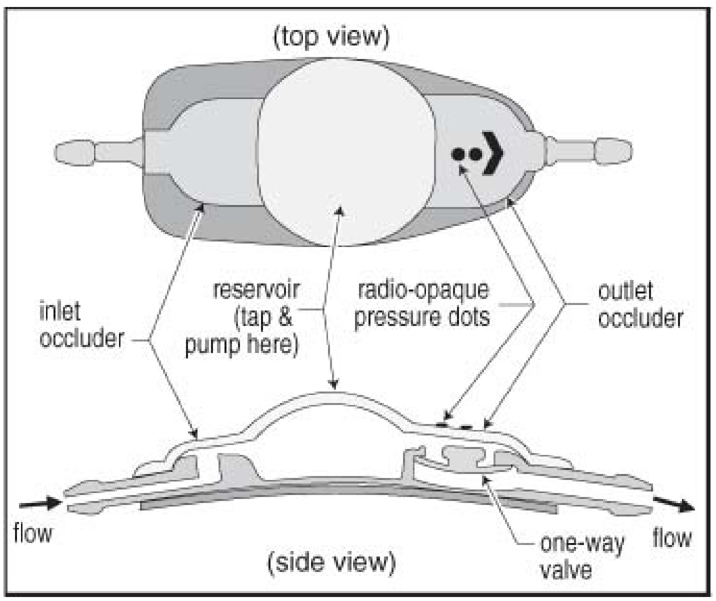

Figure 15-5 PS Medical standard contoured valve

X-ray characteristics

The three available valve pressures are indicated by radioopaque dots on the valve (allows x-ray identification of valve pressure): one dot = low pressure, two dots = medium, three dots = high.

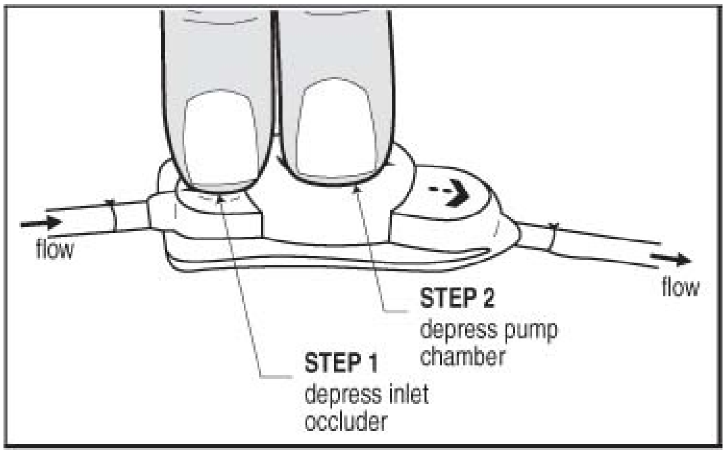

Figure 15-6 Pumping the PS Medical valve

Strata® programmable valve

The Medtronic Strata valve is an externally adjustable valve that is programmed (using a magnet) to one of five performance level ("P/L") settings (*Figure 15-7*).

Also, see general information regarding programmable valves on *page 317*.

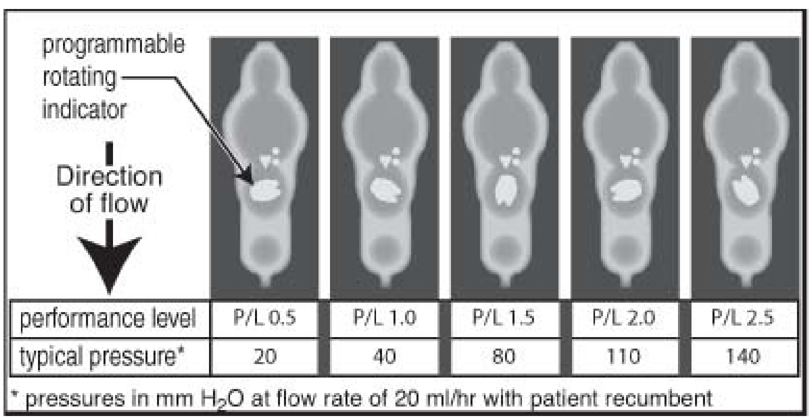

Figure 15-7 Performance level (P/L) settings for the regular size Strata valve as seen on x-ray

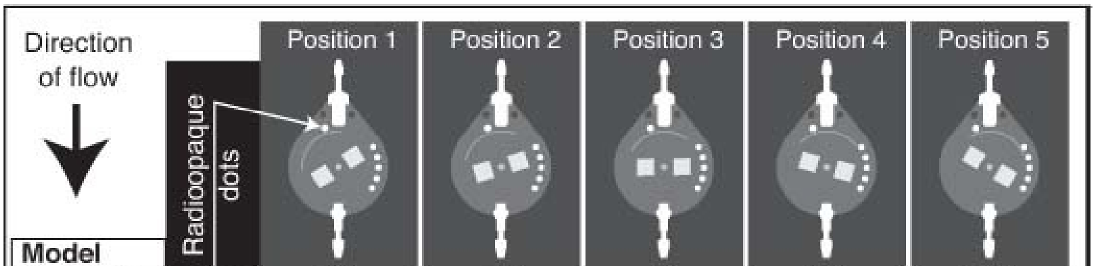
Sophysa USA

Sophysa USA, Inc.
1620 Sunflower Ave
Costa Mesa, CA 92626 USA
(714) 429-8801
www.sophysa.com

Polaris programmable valve

The Polaris valve is an externally programmable valve that uses two attracting Samarium-Cobalt magnets to lock the pressure setting and to resist inadvertent reprogramming by environmentally encountered magnets such as MRI scanners, cell phones, headphones…



Model	Radioopaque dots	Position 1	Position 2	Position 3	Position 4	Position 5
SPV-140	none	10	40	80	110	140
SPV A or B	●	30	70	110	150	200
SPV-300	●●	50	100	150	220	300
SPV-400	●●●	80	150	230	330	400

Figure 15-8 Programmable settings for Polaris valve models as seen on x-ray (pressures in mm H_2O)

Available in 4 models (different pressure ranges, each identified by a unique number of radioopaque dots), each with 5 externally adjustable positions. The x-ray appearance and corresponding pressures are shown in *Figure 15-8*.

CODMAN

Codman
325 Paramount Dr.
Raynham, MA 02767 USA
(800) 225-0460
www.codman.com

Codman Hakim programmable valve

18 pressure settings. Programmed by an AC-powered programming unit that requires confirmatory x-ray after reprogramming. Newer programming units with acoustic monitoring may obviate the need for x-ray. The manufacturer advises not to increase the pressure by > 40 mm H_2O in a 24-hour period.

X-ray appearance for various settings are shown in *Figure 15-9* (note:

settings of 70, 120 & 170 mm H_2O align with an arm of the central cross of the valve). NB: when x-rayed correctly, the x-ray beam passes first through the valve and then the patient, which causes the radioopaque marker to appear as a solid circle to the right of center as shown in *Figure 15-9*. If the marker is on the left side, the beam is passing from the bottom of the valve, and the actual pressure reading should be based on a mirror image of the x-ray.

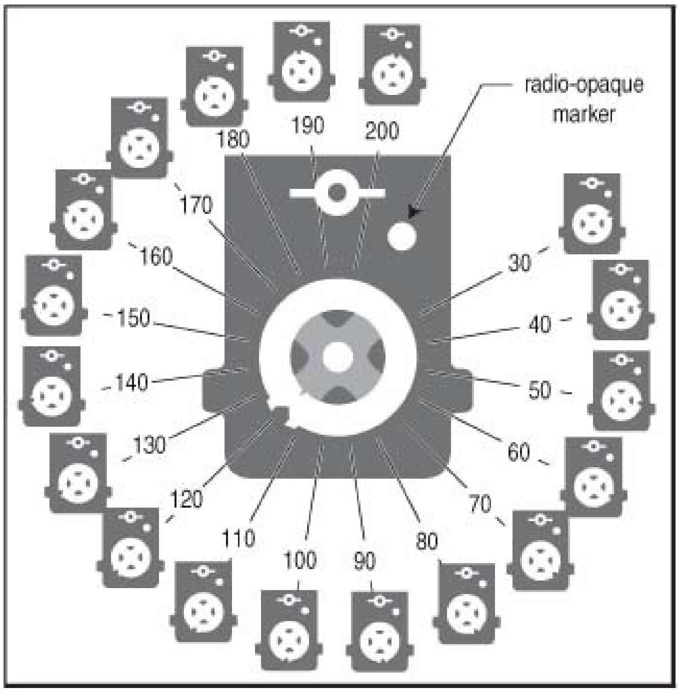


Figure 15-9 X-ray appearance of Codman Hakim programmable valve at it's various settings in mm Hg (e.g. the large central image shows a setting of 120 mm H_2O)

NeuroCare

Pleasant Prairie, WI 53158
(800) 997-4868

Heyer-Schulte

The LPV valve is shown in *Figure 15-10*. To pump the shunt, occlude inlet

port with one finger, then depress reservoir with another finger (as for the PS Medical valve, *see above*). This valve may be injected in either direction by depressing the appropriate occluder while injecting into the reservoir.

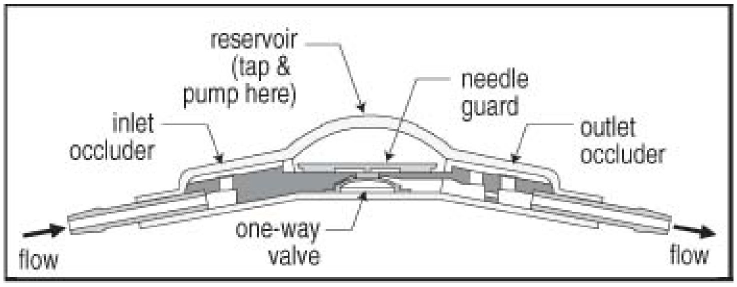

Figure 15-10 Heyer-Schulte LPV® (low-profile) valve (side view)

HAKIM SHUNT

Distributed by:
Integra Neurosciences
In the U.S.:

Plainsboro, NJ 08536
(800) 654-2873
http://www.integra-ls.com

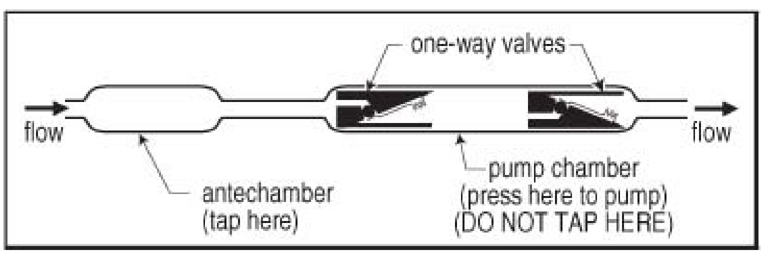

Figure 15-11 Hakim Standard Mechanism

A dual ball-valve mechanism. To pump shunt, depress the indicated portion of the valve. NB: do not tap here, as the silicone elastomer housing is not self-sealing. The antechamber is provided for this type of access.

INTEGRA (CORDIS) HORIZONTAL-VERTICAL LUMBAR VALVE

May be used in lumboperitoneal shunt to increase the transmission pressure when the patient is upright to prevent overshunting. Markings used to orient the

device during implantation:

1. an arrow on the inlet side of the unit indicates direction of flow
2. inlet tubing is clear
3. inlet tubing has smaller diameter than outlet tubing
4. outlet tubing is white
5. before positioning the valve and fastening it to the fascia with permanent suture, the valve should be connected to both the subarachnoid catheter (inlet) and the peritoneal catheter (outlet). The arrow on the inlet valve should point towards the patient's feet

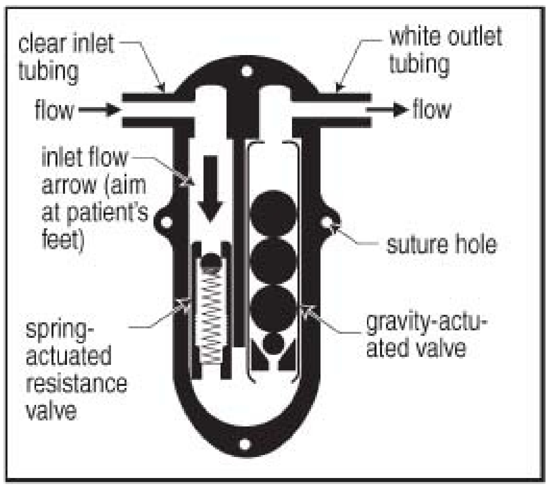

Figure 15-12 Cordis H-V valve

Holter valve

A dual slit valve mechanism (*see Figure 15-13*). Usually used in combination with a Rickham or Salmon-Rickham reservoir (*see Figure 15-14*).

To pump the shunt, simply depress the indicated portion of the valve.

X-ray characteristics

The silastic tube between the two one-way valves is radiolucent (see *Figure 15-4*, page 318).

Salmon-Rickham reservoir

Similar to standard Rickham reservoir except for lower profile (*see Figure 15-14*).

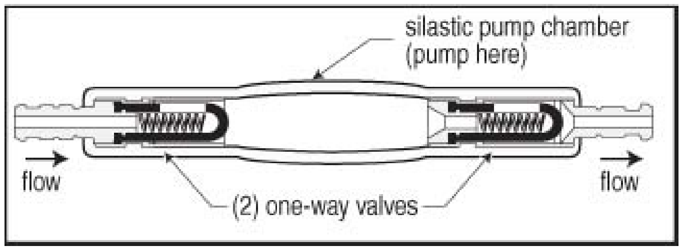

Figure 15-13 Holter valve

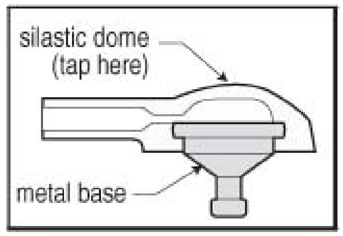

Figure 15-14 Salmon-Rick-ham Reservoir

15.2. Shunt problems

15.2.1. Problems associated with shunt insertion

1. intraparenchymal or intraventricular hemorrhage: ≈ 4% (in the absence of coagulopathy 56)
2. seizures
3. malposition
   A. of ventricular catheter
   B. of distal catheter
4. infection

15.2.2. Problems in patients with established CSF shunt

Shunt “problems” usually involve one or more of the following:

1. undershunting (*see below*): obstruction rate: ≈ 10% per year } accounts for most common shunt problems
2. infection (*see* *page 345*): range 1-40%. A serious complication. Having a

shunt infection decrease IQ } accounts for most common shunt problems

3. overshunting: slit ventricle syndrome, subdural hematomas… (*see page 325*)
4. seizures: *see page 316*
5. problems related to the distal catheter
   A. peritoneal: *see page 316*
   B. atrial: *see page 317*
6. skin breakdown over hardware: infection or silicone allergy (*see page 316*)
7. hemorrhage at time of insertion: uncommon in pediatrics

TAPPING A SHUNT

Indications to tap a shunt or ventricular access device (e.g. Ommaya reservoir) include:

1. to obtain CSF specimen
   A. to evaluate for shunt infection
   B. for cytology: e.g. in PNET to look for malignant cells in CSF
   C. to remove blood: e.g. in intraventricular hemorrhage
2. to evaluate shunt function
   A. measuring pressures
   B. contrast studies:
      1. proximal injection of contrast (iodinated or radiolabeled)
      2. distal injection of contrast
3. as a temporizing measure to allow function of a distally occluded shunt[57, 58]
4. to inject medication
   A. antibiotics: for shunt infection or ventriculitis
   B. chemotherapeutic (antineoplastic) agents
5. for catheters placed within tumor cyst (not a true shunt):
   A. periodic withdrawal of accumulated fluid
   B. for injection of radioactive liquid (usually phosphorous) for ablation

TECHNIQUE

Table 15-2 Steps in tapping a shunt

Step	Information provided
1. insert needle into reservoir and look for spontaneous flow into butterfly tubing; measure pressure in manometer	• spontaneous flow indicates proximal end not completely occluded • pressure is that of ventricular system (should be < 15 cm of CSF in relaxed recumbent patient)
2. also measure the pressure with distal occluder pressed if present	• rise in pressure indicates some function of valve and distal shunt
3. if no spontaneous flow, try to aspirate CSF with syringe	• if CSF is easily aspirated, it may be that pressure seen by ventricular system is near 0 • if no CSF obtained or if difficult to aspirate, indicates proximal occlusion
4. send CSF for: C&S, protein/glucose, cell count	• checks for infection
5. fill manometer with sterile saline, & occlude <u>proximal</u> (inlet) occluder (with Holter valve, tap the valve itself, although this is not recommended because the hole thus created may not seal)	• measures forward transmission pressure (through valve and peritoneal catheter in presence of shunt with proximal occluder); forward pressure should be less than ventricular pressure
6. repeat measurement after injecting 3-5 ml of saline	• if peritoneal catheter is in a loculated compartment the pressure will be considerably higher after injection

[(For LP shunt, see *Lumboperitoneal (LP) shunt evaluation*, page 214).

There is a risk of introducing infection with every entry into the shunt system. With care, this may be kept to a minimum.

1. shave area
2. povidone iodine solution prep **x** 5 minutes
3. use 25 gauge butterfly needle or smaller (ideally a noncoring needle should be used): for routine taps, the needle should only be introduced into shunt components specifically designed to be tapped

To measure pressures

Steps are outlined in *Table 15-2*.

INSTRUCTIONS TO PATIENTS

All patients and families of patients with hydrocephalus should be instructed regarding the following:

1. signs and symptoms of shunt malfunction or infection
2. not to pump the shunt unless instructed to do so for a specific purpose
3. prophylactic antibiotics: for the following situations (mandatory in vascular shunts, sometimes recommended in other shunts)
   A. dental procedures
   B. instrumentation of the bladder: cystoscopy, CMG, etc.
4. in a growing child: the need for periodic evaluation, including assessment

of distal shunt length

UNDERSHUNTING

The shunt malfunction rate is ≈ 17% during the first year of placement in the pediatric population.

May be due to one or a number of the following:

1. blockage (occlusion)
   A. possible causes of occlusion:
      1. obstruction by choroid plexus
      2. buildup of proteinaceous accretions
      3. blood
      4. cells (inflammatory or tumor)
      5. secondary to infection
   B. site of blockage
      1. blockage of ventricular end (most common): usually by choroid plexus, may also be due to glial adhesions, intraventricular blood
      2. blockage of intermediate hardware (valves, connectors, etc., tumor filters may become obstructed by tumor cells, antisiphon devices may close due to variable overlying subcutaneous tissue pressures[59])
      3. blocked distal end (*see page 316* for VP shunt)
   C. disconnection, kinking or breakage of system at any point: with age, silicone elastomers used in catheters calcify and break down, and become more rigid and fragile which may promote subcutaneous attachment[60]. Barium impregnation may accelerate this process. Tube fractures often occur near the clavicle, presumably due to the increased motion there

Signs and symptoms of undershunting

Signs and symptoms are those of active hydrocephalus, and include:

1. acute <u>symptoms</u> of increased intracranial pressure
   A. H/A
   B. N/V
   C. diplopia
   D. lethargy

E. ataxia
F. infants: apnea and/or bradycardia; irritability
G. seizures: new onset, increase in frequency, or difficulty in control

2. acute signs of increased intracranial pressure
   A. upward gaze palsy ("setting sun sign", see *Parinaud's syndrome*, page 114)
   B. abducens palsy: false localizing sign
   C. field cut, or blindness (see *Blindness from hydrocephalus*, page 335)
   D. papilledema (rare before age 2 yrs)
   E. infants: bulging fontanelle, prominent scalp veins
3. swelling around shunt tubing: caused by CSF dissecting along shunt tract
4. chronic changes: before sutures close, OFCs crossing curves

EVALUATION OF SHUNT FOR UNDERSHUNTING

1. history and physical directed at determining presence of above signs and symptoms, also ascertain:
   A. reason for initial insertion of shunt (MM, post-meningitis, etc.)
   B. date of last revision and reason for revision
   C. presence of accessory hardware in system (e.g. antisiphon device, etc.)
   D. for children: OFC. Plot on graph of normal curves (use existing chart for that patient if available)
   E. fontanelle tension (if open): a soft pulsating fontanelle varying with respirations is normal, a tense bulging fontanelle suggests obstruction, a sunken fontanelle may be normal or may represent overshunting
   F. ability of shunt to pump and refill
      1. caution: may exacerbate obstruction, especially if shunt is occluded by ependyma due to overshunting: controversial
      2. difficult to depress: suggests distal occlusion
      3. slow to refill (generally, any valve should refill in 15-30 secs): suggests proximal (ventricular) occlusion
   G. evidence of CSF dissecting along tract outside of shunt tubing
   H. in children presenting only with vomiting, especially those with cerebral palsy and feeding gastrostomy tubes, rule-out gastroesophageal reflux
2. radiographic evaluation
   A. "shunt series" (plain x-rays to visualize entire shunt: for VP shunt, AP & lateral skull + "low" CXR and/or abdominal x-ray)

1. R/O disconnection or migration of tip by x-rays to visualize entire shunt; note: a disconnected shunt may continue to function by CSF flow through a fibrous tract; the following hardware may be radiolucent and can mimic disconnection:
   a. the central silastic part of a Holter style valve
   b. connectors ("**Y**" & "**T**" as well as straight)
   c. antisiphon devices
   d. tumor filters
2. obtain most recent x-rays available to compare for breaks (essential for "complicated" shunts involving multiple ventricular or cyst ends or accessory hardware)

B. in patients with open fontanelles, ultrasound is optimal method of evaluation (especially if previous U/S available)

C. CT required if fontanelles closed, may be desirable in complicated shunt systems (e.g. cyst shunts)

D. MRI: shunt hardware is difficult to see. May show transependymal absorption of CSF, loculations…

E. "shunt-o-gram" if it is still unclear if shunt is functioning
   1. radionuclide: *see below*
   2. x-ray: using iodinated contrast: *see below*

3. shunt tap: indications vary, generally performed if surgical exploration is considered or if infection is strongly suspected (see *Tapping a shunt*, page 322)

4. shunt exploration: sometimes even after thorough evaluation the only means to definitively prove or disprove the functioning of various shunt components is to operate and isolate and test each part of the system independently. Even when infection is not suspected, CSF and any removed hardware should be cultured.

"Shunt-o-gram"

Procedure: shave hair over reservoir & prep with Betadine. With patient supine tap the shunt by inserting a 25 gauge butterfly needle into the reservoir. Measure the pressure with a manometer. Patients with multiple ventricular catheters need to have each injected to verify its patency.

Radionuclide "shunt-o-gram" AKA radionuclide shuntography[61]: after tapping the shunt, drain 2-3 ml of CSF and send 1 ml of CSF for C&S. Inject radio-isotope (e.g. for VP shunt in an adult, use 1 mCi of 99m-Tc (technetium)

pertechnetate (usable range: 0.5 to 3 mCi) in 1 cc of fluid) while occluding distal flow (by compressing valve or occluding ports). Flush in isotope with remaining CSF.

Immediately image the abdomen with the gamma camera to rule out direct injection into distal tubing. Image the cranium to verify flow into ventricles (proximal patency). If spontaneous flow into abdomen is not seen after 10 minutes the patient is sat up and res-canned. If flow is not seen after 10 minutes, then the shunt is pumped. Look for diffusion of the isotope within the abdomen to rule out pseudocyst formation around catheter.

X-ray "shunt-o-gram": after tapping the shunt, drain ≈ 1 ml of CSF and send for C&S. Inject e.g. iohexol (Omnipaque 180) (*see page 122*) while occluding distal flow (by compressing valve or occluding ports).

PSEDUOCYST (PERITONEAL) WITH VP SHUNT

Usually a marker for infection.

Treatment algorithm

One of many viable surgical protocols to deal with this:

1. open abdominal incision over tubing, and divide tubing at this site
2. verify which cut end is the peritoneal end and which is the distal shunt (with a working shunt, pumping the valve should cause CSF to come out the distal shunt)
3. attempt to drain the cyst through the remaining peritoneal end
    A. when you can't draw any more fluid, or if you don't get any to begin with, withdraw the catheter a little at a time and aspirate at each step
    B. send any fluid obtained for culture
    C. if tubing does not pull out smoothly, the abdomen may need to be opened (consider consulting general surgeon)
4. verify function of remaining shunt
    A. if the remaining shunt is functioning
        1. connect it to sterile collection system
        2. monitor output volumes & send surveillance cultures of CSF qod
        3. after 3 consecutive cultures are negative, internalize distal end of shunt (using fresh distal catheter). The choice of target for distal end (peritoneum, pleura, vein) depends on whether abdominal cyst fluid is infected and if the peritoneal cavity still seems suitable)
    B. if the shunt is not functioning, a new external ventricular catheter

should be inserted and connected to a collection system

1. monitor output volumes & send surveillance cultures of CSF qod
2. after 3 consecutive cultures are negative, remove the old shunt and place a totally shunt. The choice of target for distal end (peritoneum, pleura, vein) depends on whether abdominal cyst fluid is infected and if the peritoneal cavity still seems suitable)

SHUNT INFECTION

See *Shunt infection* on page 345 for evaluation and treatment.

"OVERSHUNTING"

POSSIBLE COMPLICATIONS OF OVERSHUNTING INCLUDE[62]

1. slit ventricles: including slit ventricle syndrome (*see below*)
2. intracranial hypotension: *see below*
3. subdural hematomas: *see page 327*
4. craniosynostosis and microcephaly: controversial (*see page 328*)
5. stenosis or occlusion of sylvian aqueduct

10-12% of long-term ventricular shunt patients will develop one of the above problems within 6.5 yrs of initial shunting[62]. Some experts feel that problems related to over-shunting could be reduced by utilizing LP shunts for communicating hydrocephalus, and reserving ventricular shunts for obstructive HCP[62]. VP shunts may also be more likely to overdrain than VA shunts because of the longer tubing → greater siphoning effect.

INTRACRANIAL HYPOTENSION

AKA low ICP syndrome. Very rare. Symptoms similar to those of spinal H/A (postural in nature, relieved by recumbency). Although usually not associated with the following symptoms[63], they may occur[62]: N/V, lethargy, or neurologic signs (e.g. diplopia, upgaze palsy). Sometimes the symptoms resemble those of high ICP except that they are relieved when prostrate. Acute effects that may occur include[62]: tachycardia, loss of consciousness, other brain stem deficits due to a rostral shift of the intracranial contents or to low ICP.

Etiology is a siphoning effect due to the column of CSF in the shunt tube when the patient is erect[64]. Ventricles may be slit-like (as in slit ventricle

syndrome **(SVS)**) or may be normal in appearance. Sometimes it is necessary to document a drop in ICP when going from supine to erect to diagnose this condition. These patients may also develop shunt occlusion and then the distinction from SVS blurs (*see below*).

With short-term symptoms, an ASD is the treatment of choice. However, patients with long-standing overshunting may not tolerate efforts to return intraventricular pressures to normal levels[62, 65].

SLIT VENTRICLES

"Slit ventricles" refers to complete collapse of the ventricles. In a survey, a frontal-occipital horn ratio[19] < 0.2 was most often interpreted as representing SVS. May be seen in:

1. overshunting
2. with entrapped (isolated) fourth ventricle: *see page 309*
3. some patients with idiopathic intracranial hypertension (AKA pseudotumor cerebri) (*see page 713*) have slit-like ventricles with consistently elevated ICP

May be one of the following:

1. asymptomatic:
   A. slit ventricles (totally collapsed lateral ventricles) may be seen on CT in 3 -80% of patients after shunting[63, 66], most are asymptomatic
   B. these patients may occasionally present with symptoms unrelated to the shunt, e.g. true migraine
2. **slit ventricle syndrome (SVS)**: seen in < 12% of all shunted patients. Subtypes:
   A. intermittent shunt occlusion: overshunting leads to ventricular collapse (slit ventricles) which causes the ependymal lining to occlude the inlet ports of the ventricular catheter (by coaptation) producing shunt obstruction. With time, many of these patients develop low ventricular compliance[67], where even minimal dilatation results in high pressure which produces symptoms. Expansion then eventually reopens the inlet ports allowing resumption of drainage (hence the intermittent symptoms). Symptoms may resemble shunt malfunction: intermittent headaches unrelated to posture, often with N/V, drowsiness, irritability and impaired mentation. Signs may include 6th cranial nerve palsy. Incidence in shunted patients: 2-5%[63, 68]. CT or MRI scans may also show evidence of transependymal absorption of

CSF

B. total shunt malfunction (AKA normal volume hydrocephalus[67]): may occur and yet ventricles remain slit-like if the ventricles cannot expand because of subependymal gliosis, or due to the law of Laplace (which states that the pressure required to expand a large container is lower than the pressure required to expand a small container)

C. venous hypertension with normal shunt function: may result from partial venous occlusion that occurs in some conditions (e.g. at the level of the jugular foramen in Crouzon's syndrome). Usually subsides by adulthood

3. intracranial hypotension: symptoms often relieved by recumbency (*see above*)

EVALUATION OF SLIT VENTRICLES

The shunt valve fills slowly if pumped when the ventricles are collapsed.

Monitoring CSF pressure: either via lumbar drain, or with a butterfly inserted into the shunt reservoir (with this method, pressure can be followed during postural changes to look for negative pressure when upright; possibly higher risk of infection with this). These patients are also monitored for pressure spikes, especially during sleep.

Alternatively, these patients may be evaluated by "shunt-o-gram" (*see above*).

TREATMENT

In treating a patient with slit ventricles in imaging studies, it is important to ascertain into which of the categories (*see above*) the patient falls. If the patient can be categorized, then the specific treatment listed below should be employed. Otherwise, it is probably most common to initially treat the patient empirically as intracranial hypotension, and then to move on to other methods for treatment failures.

Asymptomatic slit ventricles

Prophylactic upgrading to a higher pressure valve or insertion of an antisiphon device has largely been abandoned. However, this may be appropriate at the time of shunt revision when done for other reasons[66].

Intracranial hypotension

Postural H/A due to intracranial hypotension (true overshunting) is usually self limited, however, if symptoms persist after ≈ 3 days of bed-rest and analgesics and a trial with a tight abdominal binder, the valve should be checked for proper closing pressure. If it is low, replace with a higher pressure valve. If it is not low, an **antisiphon device (ASD)** (which, by itself, also increases the resistance of the system) alone or together with a higher pressure valve may be needed[69].

Slit ventricle syndrome

Patients with symptoms of SVS are actually suffering from intermittent *high* pressure. If total shunt malfunction is the cause, then shunt revision is indicated. For intermittent occlusion, treatment options include:

1. if symptoms occur early after shunt insertion or revision, initial expectant management may be indicated since symptoms will spontaneously resolve in many
2. revision of the proximal shunt. This may be difficult due to the small size of the ventricles. One can attempt to follow the existing tract and insert a longer or shorter length of tubing based on the pre-op imaging studies. Some advocate the placement of a second ventricular catheter, leaving the first one in place
3. patients may "respond" to either of the following interventions because the slight ventricular enlargement elevates the ependyma off of the inlet ports:
   A. valve upgrade[70] or
   B. ASD insertion[63, 69]: the procedure of choice in some opinions[62]. First described in 197371
4. subtemporal decompression[72-74] sometimes with dural incision[72]. This results in dilatation of the temporal horns (evidence for elevated pressure) in most, but not all[74] cases
5. third ventriculostomy[75]: *see page 315*

Problems unrelated to shunting

For H/A consistent with migraine that are not postural, a trial with migraine-specific medications is warranted (Fiorinal®…). For treatment of idiopathic intracranial hypertension (pseudotumor cerebri), *see page 717*.

SUBDURAL HEMATOMAS

May be due to collapse of brain with tearing of bridging veins. In the pre-CT era, the incidence of subdural hematoma **(SDH)** formation following shunt insertion was probably underestimated at ≈ 1.2%. However, more recent estimates are 4-23% in adults, 2.8-5.4% in children, and is higher with normal pressure hydrocephalus (20-46%) than with "hypertensive hydrocephalus" (0.4-5%)[76, 77]. The risk of SDH is higher in the setting of longstanding hydrocephalus with a large head and little brain parenchyma (craniocerebral disproportion) with a thin cerebral mantle, as usually occurs in children with macrocephaly and large ventricles on initial evaluation. These patients have an "extremely delicate balance between subdural and intraventricular pressure"[76]. SDH can also follow shunting in elderly patients who have severe brain atrophy. The development of SDH may also be facilitated by negative pressures in the ventricles as a result of siphoning[77, 78]. There is also a low risk of epidural hematoma following CSF shunting[77].

Characteristics of the fluid: The collections may be on the same side as the shunt in 32%, on the opposite side in 21%, and bilateral in 47%[77].

At the time of discovery, the SDHs are usually subacute to chronic, and the previously large ventricles are usually collapsed. Only 1 of 19 cases showed colorless fluid[77]. In all cases tested, protein was elevated compared to CSF.

TREATMENT

Indications for treatment

Small (< 1-2 cm thick) asymptomatic collections in patients with closed cranial sutures may be followed with serial imaging. SDH were symptomatic in ≈ 40% of cases (symptoms often resemble those of shunt malfunction), and these require treatment. Treatment of SDH in children with open sutures has been advocated[77] to prevent later symptoms and/or development of macrocrania. Many authors recommend not treating asymptomatic lesions regardless of appearance[76, 79], whereas others vary their recommendations based on diverse criteria including size, appearance (chronic, acute, mixed…), etc.

Treatment techniques

A number of techniques have been described. Most involve evacuation of the SDHs by any of the usual methods (e.g. burr holes for chronic collections, craniotomy for acute collections) together with:

1. reducing the degree of shunting (i.e. to establish a lower pressure in the subdural space than in the intraventricular space, to cause the ventricles to re-expand and to prevent reaccumulation of the SDH)
   A. in shunt dependent cases
      1. replacing the valve with a higher pressure unit (upgrading the valve)
      2. increasing the pressure on a programmable pressure valve[80, 81]
      3. using a Portnoy device that can be turned off and on externally. Be sure that care providers can reliably open the device in an emergency
   B. in non-shunt dependent cases
      1. any of the methods outlined above for shunt dependent cases, or
      2. temporarily tying off the shunt[82]
   C. insertion of an anti-siphon device[71]
2. drainage of the subdural space to
   A. the cisterna magna[83]
   B. to the peritoneum with a low pressure valve (or no valve[77]). Some authors have the care-giver frequently pump the subdural valve

The goal is to achieve a delicate balance between undershunting (producing symptoms of active hydrocephalus) and overshunting (promoting the return of the SDH). Following surgery the patient should be mobilized slowly to prevent recurrence of the SDH.

MISCELLANEOUS SHUNT ISSUES

CRANIOSYNOSTOSIS, MICROCEPHALY & SKULL DEFORMITIES

Also see *Craniosynostosis*, page 228. A number of skull changes have been described in infants after shunting, including[84]: thickening and inward growth of the bone of the skull base and cranial vault, decrease in size of the sella turcica, reduction in size of the cranial foramina, and craniosynostosis. The most common skull deformity was dolichocephaly from sagittal synostosis[85]. Microcephaly accounted for ≈ 6% of skull deformities after shunting (about half of these had sagittal synostosis). Some of these changes were reversible (except when complete synostosis was present) if intracranial hypertension recurred.

LAPAROSCOPIC SURGERY IN PATIENTS WITH VP SHUNTS

Issues regarding safety of laparoscopic surgery in patients with VP shunts:

1. laparoscopic surgery: abdominal insufflation with CO_2 is used to create a pneumoperitoneum permitting the general surgeon to work. Typical insufflation pressure: 15 mm Hg (*see page 870* for conversion factors between mm Hg and cm of water). In thin patients, 10 mm Hg may suffice. Transient additional increases in pressure may occur, e.g. when the surgeon leans on the patient's abdomen
2. concerns for patients with VP shunts:
   A. in some cases insufflation → ↑ ICP[86] which may be due to:
      1. compression of vena cava → reduced venous return from head, as in valsalva maneuver (independent of presence of a shunt)
      2. absorption of CO_2 from the peritoneum → ↑ in arterial CO_2 causing cerebral arterial dilatation thereby increasing ICP (*see page 880*)
      3. ↓ CSF drainage due to ↑ pressure against which CSF must flow
      4. retrograde passage of air/debris into intracranial compartment through an incompetent shunt valve (this also has potential for infection in the presence of peritonitis). This risk is minimal even with in vitro back-pressures up to 80 mm Hg[87]. Retrograde flow may also occur with a valveless shunt (rarely used)
      - in one case report monitoring TCDs[88], there was no change during laparoscopic surgery in a patient with a VP shunt (except during periods of very high pressure)
   B. occlusion of the distal catheter by air, debris[89] or soft tissue
   C. extremely high intraabdominal pressures (> 80 mm Hg in vitro) may damage the valve[87], which could cause malfunction after the laparoscopy

Prophylactic management options:

1. very controversial, special precautions may not be necessary[90]
2. one can temporarily occlude the peritoneal catheter (e.g. by a hemoclip applied by the general surgeon through the laparoscope under minimal initial insufflation pressure; the clip is removed at the end of the procedure), or, temporary externalization of the shunt by the neurosurgeon, with internalization at the end of the procedure (this engenders an increased risk of infection)
3. ICP monitoring during laparoscopy
4. using low insufflation pressures (e.g. < 10 mm Hg)

15.3. Normal pressure hydrocephalus

Key concepts:

- triad (not pathognomonic): dementia, gait disturbance, urinary incontinence
- communicating hydrocephalus on CT or MRI
- normal pressure on random LP
- symptoms may be remediable with CSF shunting

Normal pressure hydrocephalus **(NPH)**, AKA Hakim-Adams syndrome, first described in 196591, is clinically important because it may cause treatable symptoms, including one of the few forms of remediable dementia.

As originally described, the hydrocephalus of NPH was considered to be idiopathic. However, in some cases a predisposing condition (“secondary NPH”) may be identified:

1. post-SAH
2. post-traumatic
3. post-meningitis
4. following posterior fossa surgery
5. tumors, including carcinomatous meningitis
6. also seen in ≈ 15% of patients with Alzheimer’s disease **(AD)**
7. deficiency of the arachnoid granulations
8. aqueductal stenosis may be an overlooked cause

It is becoming increasingly acknowledged that the ventricular enlargement is likely not the underlying pathologic entity. Interest persists in effects such as impaired pulsatility. The search continues to improve the understanding of this complicated condition.

Table 15-3 Comparison of cognitive deficits in Alzheimer’s disease (AD) and NPH*†

Feature	AD	NPH
memory	↓	± auditory memory

* modified[94]

† Key: ↓ = impaired; ± = borderline impaired

‡ see Table 15-6 for definition of executive function

CLINICAL

Clinical triad[92]

The triad is not pathognomonic, and similar features may also be seen e.g. in vascular dementia[93], Alzheimer's dementia and Parkinson's disease.

1. gait disturbance: usually precedes other symptoms. Wide based with short, shuffling steps and unsteadiness on turning. Patients often feel like they are "glued to the floor" (so-called "magnetic gait") and may have difficulty initiating steps or turns. Absence of appendicular ataxia
2. dementia: primarily memory impairment with bradyphrenia (slowness of thought) and bradykinesia (*Table 15-3* shows some differentiating features with Alzheimer's disease)
3. urinary incontinence: usually unwitting (NB: a patient demented for any reason or with mobility impairment may have incontinence)

Other clinical features

Age usually > 60 yrs. Slight male preponderance. Also see *Diagnosis* below for other clinical information.

True aphasia is unusual, but speech output may be disturbed by impaired motivation or executive dysfunction[94]. As NPH progresses, cognitive impairment may become more generalized and less responsive to treatment[94]. Symptoms identical to those of idiopathic parkinsonism may occur in 11%[95].

Case reports of a variety of psychiatric disturbances associated with NPH include: depression[96], bipolar disorder[97], aggressiveness[98], paranoia[99].

Symptoms <u>not</u> expected with NPH: Although a variety of clinical features

have been demonstrated to occur infrequently (e.g. SIADH[100], syncope…), clinical features not expected solely as a result of NPH include: papilledema, seizures (prior to shunting), headaches[94].

Differential diagnosis

Table 15-4 shows conditions with presentations similar to findings in NPH in the differential diagnosis[94, 101]. *Table 15-5* compares some features of NPH, Alzheimer's disease, and Parkinson's disease.

Table 15-4 Conditions with similar presentation to NPH

Neurodegenerative disorders • Alzheimer's disease • Parkinson's disease • Lewy body disease • Huntington's disease • frontotemporal dementia • corticobasal degeneration • progressive supranuclear palsy • amyotrophic lateral stenosis • multisystem atrophy • spongiform encephalopathy
Vascular dementia • cerebrovascular disease • multi-infarct dementia • Binswanger's disease • CADASIL • vertebrobasilar insufficiency (VBI)
Other hydrocephalic disorders • aqueductal stenosis • arrested hydrocephalus • long-standing overt ventriculomegaly syndrome • noncommunicating hydrocephalus
Infectious disease • Lyme disease • HIV • syphilis
Urological disorders • urinary tract infection • bladder or prostate cancer • benign prostatic hypertrophy (BPH)
Miscellaneous • vitamin B_{12} deficiency • collagen vascular diseases • epilepsy • depression • traumatic brain injury

• spinal stenosis
• Chiari malformation
• Wernicke’s encephalopathy
• carcinomatous meningitis
• spinal cord tumor

DIAGNOSIS

PRACTICE GUIDELINE 15-1 DIAGNOSIS OF NPH

Level II[94]: Since strict diagnostic criteria cannot be formulated for NPH because of a lack of knowledge of the underlying pathophysiology at this time, it is recommended that the diagnosis be made in terms of *Probable*, *Possible*, and *Unlikely NPH* as described in *Table 15-6*

Table 15-6 Diagnostic guidelines for NPH[94]

PROBABLE NPH

History*: must include:
1. insidious onset (vs. acute)
2. onset age ≥ 40 years
3. duration ≥ 3-6 months
4. no antecedent head trauma, ICH, meningitis or other known cause of secondary hydrocephalus
5. progression over time
6. no other neurological, psychiatric or general medical conditions that are sufficient to explain the presenting symptoms

Brain imaging: CT or MRI after onset of symptoms

1. ventricular enlargement not attributable to cerebral atrophy or congenital enlargement (Evan's index[†] > 0.3 or comparable measure)
2. no macroscopic obstruction to CSF flow
3. ≥ 1 of the following supportive features
   A. enlarged temporal horns not entirely attributable to hippocampal atrophy
   B. callosal angle ≥ 40°
   C. evidence of altered brain water content, including periventricular changes not attributable to microvascular, ischemic changes, or demyelination
   D. aqueductal or 4th ventricle flow void on MRI

Other imaging findings that may support *Probable* designation but are not required:
1. pre-morbid study showing smaller or nonhydrocephalic ventricles
2. radionuclide cisternogram showing delayed clearance of radiotracer over the convexities after 48-72 hours
3. cine-MRI or other technique showing increased ventricular flow rate
4. SPECT showing decreased periventricular perfusion that is not altered by acetazolamide challenge

Physiological

CSF opening pressure **(OP)** on lateral decubitus LP: 5-18 mm Hg (70-245 mm H_2O)

Clinical: must show gait/balance disturbance, plus impairment in cognition and/or urinary function

1. **gait/imbalance**: ≥ 2 of the following (not entirely attributable to other conditions
   A. decreased step height
   B. decreased step length
   C. decreased cadence (speed of walking)
   D. increased trunk sway while walking
   E. widened standing base
   F. toes turn outward while walking
   G. retropulsion (spontaneous or provoked) must show:
   H. *en bloc* turning (≥ 3 steps to turn 180°)
   I. impaired walking balance: ≥ 2 corrections out of 8 tandem steps
2. **cognition**: documented impairment (adjusted for age & education) and/or decrease in performance on cognitive screening instrument (e.g. Monumental State examination), or evidence of ≥ 2 of the following not fully attributable to other conditions:
   A. psychomotor slowing (increased response latency)
   B. decreased fine motor speed
   C. decreased fine motor accuracy
   D. difficulty dividing or maintaining attention
   E. impaired recall, especially for recent events
   F. executive dysfunction: e.g. impairment in multistep procedures, working memory, formulation of abstractions/similarities, insight
   G. behavioral or personality changes
3. **urinary dysfunction**:
   A. any one of the following
      1. episodic or persistent incontinence not attributable to primary urological disorder
      2. persistent urinary incontinence
      3. urinary and fecal incontinence
   B. or, any 2 of the following:
      1. urinary urgency: frequent perception of a pressing need to void
      2. ↑ urinary frequency (pollakiuria): voiding > 6 times in 12 hours with normal fluid intake
      3. nocturia: needing to void > 2 times in an average night

POSSIBLE NPH

History: reported symptoms may:

1. have subacute or indeterminate mode of onset
2. onset at any age after childhood
3. duration: < 3 months or indeterminate
4. may follow events such as mild head trauma, remote history of ICH, or childhood or adult meningitis or other conditions judged not likely to be causally related
5. coexist with other neurological, psychiatric, or general medical disorders but judged not to be entirely attributable to these conditions

6. be nonprogressive or not clearly progressive	
Clinical: symptoms of either: 1. incontinence and/or cognitive impairment in the absence of observable gait/balance disturbance 2. gait disturbance or dementia alone	
Brain imaging: ventricular enlargement consistent with hydrocephalus but associated with any of the following: 1. cerebral atrophy of sufficient severity to potentially explain ventricular enlargement 2. structural lesions that may influence ventricular size	
Physiological OP not available or outside of the range delineated for *Probable NPH*	
UNLIKELY NPH	
1. no ventriculomegaly 2. signs of increased ICP (e.g. papilledema) 3. no component of the clinical triad of NPH 4. symptoms explained by other causes (e.g. spinal stenosis)	

* history should be verified by individual familiar with premorbid and current condition

† see page 310 for definition and illustration of Evan's index

LUMBAR PUNCTURE (LP) - "TAP TEST"

Opening pressure: Normal LP opening pressure **(OP)** in the left lateral decubitus position averages 12.2 ± 3.4 cm H_2O (8.8 ± 0.9 mm Hg)[102] and should be < 180 mm H_2O[A]. In NPH the average OP is 15 ± 4.5 cm H_2O (11 ± 3.3 mm Hg), slightly higher than, but overlapping with, normal. Based on expert opinion, an upper limit of **24 cm H_2O** (17.6 mm Hg) is suggested for the definition of NPH. Patients with an initial OP > 10 cm H_2O have a higher response rate to shunting.

Tap test: The tap test has not undergone rigorous prospective evaluation. A positive response[B] to withdrawal of 40-50 ml of CSF has a PPV in the range of 73-100%[104-106], but sensitivity is low (26-61%).

Send CSF for routine labs (*see page 203*).

RESISTANCE TESTING

CSF Ro is considered to be the impedance of CSF absorptive mechanisms. 1/Ro is the conductance. Techniques and thresholds are center-specific. No clinical study has adequately addressed the fact that Ro normally increases with age[107].

Determination of CSF Ro may have a higher sensitivity (57-100%) but a similar PPV (75-92%) to the tap test.

Methodology

Numerous methods have been devised to measure Ro. Two illustrative methods:

1. bolus method[108]: inject ≈ 4 ml via LP at a rate of 1 ml/sec
2. Katzman test[109]: infuse saline through LP at a known rate, Ro is given by *Eq 15-1* (up to 19% of patients experience H/A after infusion studies[110])

$$\mathrm{Ro} = \frac{(\text{final steady state pressure}) - (\text{initial pressure})}{\text{infusion rate}} \qquad \textbf{Eq 15-1}$$

AMBULATORY LUMBAR DRAINAGE[104] (ALD)

A lumbar subarachnoid drain is placed with Tuohy needle, connected through a drip chamber to a closed drainage system (*see* *page 202*). The drip chamber is placed at the level of the patient's ear when recumbent, or at the level of the shoulder when sitting or ambulating.

A properly functioning drain should put out ≈ 300 ml of CSF per day.

If symptoms of nerve root irritation develop during the drainage, the catheter should be withdrawn several millimeters. Daily surveillance CSF cell counts and cultures should be performed (NB: a pleocytosis of ≈ 100 cells/mm^3 is expected just with the presence of the drain).

A 5 day trial is recommended (mean time to improvement: 3 days).

CONTINUOUS CSF PRESSURE MONITORING

Some patients with normal OP on LP demonstrate pressure peaks > 270 mm H_2O or recurrent B-waves[111]. These patients may have a higher response rate to shunting.

CT AND MRI

Features on CT[112] and MRI[113]

1. prerequisite: communicating hydrocephalus
2. features that correlate with favorable response to shunt (these features suggest that the hydrocephalus is <u>not</u> due to atrophy alone[C]):
   A. periventricular low density on CT or high intensity on T2WI MRI: may represent transependymal absorption of CSF. May resolve with shunting
   B. compression of convexity sulci (*focal* sulcal dilation may sometimes

be seen and may represent atypical reservoirs of CSF which may diminish after shunting and should not be considered as atrophy[115])

C. rounding of the frontal horns

A. OP > 24 cm H_2O suggests noncommunicating hydrocephalus rather than NPH[94, 103]

B. what constitutes a "significant response" has not been standardized, most experts prefer demonstrating objective improvement in gait, taking into account the fact that NPH patients can have day-to-day fluctuations in symptoms

C. atrophy (hydrocephalus ex vacuo), as in conditions such as Alzheimer's disease, lessens the chance of, but does not preclude, responding to a shunt (cortical atrophy is a common finding in healthy individuals of advanced age[114])

Although some patients improve with no change in ventricles[116], clinical improvement most often accompanies reduction of ventricular size.

Radionuclide cisternography

Usefulness remains controversial. One study found that the cisternogram does not increase the diagnostic accuracy of clinical and CT criteria[117].

Technique: Lumbar subarachnoid injection of radio-isotope (e.g. 2.7 mCi of ^{99m}Tc-DTPA diluted to 1 cc with saline). Cisternograms are obtained by planar scintigraphy at 3, 6, and 24 hrs after injection (images may be obtained at 48 hrs if intraventricular activity is still seen at 24 hrs, however, an isotope other than ^{99m}Tc-DTPA must be used for such delayed images).

Conventional criteria for a normal study: Radioactivity is symmetrically distributed over the convexity 24 hrs after injection, with no intraventricular activity at any point. However, up to 41% of normals will demonstrate transient (up to 24 hrs, but not longer) activity in the ventricles[118].

Findings that may indicate a better chance for response to shunting: Of the following, only #2 is a reliable marker for NPH.

1. early scan (4-6 hrs after injection): activity in ventricles (presumed reflux from obstructed outflow). May also occur in normals (*see above*) for < 24 hrs
2. late scan (48-72 hrs): persistence of ventricular activity. Patients with this finding are most likely to improve with shunting (≈ 75% chance)
3. retained activity over convexity: these patients are less likely to improve

4. quantitative cisternography
   A. patients who clear over 50% of total intracranial radioactivity within 24 hrs are considered to have an adequate overall absorption rate, and are unlikely to improve with shunting. However others have found no correlation of clearance to shunt response
   B. one study found that if the ratio of ventricular to total intracranial activity (V/T) at 24 hours is > 32%, there would be a response to shunting, whereas V/T < 32% did not exclude the possibility of improvement[119]

Miscellaneous

Cerebral blood flow (CBF) measurements: Although some studies indicate otherwise, CBF measurements show no specific findings in NPH, and are not helpful in predicting who will respond to shunting. However, increased CBF after shunting correlates with clinical improvement[120].

EEG: No specific findings on EEG in NPH.

Treatment

Management algorithm

1. based on history, physical exam, and imaging studies, categorize as probable, possible, or unlikely NPH based on *Table 15-6*, page 331. For *probable* and *possible* NPH, without further testing, the degree of certainty of the diagnosis of NPH is ≈ 50-61%[117, 121, 122]. In an otherwise healthy patient in whom the diagnosis of NPH seems highly probable, it is not unreasonable to proceed to shunting[103]
2. otherwise, to increase the certainty of response to shunting, one or more of the following tests is recommended[103]
   A. "tap test": withdrawal of 40-50 ml of CSF via LP
      1. positive response (*see page 332*) increases likelihood of responding to a shunt (PPV) to the range of 73-100%
      2. due to low sensitivity (26-61%), a negative response does not rule out the possibility of responding, and a subsequent supplemental test should be performed[103]
      3. if OP > 17.6 mm Hg (24 cm H_2O), consider further search for cause of secondary hydrocephalus (does not rule-out shunting as a treatment)

B. resistance testing: sensitivity (57-100%) > tap test, similar PPV (75-92%)
C. external lumbar drainage

CSF DIVERSIONARY PROCEDURES

VP shunt is the procedure of choice. Lumbar-peritoneal shunts have been used, but disadvantages include: tendency to overshunt, difficult to tap, tendency to migrate. For most, use a medium pressure valve[123] (closing pressure 65-90 mm H_2O) to minimize the risk of subdural hematomas (*see below*), although response rate may be higher with a low-pressure valve[124]. Gradually sit patient up over a period of several days; proceed more slowly in patients who develop low-pressure headaches. Alternatively, the risk of developing SDH may be decreased with use of a programmable shunt valve, set initially at a high pressure (to reduce risk of subdural hematoma) and gradually decreasing the pressure setting over a number of weeks.

Follow patients clinically and with CT for ≈ 6-12 months.

Patients who do not improve and whose ventricles do not change should be evaluated for shunt malfunction. If not obstructed, a lower pressure valve should be tried (or a lower pressure selected on a programmable shunt).

Endoscopic third ventriculostomy (ETV): Initially reported for NPH in 1999125. Mechanistically, it is difficult to explain why ETV would work for NPH, but it has been advocated by some[33] in highly selected patients, using nonvalidated outcome measures, quoting post-op improvement in 69% of patients. At this time, ETV should not be considered a first line treatment for most cases of NPH.

POTENTIAL COMPLICATIONS OF SHUNTING FOR NPH

Complication rates may be as high as ≈ 35% (due to the frailty of the elderly brain)[126, 127].

Potential complications include[128]:

1. subdural hematomas or hygroma (also *see page 327*): higher risk with low pressure valve and older patients who tend to have cerebral atrophy. Usually accompanied by headache, most resolve spontaneously or remain stable. Approximately one third require evacuation and tying off of shunt (temporarily or permanently). Risk may be reduced by gradual mobilization post-op

2. shunt infection
3. intracerebral hemorrhage
4. seizures: *see page 316*
5. delayed complications include: above, plus shunt obstruction or disconnection

OUTCOME

The most likely symptom to improve with shunting is incontinence, then gait disturbance, and lastly dementia. Black et al.[123] give the following markers for good candidates for improvement with shunting:

- clinical: presence of the classic triad[126] (*see page 329*). Also 77% of patients with gait disturbance as the primary symptom improved with shunting. Patients with dementia and no gait disturbance rarely respond to shunting
- LP: OP > 100 mm H_2O
- isotope cisternogram: typical NPH pattern. The mixed or normal pattern has no correlation with response to shunting
- continuous CSF pressure recording: pressure > 180 mm H_2O or frequent Lundberg B waves (*see page 872*)
- CT or MRI: large ventricles with flattened sulci (little atrophy)

Response is better when symptoms have been present for a shorter time.

NB: NPH patients with co-existing Alzheimer's disease **(AD)** may still improve with VP shunts, thus AD should not exclude these patients from shunting[129]. However, patients with AD alone did not respond to shunting in a RPDB placebo-controlled trial[130].

Some responders may subsequently deteriorate. Shunt malfunction and subdural collections must be ruled out before ascribing this to the natural course of the condition.

15.4. Blindness from hydrocephalus

A rare complication of hydrocephalus and/or shunt malfunction. Possible causes include:

1. occlusion of posterior cerebral arteries **(PCA)** caused by downward transtentorial herniation

2. chronic papilledema causing injury to optic nerve at the optic disc

3. dilatation of the 3rd ventricle with compression of optic chiasm

Ocular motility or visual field defects are more common with shunt malfunction than is blindness[131-134]. One series found 34 reported cases of permanent blindness in children attributed to shunt malfunction with concomitant increased ICP[135] (these authors were based in a referral center for visually impaired children, thus incidence not estimated). Another series of 100 patients with tentorial herniation (most from acute EDH and/or SDH) proven by CT; 48 patients operated; only 19 of 100 survived > 1 month (all were in operated group); 9 of 100 developed occipital lobe infarct (2 died, 3 vegetative state, remaining 4 moderate to severe disability)[136].

TYPES OF VISUAL DISTURBANCE

9 of 14 had pregeniculate (anterior visual pathway) blindness with marked optic nerve atrophy (early), and reduced pupillary light reflexes. 5 of 14 had postgeniculate (cortical) blindness with normal light responses and minimal or no optic nerve atrophy (or atrophy late). A few patients had evidence of damage in both sites.

Cortical blindness: due to lesions posterior to lateral geniculate bodies **(LGB)**, may also be seen with hypoxic injuries or trauma[137]. Occasionally associated with **Anton's syndrome** (denial of visual deficit) and with Ridoch's phenomenon (appreciation of moving objects without perception of stationary stimuli).

PATHOPHYSIOLOGY

In patients with occipital lobe infarction

Occipital lobe infarctions **(OLI)** in PCA distribution are seen either bilaterally, or if unilateral are associated with other injuries to optic pathways posterior to LGB. The most often cited mechanism is compression of PCA resulting from brain herniating downward. Alternatively, upward cerebellar herniation (e.g. from ventricular puncture in face of a p-fossa mass) may impinge on PCA or branches with the same results[138].

OLIs are more likely with a rapid rise in ICP (doesn't allow compensatory shifts and collateral circulation to develop)[139]. Macular sparing is common.

Reported causes of OLI include: post traumatic edema, tumor, abscess, SDH, unshunted hydrocephalus, and shunt malfunction[140-142].

The occipital poles are also particularly vulnerable to diffuse hypoxia[143]; attested to by cases of cortical blindness after cardiac arrest[144]. Hypotension superimposed on compromised PCA circulation (from herniation or elevated ICP) may thus increase the risk of postgeniculate blindness[135, 139].

Both coup and contrecoup trauma may produce OLI. Unlike a PCA occlusion infarct, macular sparing is not expected in traumatic occipital lobe injury[140].

In patients with pregeniculate blindness

Elevated ICP transmits pressure to retina → bloodflow stasis, as well as mechanical trauma to optic chiasm from enlarging third ventricle (latter more commonly thought to be responsible for bitemporal hemianopia[131], but could, if unchecked, progress to complete visual loss). Also, if hypotension and anemia were present, consider the possibility of ischemic optic neuropathy[145-147] which may be anterior, or posterior (the latter of which carries a poorer prognosis).

Presentation

These deficits are frequency unsuspected (altered mental state and the youth of many of these patients[135] makes detection difficult); an examiner must persevere to detect homonymous hemianopsias in an obtunded patient[140].

Pregeniculate blindness is less often associated with depressed sensorium than is postgeniculate (where direct compression and vascular compromise of midbrain are more likely[135]).

Prognosis

Cortical blindness after diffuse anoxia frequently improves (occasionally to normal); usually slowly (weeks to years quoted; several mos usually adequate)[144]. Many reports of blindness after shunt malfunction are pre-CT era, thus the presence or extent of occipital lobe infarction not ascertained. Some optimistic outcomes reported[148], however, permanent blindness or severe visual handicap are described[140, 142]; no reliable predictor has been identified. As with infarcts elsewhere, younger patients fare better[143], but extensive calcarine infarcts on CT are probably incompatible with significant visual recovery.

15.5. Hydrocephalus and pregnancy

Patients with CSF shunts may become pregnant, and there are at least 4 case reports of patients developing hydrocephalus during pregnancy requiring shunting[149].

With VP shunts, distal shunt problems may be higher in pregnancy. The following are management suggestions modified from Wisoff et al.[149].

Preconception management of patients with shunts

1. evaluation, including:
   A. evaluation of shunt function: preconception baseline MRI or CT. Further evaluation of shunt patency if any suspicion of malfunction. Patients with slit ventricles may have reduced compliance and may become symptomatic with very small changes in volume
   B. assessment of medications, especially anticonvulsants
2. counselling, including:
   A. genetic counselling: if the HCP is due to a neural tube defect **(NTD)**, then there is a 2-3% chance that the baby will have a NTD
   B. other recommendations include early administration of prenatal vitamins, and avoiding teratogenic drugs and excessive heat (e.g. hottubs): see *Neural tube defects, Risk factors* on page 245.

Gravid management

1. close observation for signs of increased ICP: headache, N/V, lethargy, ataxia, seizures… Caution: these signs may mimic pre-eclampsia (which must also be ruled out). 58% of patients exhibit signs of increased ICP, which may be due to:
   A. decompensation of partial shunt malfunction
   B. shunt malfunction
   C. some show signs of increased ICP in spite of adequate shunt function, may be due to increased cerebral hydration and venous engorgement
   D. enlargement of tumor during pregnancy
   E. cerebral venous thrombosis: including dural sinus thrombosis & cortical venous thrombosis
   F. encephalopathy related to disordered autoregulation (*see page 73*)
2. patients developing symptoms of increased ICP should have CT or MRI
   A. if no change from preconception study, puncture shunt to measure ICP and culture CSF. Consider radioisotope shunt-o-gram

B. if all studies are negative, then physiologic changes may be responsible. Treatment is bed rest, fluid restriction, and in severe cases steroids and/or diuretics. If symptoms do not abate, then early delivery is recommended as soon as fetal lung maturity can be documented (give prophylactic antibiotics for 48 hrs before delivery)

C. if ventricles have enlarged and/or shunt malfunction is demonstrated on testing, shunt revision is performed
   1. in first two trimesters: VP shunt is preferred (do not use peritoneal trocar method after first trimester) and is tolerated well
   2. in third trimester: VA or ventriculopleural shunt is used to avoid uterine trauma or induction of labor

Intrapartum management

1. prophylactic antibiotics are recommended during labor and delivery to reduce the incidence of shunt infection. Since coliforms are the most common pathogen in L&D, Wisoff et al. recommend ampicillin 2 gm IV q 6 hrs, and gentamicin 1.5 mg/kg IV q 8 hrs in labor and **x** 48 hrs post partum[149]
2. in patients without symptoms: a vaginal delivery is performed if obstetrically feasible (lower risk of forming adhesions or infection of distal shunt). A shortened second stage is preferred since the increase in CSF pressure in this stage is probably greater than during other valsalva maneuvers[150]
3. in the patient who becomes symptomatic near term or during labor, after stabilizing the patient a C-section under general anesthesia (epidurals are contraindicated with elevated ICP) is performed with careful fluid monitoring (e.g. PA catheter) and, in severe cases, steroids and diuretics

NOTES

16. Infections

16.1. Prophylactic antibiotics

General principles[3]

1. antibiotics must be in tissues at time of contamination (thus, avoid "on-call" antibiotics; give 60 minutes prior to incision)
2. repeated administration is vital in prolonged procedures
3. typical infecting organisms are usually predictable. Coverage for these organisms is adequate (broadening spectrum is of no value)
4. in low risk operations (e.g. carotid endarterectomy, where infections rare and seldom life-threatening) may cost more to prevent than to treat
5. prolongation of antibiotics beyond first post-op day provides no additional protection (may not be true in patients with surgical drains)
6. theoretical side effects (alteration of patient's flora, development of resistant strains in patient or hospital) have not been realized without prolonged administration of pre-op or post-op antibiotics
7. factors that increase risk of operative wound infection include:
   A. systemic factors: malnutrition, reoperation, infection at secondary site (especially UTI when GU tract manipulated), prolonged administration of antibiotics
   B. local factors: epinephrine, dehydration, hypoxia

Specific agents for prophylaxis

1. **cephalosporins**:
   A. agents of choice where skin flora (coagulase (–) or (+) staph) are likeliest pathogens
   B. may safely be given even with history of mild, non-immediate manifestations of PCN allergy (e.g. "rashes"). Contraindicated if history of immediate or accelerated reaction (shock, bronchospasm, urticaria)

C. **cefazolin** (Ancef®, Kefzol®):
- effective, widely studied, therapeutic levels in brain tissue after systemic administration[4], long half-life
- prophylactic dose: 1-2 gm (peds: 25 mg/kg up to 1 gm) IV 60 min before surgery, then q 6 hr **x** 24 hrs post-op

D. some *S. aureus* strains are efficient in ß-lactamase degradation of cephalosporins, and cefazolin is particularly susceptible. Lower infection rates may result with cefamandole (2 gm initially, and then 1 gm q 2-3 hrs intraoperatively)[5]

E. a semisynthetic penicillin may be more appropriate if good CSF penetration is necessary

2. **vancomycin**: alternative if cephalosporin contraindicated (incidence of anaphylactic reactions is too high for routine use). Dose (empiric): 15 mg/kg (up to 1 gm) IV pre-op, then 10 mg/kg q 8 hrs for 24 hrs post-op
3. **penicillins**: disadvantages: probably less safe, shorter half-life, may prolong bleeding times. Nafcillin is probably the best agent in this group

PROPHYLACTIC ANTIBIOTICS FOR SPECIFIC NEUROSURGICAL PROCEDURES

1. **carotid endarterectomy**: routine use not indicated (infection risk too low); when risk of infection is high, use cefazolin (as for general prophylaxis, *see above*)
2. **craniotomy**: risk of infection may be increased in prolonged or microsurgical procedures and in reoperations. No significant difference in the specific regimen used was detected in meta-analysis[6]. Options include:
   - cefazolin (*see above*)
   - clindamicin (300 mg IV) pre-op & q 4 hrs
   - vancomycin (*see above*)
   - some add gentamicin (80 mg IM) pre-op to any of these
3. **CSF shunting procedures**: efficacy has been documented when the infection rate is unusually high for some reason (e.g. ≈ 15%). Antibiotics possibly reduce early infections, i.e. ≈ first week post-op

   A. for general use

   1. select one of the following:
      - cefazolin (*see above*)
      - a 1st generation cephalosporin (e.g. cephapirin (Cefadyl®) 25 mg/kg (up to 1 gm)) IVP intra-op and 6 hrs post-op

- nafcillin 50 mg/kg (up to 2 g) IV 60 min before surgery and q 4 hrs post-op **x** 5 doses total

2. PLUS
   - intrathecal gentamicin 4 mg injected into shunt at time of placement (no longer available in U.S., but preservative-free pediatric gentamicin may be diluted appropriately and used)

B. Kaiser: suggests no antibiotics if infection rate low (< 10%). If high (> 20%) use trimethoprim (160 mg IV) plus sulfamethoxazole (800 mg IV) pre-op and q 12 hrs **x** 3 doses post-op (NB: this latter infection rate is very high, and results are thus questionable 7)

4. ICP monitors: *see page 869*
5. procedures involving incisions through **oral or pharyngeal mucosa**: gentamicin (1.7 mg/kg IV) and clindamicin (300 mg IV) pre-op & q 8 hrs post op **x** 24 hrs. Cefazolin & 3rd generation cephalosporin also effective when given over 24 hr period pre-op
6. **spinal surgery**: reduction of infection was *suggested* but was not statistically significant (low incidence would require large study)

A single blind prospective study[7] showed the incidence of post-neurosurgical operative wound infections were reduced with cefazolin (1 gm IV) plus gentamicin (80 mg IV) given one hr before incision and q 6 hrs intra-op (none post-op) with significant results in patients without foreign implants (especially craniotomies; no significant difference for spinal operations, but numbers were small). All infections were *Staph. aureus* or *epidermidis* (makes use of gentamicin questionable).

16.2. Meningitis

Community acquired meningitis **(CAM)** is generally more fulminant than meningitis following neurosurgical procedures (the former tend to occur with more virulent organisms or impaired host defenses). Waterhouse-Friderichsen syndrome: occurs in 10-20% of children with meningococcal infection (usually disseminated infection in age< 10 yrs), produces large petechial hemorrhages in the skin and mucous membranes, fever, septic shock, adrenal failure (due to hemorrhage into adrenal glands) and DIC. Focal neurologic signs are rare in acute purulent meningitis. Meningitis is a medical emergency, and should be treated immediately. See *Lumbar puncture* on page 201 for a discussion about

when to perform an LP.

16.2.1. Post-neurosurgical procedure meningitis

1. usual organisms: *S. aureus*, Enterobacteriaceae, Pseudomonas sp., *pneumococci*
2. empiric antibiotics: vancomycin (to cover MRSA) + ceftazidime specifically: **vancomycin (adult) 1 gm IV q 8 hrs:** (check level before and after 3rd dose and adjust accordingly) + **ceftazidime (Fortaz®) 1-2 gm IV q 8 hrs**
3. for pseudomonas, add gentamicin (IV & IT)
4. if organism turns out to be non-MRSA *S. aureus*, change vancomycin to IV PRSP (e.g. nafcillin)

16.2.2. Post craniospinal trauma meningitis (post-traumatic meningitis)

Epidemiology

Occurs in 1-20% of patients with moderate to severe head injuries[8]. Most cases occur within 2 weeks of trauma, although delayed cases have been described[9]. 75% of cases have demonstrable basal skull fracture (*see page 887*), and 58% had obvious CSF rhinor-rhea.

Pathogens

As expected from above, there is a high rate of infection with organisms indigenous to the nasal cavity. The most common organisms in a series from Greece were Gram-positive cocci (*Staph. hemoliticus*, *S. warneri*, *S. cohnii*, *S. epidermidis*, and *Strep. pneumonia*) and Gram-negative bacilli (*E. coli*, *Klebsiella pneumonia*, *Acinetobacter anitratus*)[8].

Treatment

1. also see *CSF Fistula, Treatment* on page 303
2. antibiotics: appropriate antibiotics are selected based on CSF penetration and organism sensitivities (adapted to the pathogens common in the

patient's locale; in the above series, all Gram-negative strains appeared resistant to ampicillin and third-generation cephalosporins, but were sensitive to imipenem and ciprofloxacin; Gram-positive strains were all sensitive to vancomycin). For empiric antibiotics *see page 343*

3. surgical treatment vs. "conservative treatment": controversial. Some feel that any case of posttraumatic CSF rhinorrhea should be explored[10, 11], and that cases of spontaneous cessation often represent obscuration by incarcerated brain, so-called "sham healing" with the potential for later CSF leak and/or meningitis[9]. Others support the notion that cessation (possibly with the assistance of lumbar spinal drainage) is acceptable
4. continue antibiotics for 1 week after CSF is sterilized. If rhinorrhea persists at this time, surgical repair is recommended

16.2.3. Recurrent meningitis

Patients with recurrent meningitis must be evaluated for the presence of abnormal communication with the intraspinal/intracranial compartment. Etiologies include dermal sinus (either spinal or cranial, *see page 252*), CSF fistula (*see page 300*), or neurenteric cyst (*see page 227*).

16.2.4. Antibiotics for specific organisms in meningitis

Route is IV unless specified otherwise.

- *S. pneumoniae*: PCN G (2nd choice: chloramphenicol)
- *N. meningitidis*: PCN G (2nd choice: chloramphenicol)
- *H. influenza*:
  - A. non-penicillinase producing: ampicillin
  - B. penicillinase producing: chloramphenicol
- Group B strep: ampicillin
- *L. monocytogenes*: ampicillin
- *S. aureus*
  - A. initially before sensitivities known, or if MRSA or multiply resistant strains or resistant coagulase negative *S. aureus* prevalent or suspected: vancomycin + PO rifampin + PO trimethoprim
  - B. once it is known that the staph is not MRSA:
    1. infant (< 7 d): methicillin

2. all others: nafcillin
3. PCN allergy: vancomycin or (cefazolin via both IV + IT)

- aerobic Gram negative rods (GNR)
  A. ceftriaxone, or cefotaxime, or moxalactam (in order of preference, make alterations based on sensitivities)
  B. if aminoglycoside required, intraventricular therapy is indicated after the newborn period
- *P. aeruginosa*
  A. ceftazidime (Fortaz®) alone if not life threatening
  OR
  B. more serious infections require 2 agents (aminoglycoside gives more rapid kill, and may be used initially for 3 days and then stopped if sensitivities to ceftazidime are acceptable): ceftazidime + APAG + IT gentamicin 4 mg q 12 hrs (give via intraventricular route if **ventriculitis** is present)
  OR
  C. for overwhelming infection:
  ceftazidime + tobramicin + ticarcillin
- *candida spp.*
  A. premedicate with the following prior to amphotericin infusion:
    1. IV bolus of NS (e.g. 500 ml) 2 hrs prior to amphotericin infusion to maintain renal blood flow
    2. Demerol 50 mg IV q 1 hr during amphotericin therapy PRN for rigors
    3. acetaminophen 650 mg po or per-NG 30 minutes prior to amphotericin infusion
  B. amphotericin B deoxycholate (not the lipid form) 1 mg/kg IV over 4-6 hr, hold for hypotension (e.g. SBP < 90 mm Hg), cannot be given through peripheral IV because of phlebitis (central line or PICC line needed)
  C. 5-fluorocytosine (5-FC) 25 mg/kg po or per-NG q 6 hrs

16.3. Shunt infection

Risk of early infection after shunt surgery: reported range is 3-20% per procedure (typically ≈ 7%).

Acceptable infection rate[12]: < 5-7% (although many published series have a rate near 20%[13], possibly due to different patient population).

Risk factors for shunt infection

Many factors have been blamed. Some that seem to be better documented include:

1. young age of patient[13]: in myelomeningocele **(MM)** patients, waiting until the child is 2 weeks old may significantly lower the infection rate
2. length of procedure
3. open neural tube defect

Morbidity of shunt infections in children

Children with shunt infections have a increased mortality rate and risk of seizure than those without shunt infection. Those with myelomeningocele who develop ventriculitis after shunting have a lower IQ compared to those without infection[14]. Mortality ranges from 10-15%.

Pathogens

Over 50% of staph infections occur within 2 weeks post-shunt, 70% within 2 mos. Source is often the patient's own skin[12]. It is estimated that in ≈ 3% of operations for shunt insertion the CSF is already infected (therefore culture CSF during insertion).

Early infection

Most commonly:

1. *Staph. epidermidis* (coagulase-negative staph): 60-75% of infections (most common)
2. *S. aureus*
3. Gram-negative bacilli **(GNB)**: 6-20% (may come from intestinal perforation)

In neonates *E. coli* and *Strep. hemoliticus* dominate.

Late infection (> 6 months after procedure)

Risk: 2.7-31% per patient (typically 6%). Almost all *S. epidermidis*. Tends to

be internal type. 3.5% of patients account for 27% of infections[15].

"Late" shunt infections may be due to:

1. an indolent infection due to *Staph. epidermidis*
2. seeding of a vascular shunt during episode of septicemia (probably very rare)
3. colonization from an episode of meningitis

Candida spp. infections

Candida spp. are responsible for the majority of fungal ventricular shunt infections. Usually occurs in children < 1 year age. Incidence: 1-7%[16]. The 4th leading pathogen causing meningitis in neurosurgical patients in 1 study[17], possibly related to the use of prophylactic antibiotics used for ICP monitoring and CSF drainage. Higher incidence in VP shunt patients with abdominal infections and shunts placed in patients with previous bacterial meningitis[18]. CSF typically shows: elevated WBCs and protein, normal glucose. Management recommendations:

1. completely remove the contaminated shunt (may be more important than with bacterial infections)
2. place a fresh external ventricular drain (if patient is shunt dependent)
3. treat with antifungal therapy: *see page 345*
4. place a fresh shunt after ≥ 5-7 days of therapy and clinical response is apparent
5. continue antifungal agents for 6-8 weeks

Presentation

Non-specific syndrome: fever, N/V, lethargy, anorexia, irritability; may mimic acute abdomen. May also present as malfunction; 29% of patients presenting with shunt malfunction had positive cultures. In neonates may manifest as apneic episodes, anemia, hepatosplenomegaly, and stiff neck[19]. *S. epidermidis* infections tend to be indolent (smoldering). GNB infections usually cause more severe illness; abdominal findings more common; main clinical manifestation is fever, usually intermittent and low grade. Erythema and tenderness along shunt tubing occurs occasionally.

Shunt nephritis[20]: may occur with chronic low level infection of a ventriculovascular shunt causing immune complex deposition in renal glomeruli, characterized by proteinuria and hematuria.

Blood tests

WBC: < 10K in one fourth of shunt infections. It is > 20K in one third.

ESR: rarely normal in shunt infections.

Blood cultures: positive in less than one third of cases.

CSF: WBC is usually not > 100 cells/mm^3. Gram stains may be positive ≈ 50% (yield with *S. epidermidis* is much lower). Protein is often elevated, glucose may be low or normal. Rapid antigen tests used for community acquired meningitis are usually not helpful for the organisms that tend to cause shunt infections. CSF cultures are negative in 40% of cases (higher culture yield if CSF WBC count is > 20K).

EVALUATION OF SHUNT FOR INFECTION

1. history and physical directed at determining presence of above signs and symptoms with emphasis on
   A. history suggestive of infection at another site
      1. exposure to others with viral syndromes, including sick siblings
      2. GI source (e.g. acute gastroenteritis). Often associated with diarrhea. Diarrhea is a symptom that usually exonerates shunt infection
      3. otitis media (check tympanic membranes)
      4. tonsillitis/pharyngitis
      5. appendicitis (peritoneal inflammation may impede VP shunt outflow)
      6. URI
      7. UTI
      8. pneumonia
   B. physical exam to R/O meningismus (stiff neck, photophobia…)
2. serum WBC count with differential
3. shunt tap: should be done in cases of suspected shunt infection. Shave and prep carefully to avoid introducing infection. GNB requires different therapy and has higher morbidity than staph, thus it is desirable to identify these rare patients: > 90% of these had positive Gram-stained CSF smear (only a few Gram-positive infections have positive results). GNB have higher protein and lower glucose, and neutrophils predominate in differential (unpublished data[12])
4. CT: usually not helpful for diagnosing infection. Ependymal enhancement when it occurs is diagnostic of **ventriculitis**. CT may demonstrate shunt

malfunction
5. abdominal U/S or CT: abdominal pseudocyst is suggestive of infection
6. ✖ LP: usually NOT recommended. May be hazardous in obstructive hydrocephalus **(HCP)** with a nonfunctioning shunt. Often does not yield the pathogen

TREATMENT

Antibiotics alone (without removal of shunt hardware)

Although eradication of shunt infections without removal of hardware has been reported[21 (p 595-7), 22], this has a lower success rate than with shunt removal[23], may require protracted treatment (up to 45 days in some), risks problems associated with draining infected CSF into the peritoneum (reduced CSF absorption, abdominal signs/symptoms including tenderness to full-blown peritonitis[21 (p 235)]) or vascular system (shunt nephritis (*see page 346*), sepsis…), and often requires at least partial shunt revision at some point in most cases. Treatment with antibiotics without shunt removal is therefore recommended only in cases where the patient: is terminally ill, is a poor anesthetic risk, or has slit ventricles that might be difficult to catheterize.

Removal of shunt hardware

In most instances, during the initial treatment with antibiotics the shunt is either externalized (i.e. tubing is diverted at some point distal to the ventricular catheter and connected to a closed drainage system), or sometimes the entire shunt may be removed. In the latter case, some means of CSF drainage must be provided in shunt dependent cases; either by insertion of an external ventricular drain **(EVD)**, or by intermittent ventricular taps or LPs (with communicating HCP). EVD allows easy monitoring of CSF flow, control of ICP, and repeated sampling for WBC determinations and cultures. In symptomatic patients or those with a positive CSF culture[24], any hardware removed should be cultured as only ≈ 8% are sterile in shunt infections. Skin organisms are fastidious and may take several days to grow.

If there is an abdominal pseudocyst, the fluid should be drained through the perito-neal catheter before removing it.

Empiric antibiotics

1. IV vancomycin used initially (penetration into CSF results in concentrations 18% that of serum).
2. PO rifampin may be added for increased coverage (10 mg/kg/day PO q 12 hrs)
3. when cultures return, change vancomycin to IV nafcillin unless patient is PCN allergic or cultures show MRSA (good penetration of inflamed meninges, lower toxicity than methicillin). If bactericidal activity is < 1:8, again consider adding rifampin
4. intraventricular injection of preservative-free antibiotics may be used in addition to IV therapy, clamp EVD x 30 minutes after injection

Treatment for specific organisms

Positive cultures from shunt hardware removed at the time of shunt revision in the absence of clinical symptoms or a positive CSF culture may be due to contamination and do not require treatment[24].

1. *S. aureus* and *S. epidermidis*
   A. if sensitive (MIC ≤ 1.0 μg/ml): IT gent + (IV nafcillin, or cefazolin, or cephalothin, or cephapirin)
   B. if resistant to nafcillin (i.e. MRSA), cephalothin, or cephapirin: PO rifampin + PO trimethoprim + IV & IT vancomycin
2. Enterococcus: IV/IT ampicillin + IT gent (if intravascular shunt: add IV gent)
3. other streptococci: either antistreptococcal or above enterococcal regimen
4. aerobic GNR: base on susceptibilities; both beta-lactam & APAG IV & IT indicated
5. *Serratia marcescens*: a rare cause of VP shunt infection[25] but the high morbidity may warrant aggressive antibiotic (IV + IT) and surgical therapy
6. *Corynebacterium spp.* & *Proprionibacterium spp.* (diphtheroids)
   A. if PCN sensitive: use enterococcal regimen above
   B. if PCN resistant: IV + IT vancomycin
7. *Candida spp.*: *see* page 346 for protocol, *see* page 345 for drugs

Intrathecal (IT) therapy

Yogev[12] cautions against high levels (caused neurologic effects in rabbits), he suggests striving for CSF concentrations comparable to peak blood values (e.g. 10-12 μg/ml for gent, or 25-30 μg/ml for amikacin).

Subsequent management

Once the CSF is sterile **x** 3 days, convert the EVD to a shunt (if an EVD was not used, it is still recommended that the shunt be replace with new hardware). Continue antibiotics an additional **10-14** days.

MANAGING VENTRICULOPERITONEAL SHUNTS IN PATIENTS WITH PERITONITIS

Peritonitis may occur as a result of:

1. perforation of a viscus (sometimes as a result of penetration by the peritoneal catheter tip[26], more common with obsolete Raimondi wire-reinforced tubing)
2. spontaneous bacterial peritonitis **(SBP)**: absence of an identifiable intraabdominal source. Most commonly diagnosed in patients with cirrhotic ascites[27]
3. or as a result of seeding through a VP shunt in a patient with a shunt infection: predominantly gram-positive, cutaneous organisms[28]

Concerns following en episode of peritonitis in a patient with VP shunt:

1. ascending infection into the CNS: uncommon, especially in the acute setting while on appropriate antibiotics with shunts containing a 1-way valve (as most do). CSF grows predominantly mixed, gram-negative intestinal flora[28]
2. contamination of the distal shunt: prevents permanent eradication of infection (appendicitis in the absence of peritonitis does not produce shunt infection[28])
3. shunt malfunction due to distal shunt obstruction: often as a result of walling off of the catheter tip, usually by omentum in reaction to the infection

Management recommendations following an episode of peritonitis (many viable options):

1. immediate appropriate treatment of peritonitis, usually managed by general surgeon (e.g. for ruptured appendix: appendectomy and appropriate antibiotics), with initial attempt to address shunt not being

mandatory

2. anecdotally, cases have been managed successfully by cleaning off the peritoneal catheter with bacitracin solution, and then wrapping the catheter in a bacitracin soaked lap sponge until the time to close the abdomen
3. if the peritonitis was diffuse or if the shunt catheter is believed to have been contaminated, an option is to externalize the distal catheter, preferably once the patient has stabilized from the peritonitis (afebrile, stable vital signs, normal WBC)
   A. externalization is done in a manner to avoid pulling contaminated catheter up towards hopefully sterile portions of the shunt. This can be accomplished by reopening the skin incision used for inserting the peritoneal catheter, and making a second incision over the shunt tubing, well above this entry point. The catheter is then divided at the upper incision. The catheter is grasped at the lower incision and is pulled, extracting both ends (the peritoneal end and the end just cut). The remaining catheter coming from above is connected to an external drainage system
   B. CSF cultures are monitored daily
   C. if 3 consecutive cultures are negative, a new distal catheter may be implanted
   D. if cultures continuously grow organisms, then the shunt may be contaminated and should then be replaced with an entirely new shunt system
   E. when it is time to replace the shunt, some authors[29, 30] recommend using an alternative site other than the peritoneum, but this is not mandatory[28]

16.4. Wound infections

16.4.1. Laminectomy wound infection

Occurs in 0.9-5% of cases[31]. May range from superficial to severe dehiscent wound infection. The risk is increased with age, long term steroid use, obesity, and possibly DM. Intraoperative mild hypothermia (as commonly occurs in the operating room) may also increase the risk of wound infection (as demonstrated

with colorectal resection[32]). Most are caused by *S. aureus*.

Management

1. culture the wound and/or any purulent drainage
2. start the patient empirically on vancomycin plus a third generation cephalosporin (e.g. ceftazidime)
3. modify antibiotics appropriately when culture and sensitivity results available
4. debride wound of all necrotic and devascularized tissue and any visible suture material (foreign bodies). Superficial wounds may be debrided in the office or treatment room, deep infections must be done in OR
5. shallow defects may be allowed to heal by secondary intention, and the following is one possible regimen
   A. pack the wound defect with 1/4” Iodophor® gauze
   B. dressing changes at least BID (for hospitalized patients, change q 8 hrs), remove and trim ≈ 0.5-1” of packing with each dressing change
      1. while wound is purulent, utilize 1/2 strength Betadine® wet to dry dressings
      2. when purulence subsides, switch to normal saline wet to dry
   C. antibiotics, may be useful as an adjunct to wound treatment initially, switch to oral antibiotics as early as possible, a duration of 10-14 days total is probably adequate if local wound care is being done
6. some prefer to close wound by primary intention[33], it is critical that there be no tension on the wound for healing to occur. Some close over an irrigation system or antibiotic beads. Retention sutures may be helpful[34]
7. with large defects or when bone and/or dura becomes exposed, the use of a muscle flap (often performed by a plastic surgeon) is probably required[31]
8. CSF leakage requires exploration in the OR with watertight dural closure to prevent meningitis

16.4.2. Craniotomy infection

Also, *see page 343* under meningitis, post-neurosurgical procedure.

C-reactive protein

Following uncomplicated craniotomy for microsurgery for brain tumors, C-

reactive protein (CRP) peaked on post-op day **(POD)** 2 with a mean value of 32 ± 38 mg/l[35]. Values declined from POD 3 through 5, reaching a mean of 6.7 ± 11 on POD 5. These values may be lower than with most post-op infections.

16.5. Osteomyelitis of the skull

The skull is normally very resistant to osteomyelitis, and hematogenous infection is rare. Most infections are due to contiguous spread (usually from an infected air sinus, occasionally from scalp abscess) or to penetrating trauma (including surgery and fetal scalp monitors[36]). With longstanding infection, edema and swelling in the area may become visible (usually over the forehead, but also may occur over the mastoids), and is called "**Pott puffy tumor**".

Staphylococcus is the most common organism, with *S. aureus* predominating, followed by *S. epidermidis*. In neonates, *E. coli* may be the infecting organism.

Imaging findings may include: bony resorption, periosteal reaction, contrast enhancement.

Treatment

Antibiotics alone are rarely curative. Treatment is usually surgical debridement of infected skull, biting off infected bone with rongeurs until a normal snapping sound replaces the more muted sound made by rongeuring infected bone. In the case of an infected craniotomy bone flap, the flap usually must be removed and the edges of the skull rongeured back to healthy bone. Closure of the scalp without cranioplasty is performed.

Surgery is followed by at least 6-12 weeks of antibiotics[37], usually IV for the first 1-2 weeks, then orally for the remainder. Until MRSA is ruled out, vancomycin + a 3rd generation cephalosporin are used. Once MRSA is ruled out, vancomycin may be changed to a penicillinase resistant synthetic penicillin (e.g. nafcillin). Most treatment failures occurred in patients treated with < 4 weeks of antibiotics following surgery.

Cranioplasty may be performed ≈ 6 mos post-op if there are no signs of infection,

16.6. Cerebral abscess

Key concepts:

- may arise from hematogenous spread, contiguous spread, or direct trauma
- risk factors: pulmonary abscess or AV fistulas, congenital cyanotic heart disease, immune compromise, chronic sinusitis/otitis, dental procedures
- symptoms are similar to any other mass lesions but tend to progress rapidly
- peripheral WBC may be normal or slightly ↑, CRP usually ↑
- organisms: Streptococcus is most common, up to 60% are polymicrobial
- imaging: usually round with thin enhancing ring on CT or MRI. T2WI → high signal lesion with thin rim of low intensity surrounded by hi signal (edema). Unlike with tumor, DWI often shows core of restricted diffusion (not reliable)
- treatment: IV antibiotics, needle drainage for some, excision infrequently (for fungal and resistant abscess)

Epidemiology

Approximately 1500-2500 cases per year in the U.S. Incidence is higher in developing countries. Male:female ratio is 1.5-3:1.

Risk factors

Risk factors include: pulmonary abnormalities (infection, AV-fistulas…, *see below*), congenital cyanotic heart disease (*see below*), bacterial endocarditis, penetrating head trauma (*see below*), chronic sinusitis or otitis media, and AIDS.

Vectors

Prior to 1980, the most common source of cerebral abscess was from contiguous spread. Now, hematogenous dissemination is the most common vector. In 10-60% no source can be identified[38].

Hematogenous spread

Abscesses arising by this means are multiple in 10-50% of cases[39]. No source can be found in up to 25% of cases. The chest is the most common origin:

- in adults: lung abscess (the most common), bronchiectasis and empyema
- in children: **congenital cyanotic heart disease (CCHD)** (estimated risk of abscess is 4-7%), especially tetralogy of Fallot. The increased Hct and low

PO_2 provides an hypoxic environment suitable for abscess proliferation. Those with rightto-left (veno-atrial) shunts additionally lose the filtering effects of the lungs (the brain seems to be a preferential target for these infections over other organs). Streptococcal oral flora is frequent, and may follow dental procedures. Coexisting coagulation defects often further complicate management[40]

- pulmonary arteriovenous fistulas: ≈ 50% of these patients have **Osler-Weber-Rendu syndrome** (AKA hereditary hemorrhagic telangiectasia), and in up to 5% of these patients a cerebral abscess will eventually develop
- bacterial endocarditis: only rarely gives rise to brain abscess[41]. More likely to be associated with acute endocarditis than with subacute form
- dental abscess
- GI infections: pelvic infections may gain access to the brain via Batson's plexus

In patients with septic embolization, the risk of cerebral abscess formation is elevated in areas of previous infarction or ischemia[42].

Contiguous spread

1. from purulent sinusitis: spreads by local osteomyelitis or by phlebitis of emissary veins. Virtually always singular. Rare in infants because they lack aerated para-nasal and mastoid air cells. This route has become less common due to improved treatment of sinus disease
   A. middle-ear and mastoid air sinus infections → temporal lobe and cerebellar abscess. The risk of developing a cerebral abscess in an adult with active chronic otitis media is ≈ 1/10,000 per year[43] (this risk appears low, but in a 30 year-old with active chronic otitis media the lifetime risk becomes ≈ 1 in 200)
   B. ethmoidal and frontal sinusitis → frontal lobe abscess
   C. sphenoid sinusitis: the least common location for sinusitis, but with a high incidence of intracranial complications due to venous extension to the adjacent cavernous sinus → temporal lobe
2. odontogenic → frontal lobe. Rare. Associated with a dental procedure in the past 4 weeks in most cases[44]. May also spread hematogenously

Following penetrating cranial trauma or neurosurgical procedure

Post-neurosurgical: especially with traversal of an air sinus. The risk of

abscess formation following civilian gunshot wounds to the brain is probably very low with the use of prophylactic antibiotics, except in cases with CSF leak not repaired surgically following traversal of an air sinus. An abscess following penetrating trauma cannot be treated by simple aspiration as with other abscesses, open surgical debridement to remove foreign matter and devitalized tissue is required. Abscess has been reported following use of intracranial pressure monitors and halo traction[45].

PATHOGENS

1. cultures from cerebral abscesses are sterile in up to 25% of cases
2. organisms recovered varies with the primary source of infection
3. in general: Streptococcus is the most frequent organism, 33-50% are anaerobic or microaerophilic. Multiple organisms may be cultured to varying degrees, usually in only 10-30% of cases, but can approach 60%[38], and usually includes anaerobes (Bacteroides sp. common)
4. when secondary to fronto-ethmoidal sinusitis: *Strep. milleri* and *Strep. anginosus* may be seen
5. from otitis media, mastoiditis, or lung abscess: usually multiple organisms, including anaerobic strep., Bacteroides, Enterobacteriaceae (Proteus)
6. post traumatic: usually due to *S. aureus* or Enterobacteriaceae
7. odontogenic (dental) source: may be associated with Actinomyces
8. following neurosurgical procedures: *Staph. epidermidis* and *aureus* may be seen
9. immunocompromised hosts including transplant patients (both bone marrow and solid organ) and AIDS: fungal infections are more common than otherwise would be seen. Organisms include:
   A. *Toxoplasma gondii*: *see page 365* and *page 367*
   B. *Nocardia asteroides*: *see page 356*
   C. *Candida albicans*
   D. *Listeria monocytogenes*
   E. mycobacterium
   F. *Aspergillus fumigatus* often from a primary pulmonary infection
10. infants: Gram negatives are common because IgM antibodies don’t cross placenta

PRESENTATION

Symptoms: none are specific for abscess, and many are due to edema

surrounding the lesion. Most are due to increased ICP (H/A, N/V, lethargy). Hemiparesis and seizures develop in 30-50% of cases. Papilledema is rare before 2 yrs of age. Symptoms tend to progress more rapidly than with neoplasms.

Newborns: patent sutures and poor ability of infant brain to ward off infection → cranial enlargement. Common: seizures, meningitis, irritability, increasing OFC, and failure to thrive. Some authors say most newborns with abscess are afebrile. Tend not to do well.

EVALUATION

BLOODWORK

Peripheral WBC: may be normal or only mildly elevated in 60-70% of cases (usually > 10,000).

Blood cultures: should be obtained when abscess is suspected, usually negative.

ESR: may be normal (especially in congenital cyanotic heart disease where polycythemia lowers the ESR).

C-reactive protein **(CRP)**: infection anywhere in body (including brain abscess and dental abscess) can raise the CRP level. May also be elevated in noninfectious inflammatory conditions and brain tumor. Sensitivity for abscess is ≈ 90%, specificity is ≈ 77%[46]. For normal values *see page 387*.

LUMBAR PUNCTURE (LP)

The role of LP is very dubious in abscess. Although LP is abnormal in > 90%, there is no characteristic finding diagnostic of abscess. The OP is usually increased, and the WBC count and protein may be elevated. The offending organism can rarely be identified from CSF obtained by LP (unless abscess ruptures into ventricles) with positive cultures in ≈ 6-22%[47]. There is a risk of transtentorial herniation, especially with large lesions (*see page 203* for discussion).

Σ ✖ Due to the risk involved and the low yield of useful information, avoid LP if not already done.

BRAIN IMAGING

CT: ring enhancing. Sensitivity ≈ 100%. For CT staging of abscess *see below*.

MRI: *see Table 16-2* for findings. Enhanced T1WI → thin-walled ring enhancement surrounding low intensity central region (*Figure 35-1*, page 1214).

Fluid-fluid levels may be seen. Occasionally gas producing organisms may cause pneumocephalus.

Diffusion MRI: DWI → bright, ADC → dark (restricted diffusion suggesting viscous fluid)[48] (see *Figure 35-1*, page 1214). Unlike most tumors which are dark on DWI (see *Figure 35-2*, page 1214). More reliable with pyogenic abscess, less reliable e.g. with fungal[49] or TB abscess).

MR-spectroscopy: amino acids and acetate or lactate are diagnostic for abscess.

Leukocyte scan with ^{99m}Tc-HMPAO: patient's own WBCs are tagged and reinjected. Close to 100% sensitivity and specificity (sensitivity will be reduced if patient is treated with steroids within 48 hrs prior to the scan)[46].

ADDITIONAL EVALUATION

CXR and chest CT (if indicated) to look for pulmonary source.

Cardiac echo (Doppler and/or echo with agitated saline injection (bubble study)): for suspected hematogenous spread, to look for patent foramen ovale or cardiac vegetations.

STAGING OF CEREBRAL ABSCESS

Table 16-1 shows the four well recognized histologic stages of cerebral abscess, and correlates this with the resistance to insertion of an aspirating needle at the time of surgery. It takes at least 2 weeks to progress through this maturation process, and steroids tend to prolong it.

Table 16-1 Histologic staging of cerebral abscess

Stage	**Histologic characteristics** (days shown are general estimates)	**Resistance to aspirating needle**
1	**early cerebritis**: (days 1-3) early infection & inflammation, poorly demarcated from surrounding brain, toxic changes in neurons, perivascular infiltrates	intermediate resistance
2	**late cerebritis**: (days 4-9) reticular matrix (collagen precursor) & developing necrotic center	no resistance
3	**early capsule**: (days 10-13) neovascularity, necrotic center, reticular network surrounds (less well developed along side facing ventricles)	no resistance
4	**late capsule**: (> day 14) collagen capsule*, necrotic center, gliosis around capsule	firm resistance, "pop" on entering

* abscess is ≈ the only process in the brain that leaves a collagen scar, all other scars are glial scars

CT staging

Late cerebritis (stage 2) has similar features to early capsule (stage 3) on routine contrast and non-contrast CT. There is some therapeutic importance in differentiating these two stages; the following aids in distinguishing[50]:

- cerebritis: tends to be more ill-defined
  A. ring-enhancement: usually appears by late cerebritis stage, usually thick
  B. further diffusion of contrast into central lumen, and/or lack of decay of enhancement on delayed scan 30-60 min after contrast infusion
- capsule:
  A. faint rim present on pre-contrast CT (necrotic center with edematous sur-rounding brain cause collagen capsule to be seen)
  B. thin ring enhancement AND delayed scans → decay of enhancement

NB: Thin ring enhancement but lack of delayed decay correlates better with cerebritis

NB: Steroids reduce degree of contrast enhancement (especially in cerebritis)

MRI staging

Table 16-2 shows MRI findings in cerebral abscess. In the cerebritis stage, the margins are ill defined.

Table 16-2 MRI findings with cerebral abscess

Stage	T1WI	T2WI
cerebritis	hypointense	hi signal
capsular	lesion center → low signal, capsule → mildly hyperintense, perilesional edema → low signal	center → iso- or hyperintense, capsule → dark (collagen), perilesional edema → hi signal

TREATMENT

"There is no single best method for treating a brain abscess." Treatment usually involves surgical drainage or excision, correction of the primary source, and long-term use of antibiotics (often IV **x** 6-8 weeks followed by oral route **x** 4-8 weeks).

SURGICAL VS. PURE MEDICAL MANAGEMENT

In a patient with suspected cerebral abscess, tissue should be obtained in almost every case to confirm diagnosis and to identify pathogens (preferably

before antibiotics).

Medical treatment

In general, surgical drainage or excision is employed in the treatment. Purely medical treatment of early abscess (cerebritis stage)[51], is controversial. NB: pathogens were cultured from well encapsulated abscesses despite adequate levels of appropriate antibiotics in 6 patients who failed medical therapy[52]. Failure may be due to poor blood supply and acidic conditions within the abscess (which may inactivate antibiotics in spite of concentrations exceeding the MIC).

Medical therapy alone is more successful if:

1. treatment begun in cerebritis stage (before complete encapsulation), even though many of these lesions subsequently go on to become encapsulated
2. small lesions: diameter of abscesses successfully treated with antibiotics alone were 0.8-2.5 cm (1.7 mean). Those that failed were 2-6 cm (4.2 mean). ★ **3 cm** is suggested as a cutoff[53], above this surgery should be included
3. duration of symptoms ≤ 2 wks (correlates with cerebritis stage)
4. patients show definite clinical improvement within the first week

Medical management alone considered if:

1. poor surgical candidate (NB: with local anesthesia, stereotactic biopsy can be done in almost any patient with normal blood clotting)
2. multiple abscesses, especially if small
3. abscess in poorly accessible location: e.g. brain stem[54]
4. concomitant meningitis/ependymitis

Surgical treatment

Indications for initial surgical treatment include:

1. significant mass effect exerted by lesion (on CT or MRI)
2. difficulty in diagnosis (especially in adults)
3. proximity to ventricle: indicates likelihood of intraventricular rupture which is associated with poor outcome[40, 55]
4. evidence of significantly increased intracranial pressure
5. poor neurologic condition (patients responds only to pain, or does not even response to pain)
6. traumatic abscess associated with foreign material

7. fungal abscess
8. multiloculated abscess
9. follow-up CT/MRI scans cannot be obtained every 1-2 weeks

Surgical intervention in patient being treated medically:

Intervention if neurological deterioration, progression of abscess towards ventricles, or after 2 wks if the abscess is enlarged. Also considered if no decrease in size by 4 wks.

SPECIFIC MANAGEMENT

- obtain blood cultures (rarely helpful)
- initiate antibiotic therapy (preferably after biopsy specimen obtained), regardless of which mode of treatment (medical vs. surgical) is chosen (*see below*)
- LP: avoid in most cases of cerebral abscess (*see page 352*)
- anticonvulsants: indicated for seizures, prophylactic use is optional
- steroids: controversial. Reduces edema, but may impede therapy (*see below*)

ANTIBIOTICS

1. initial antibiotics of choice (when pathogen unknown, and especially if *S. aureus* suspected), make appropriate changes as sensitivities become available. If there is no history of trauma or neurosurgical procedure, then the risk of MRSA is low:
   - vancomycin: covers MRSA. Adult: 1 gm IV q 12 hr. Peds: 15 mg/kg q 8 hr. Check peak & trough levels and adjust dose accordingly

   PLUS
   - a 3rd generation cephalosporin (e.g. cefotaxime (Claforan®))

   PLUS
   - one of the following
     - ◆ metronidazole (Flagyl®). Adult: 30 mg/kg/d total usually IV (divided q 12 hrs or q 6 hrs, not to exceed 4 gm/d). Peds: 10 mg/kg IV q 8 hrs

     OR
     - ◆ chloramphenicol. Adult: 1 gm IV q 6 hr. Peds: 15-25 mg/kg IV q 6 hr OR
     - ◆ for post-traumatic abscess, use PO rifampin 9 mg/kg/d as 1 dose
2. if culture shows no staph (as is usual in non-traumatic abscess), change

nafcillin to PCN G (high dose): adult: 5 M units IV q 6 hr; peds: 50,000-75,000 units/kg IV q 6 hr
3. if culture shows only strep, may use PCN G (high dose) alone
4. if cultures show staph that is not MRSA and the patient is not allergic to penicillin or nafcillin, substitute nafcillin for the vancomycin. Adult: 2 gm IV q 4 hrs. Peds: 25 mg/kg IV q 6 hrs
5. *Cryptococcus neoformans, Aspergillus sp., Candida sp.*:
   A. amphotericin B: 0.5-1 mg/kg/day. Abelcet® (amphotericin B lipid complex) 5 mg/kg/d should be used when renal function is compromised
   B. or liposomal amphotericin B: 3 mg/kg/day, increase to 15 mg/kg/d
6. in AIDS patients: *Toxoplasma gondii* is a common pathogen, and initial empiric treatment with sulfadiazine + pyrimethamine is often used (*see page 366*)

Duration of antibiotics

IV antibiotics for 6-8 wks (most commonly 6), may then D/C even if the CT abnormalities persist (neovascularity remains). NB: CT improvement may lag behind clinical improvement. Duration of treatment may be reduced if abscess and capsule entirely excised surgically. Oral antibiotics may be used following IV course. 5-20% of abscesses recur within 6 weeks of discontinuing antibiotics.

Steroids

Reduces edema, Decreases likelihood of fibrous encapsulation of abscess. May reduce penetration of antibiotics into abscess 53. Immune suppression may also be deleterious. ★ Reserved for patients with clinical and imaging evidence of deterioration from marked mass effect, and duration of therapy should be minimized.

Follow-up imaging

If therapy is successful, imaging should show decrease in:
1. degree of ring enhancement
2. edema
3. mass effect
4. size of lesion: takes 1 to 4 wks (2.5 mean). 95% of lesions that will resolve with antibiotics alone decrease in size by 1 month

SURGICAL TREATMENT

Current options[56]:

1. needle aspiration: the mainstay of surgical treatment. Especially well-suited for multiple or deep lesions (*see below*)
2. surgical excision: prevents recidivism. Shortens length of time on antibiotics. Recommended in traumatic abscess to debride foreign material (especially bone), and in fungal abscess because of relative antibiotic resistance (*see below*)
3. external drainage: controversial. Not frequently used
4. instillation of antibiotics directly into the abscess: has not been extremely efficacious, although it may be used as for refractory *Aspergillus* abscesses

NEEDLE ASPIRATION

If necessary, may be performed under local anesthesia. May be combined with irrigation with antibiotics or normal saline. Needs to be repeated in up to 70% of cases. May be the only surgical intervention required, but sometimes must be followed with excision (especially with multiloculated abscess). Stereotactic drainage may be ideal for deep lesions[57].

Performed through a trajectory chosen to:

1. minimize the path length through the brain
2. avoid traversing the ventricles or vital neural or vascular structures
3. avoid traversing infected structures outside the intracranial compartment (infected bone, paranasal sinuses, and scalp wounds)
4. in cases of multiples abscesses, target[39]:
    A. the largest lesion or the one causing the most symptoms
    B. once the diagnosis of abscess is confirmed
        1. any lesion ≥ 2.5 cm diameter
        2. lesions causing significant mass effect
        3. enlarging lesions

Cultures

Send aspirated material for the following:

1. stains
    A. Gram stain
    B. acid-fast stain (AFB stain) for Mycobacterium
    C. modified acid-fast stain (for Nocardia, *see below*) looking for

branching acid fast bacillus

D. special fungal stains (e.g., methenamine silver, mucicarmine)

2. culture

A. routine cultures: aerobic and anaerobic

B. fungal culture: this is not only helpful for identifying fungal infections, but since these cultures are kept for longer period and any growth that occurs will be further characterized, fastidious or indolent bacterial organisms may sometimes be identified

C. TB culture

EXCISION

Can only be performed during the "chronic" phase (late capsule stage). Abscess is removed as any well encapsulated tumor. The length of time on antibiotics can be shortened to ≈ 3 days in some cases following total excision of an accessible, mature abscess (e.g. located in pole of brain). Recommended for abscesses associated with foreign body and most *Nocardia* abscesses (*see below*). May also be needed necessary for: fungal abscess, multiloculated or resistant lesions.

Table 16-3 Outcomes with cerebral abscess

mortality (CT era data)[39, 58]	0-10%
neurologic disability	45%
late focal or generalized seizures	27%
hemiparesis	29%

OUTCOME

In the pre-CT era, mortality ranged form 40-60%. With improvement in antibiotics, surgery, and the improved ability to diagnose and follow response with CT/MRI, mortality rate has been reduced to ≈ 10%, but morbidity remains high with permanent neurologic deficit or seizures in up to 50% of cases. Current outcomes are shown in *Table 16-3*. A worse prognosis is associated with poor neurologic function, intraventricular rupture of abscess, and almost 100% mortality with fungal abscesses in transplant recipients.

16.6.1. Some unusual organisms producing abscess

Nocardia

Nocardiosis is caused primarily by *Nocardia asteroides* (other Nocardia species such as *N. brasiliensis* are less common), a soil-born aerobic actinomycete (a bacteria, not a fungus) that is usually inoculated through the respiratory tract and produces a localized or disseminated infection. Hematogenous spread frequently results in cutaneous lesions and CNS involvement. Nocardia is responsible for 2% of all brain abscesses, the majority of these are *N. asteroides*.

Nocardiosis occurs primarily in patients with chronic debilitating illnesses including:

1. neoplasms: leukemia, lymphoma…
2. conditions requiring long-term corticosteroid treatment
3. Cushing's disease
4. Paget's disease of bone
5. AIDS
6. renal or cardiac organ transplant recipients

The diagnosis is suspected in high-risk patients presenting with soft-tissue abscesses and CNS lesions. CNS involvement occurs in about one-third and includes:

1. cerebral abscess: often multiloculated
2. meningitis
3. ventriculitis in patients with CSF shunt[59]
4. epidural spinal cord compression from vertebral osteomyelitis[60]

Diagnosis

Brain biopsy may not be needed in high-risk patients with confirmed nocardia infection in other sites[59], except possibly in AIDS patients where the risk of multiple organism infections or infection plus tumor (particularly lymphoma) is considerable.

Treatment

As for most abscesses, very small ones may be treated medically, lesions up to about 3 cm may undergo needle aspiration first, and larger lesions or those that grow despite medical therapy may require excision followed by antibiotics.

Medical treatment: Primary choice is trimethoprim-sulfamethoxazole **(TMP-SMZ)**.

Rx: start with 15 mg/kg/d of TMP & 75 mg/kg/d of SMZ IV or PO divided in 2-4 doses. After 3-4 weeks, decrease to 10 mg/kg/d TMP in 2-4 doses PO. Check serum levels.

Alternatives: imipenem + amikacin. Also possibly effective: linezolid[61].

Duration: because of risks of relapse or hematogenous spread, treatment is recommended for 3 months in immunocompetent hosts and 6 months for immunocompromised.

16.7. Subdural empyema

Referred to as subdural abscess prior to 194362. Subdural empyema **(SDE)** is a suppurative infection that forms in the subdural space, which has no anatomic barrier to spread[63] Antibiotic penetration into this space is poor. Distinguished from abscess which forms within brain substance, surrounded by tissue reaction with fibrin and collagen capsule formation. Hence, SDE tends to be more emergent.

SDE may be complicated by cerebral abscess (seen in 20-25% of imaging studies), cortical venous thrombosis with risk of venous infarction, or localized cerebritis.

Epidemiology

Less common than cerebral abscess (ratio of abscess:empyema is ≈ 5:1). Found in 32 cases in 10,000 autopsies. Male:female ratio is 3:1.

Location: 70-80% are over the convexity, 10-20% are parafalcine.

Etiologies

See *Table 16-4*. Most often occurs as a result of direct extension of local infection (rarely following septicemia). Spread of the infection to the intracranial compartment may occur through the valveless diploic veins, often with associated thrombophlebitis[66].

Chronic otitis media was the leading cause of SDE in the preantibiotic era, but has now been surpassed by paranasal sinus disease especially with frontal sinus involvement[64] (may also follow mastoid sinusitis). SDE is a rare but sometimes fatal complication of cranial traction devices[64, 67]. Infection of

preexisting subdural hematomas (both treated and un-treated, in infants and adults) have been reported[64].

Trauma includes compound skull fractures and penetrating injuries. Other etiologies include: osteomyelitis, pneumonia, unrelated infection in diabetics.

Table 16-4 Etiologies of SDE

Location	%
paranasal sinusitis (especially frontal)*	67-75
otitis (usually chronic otitis media)†	14
post surgical (neuro or ENT)	4
trauma	3
meningitis (more common in peds[65])	2
congenital heart disease	2
misc. (including pulmonary suppuration)	4
undetermined	3

* more common in adults

† no cases from otitis in a recent series[64]

Presentation

Neurologic findings are shown in *Table 16-5*. Symptoms are due to mass effect, inflammatory involvement of the brain and meninges, and thrombophlebitis of cerebral veins and/or venous sinuses. SDE should be suspected in the presence of meningismus + unilateral hemisphere dysfunction. Marked tenderness to percussion or pressure over affected air sinuses is common[63]. Forehead or eye swelling (from emissary vein thrombosis) may occur.

Focal neurologic deficit and/or seizures usually occur late.

Table 16-5 Findings on presentation with SDE*

Finding	%
fever	95
H/A	86
meningismus (nuchal rigidity…)	83
hemiparesis	80

altered mental status	76
seizures	44
sinus tenderness, swelling or inflammation	42
nausea and/or vomiting	27
homonymous hemianopsia	18
speech difficulty	17
papilledema	9

* from a review of multiple articles[64]

Evaluation

- **CT**: IV contrast is usually helpful. CT may miss some cases (related to early generation scanners, failure to give IV contrast, poor scan quality…). If normal, repeat the CT at a later time or do an MRI if clinical suspicion persists. Findings: hypodense (but denser than CSF) crescentic or lenticular extracerebral lesion with dense enhancement of medial membrane; inward displacement of gray-white interface; ventricular distortion and effacement of basal cisterns are common findings[68]
- **MRI**: low signal on T1WI, high signal on T2WI. Pial ependymal line: a non-specific MRI finding in CNS infection
- **LP**: ✖ potentially hazardous (risk of herniation). Organisms are usually present only in cases originating from meningitis. If no meningitis: moderate sterile pleocytosis (150-600 WBC/mm^3) with PMNs predominating; glucose normal; opening pressure is usually high[63]; protein is usually elevated (range: 75-150 mg/dl)

Table 16-6 Organisms in adult cases of SDE associated with sinusitis

aerobic streptococcus	30-50%
staphylococci	15-20%
microaerophilic and anaerobic strep	15-25%
aerobic Gram-negative rods	5-10%
other anaerobes	5-10%

Table 16-7 Organisms in SDE in childhood (age < 5 years)

Organisms are similar to meningitis for the same age group. Antibiotics choice is the same as for meningitis

ORGANISMS

The causative organism varies with the specific source of the infection. SDE associated with sinusitis is often caused by aerobic and anaerobic streptococci (*see Table 16-6*). Following trauma or neurosurgical procedures, staphylococci and Gram-negative species predominate. Sterile cultures occur in up to 40%. For SDE in peds, *see Table 16-7*.

TREATMENT

1. surgical drainage: indicated in most cases (nonsurgical management has been reported[69], but should only be considered with minimal neurologic involvement, limited extension and mass effect of SDE, and early favorable response to antibiotics) usually done relatively emergently

- early in the course, the pus tends to be more fluid and may be more amenable to burr hole drainage; later, loculations develop which may necessitate craniotomy
- there has been controversy over the optimal surgical treatment. Early studies indicated a better outcome with craniotomy. Recent studies show less difference
    A. critically ill patients with localized SDE may be candidates for burr-hole drainage (usually inadequate if loculations are present). Repeat procedures may be needed, and up to 20% will later require a craniotomy
    B. craniotomy: to debride and, if possible, drain. A wide craniotomy is often required because of septations. The dura appears white because of pus underneath. Open and wash out subdural space. Do not try to remove material adherent to cortex (may cause infarction)

2. antibiotics: similar to treatment for cerebral abscess
    - initially: a penicillin and a third-generation cephalosporin (e.g. cefotaxime)
    - metronidazole is added if there is a high suspicion of anaerobes
    - for post-op SDE: substitute vancomycin for PCN (switch vancomycin to a PCN if there is no staphylococcus)
    - modify antibiotics based on culture results
    - duration: usually 4-6 weeks

- anticonvulsants: usually used prophylactically, mandatory if seizures occur

OUTCOME

See *Table 16-8*. Neurologic deficits were present in 55% of patients at the time of discharge[64]. Age ≥ 60 years, obtundation or coma at presentation, and SDE related to surgery or trauma carry a worse prognosis[64]. Burr-hole drainage may be associated with a worse outcome than with craniotomy, but this may have been influenced by the poorer condition of these patients. Fatal cases may have associated venous infarction of the brain.

Table 16-8 Outcome with SDE

persistent seizures	34%
residual hemiparesis	17%
mortality	10-20%

16.8. Viral encephalitis

Encephalitides that come to the attention of the neurosurgeon usually cause imaging findings that may mimic mass lesions. Biopsy is helpful in some instances, and shunting for hydrocephalus may occasionally be needed. Those covered in this book:

1. herpes simplex encephalitis: *see below*
2. multifocal herpes varicella-zoster virus leukoencephalitis: *see page 360*
3. progressive multifocal leukoencephalopathy **(PML)**: *see page 364*

16.8.1. Herpes simplex encephalitis

Key concepts:

- a hemorrhagic viral encephalitis with a predilection for temporal lobes
- definitive diagnosis requires brain biopsy
- optimal treatment: early administration of IV acyclovir

Herpes simplex encephalitis **(HSE)** AKA multifocal necrotizing encephalomyelitis, is caused by the herpes simplex virus **(HSV)** type I. It produces an acute, often (but not always) hemorrhagic, necrotizing encephalitis with edema. There is a predilection for the temporal and orbitofrontal lobes and limbic system.

EPIDEMIOLOGY[70]

Estimated incidence of HSE: 1 in 750,000 to 1 million persons/yr. Equally distributed between male and females, in all races, in all ages (over 33% of cases occur in children 6 mos to 18 yrs), throughout the year.

PRESENTATION

Patients are often confused and disoriented at onset, and progress to coma within days. Adult presentations are shown in *Table 16-9*, and for pediatrics in *Table 16-10*. Other symptoms include headache.

Table 16-9 Adult presentation

altered consciousness	97%
fever	90%
seizures (usually focal onset)	67%
personality changes	71%
hemiparesis	33%

Table 16-10 Presentation in age < 10 yrs

irritability	altered mentation
malaise	seizure
disorientation	dysphasia
hemiparesis	fever
papilledema (except in age ≤ 2 yrs)	

DIAGNOSTIC STUDIES

Diagnosis can often be made on the basis of history, CSF, and MRI. Treatment should be instituted rapidly without waiting for biopsy, before the onset of coma.

1. **CSF:** leukocytosis (mostly monos), RBCs 500-1000/mm^3, (NB: 3% have no pleocytosis), protein rises markedly as disease progresses. HSV antibodies may appear in the CSF but takes at least ≈ 14 days and is thus not useful for early diagnosis
2. **EEG:** periodic lateralizing epileptiform discharges **(PLEDs)** (triphasic high-voltage discharges every few seconds) usually from the temporal

lobe. EEG may vary rapidly over few days (unusual in conditions mimicking HSE)

3. **CT:** edema predominantly localized in temporal lobes (poorer prognosis once hemorrhagic lesions visible). In one review, 38% of initial CTs were normal[71] (many were on early generation CT scanners or were done within 3 days of onset). Hemorrhages were apparent in only 12% of the initially abnormal CTs
4. **MRI:** more sensitive than CT[72], demonstrates edema as high signal on T2WI, primarily within the temporal lobe, with some extension across sylvian fissure ("transsylvian sign")[71], especially suggestive of HSE if bilateral. Differentiate from MCA infarct (which may also span sylvian fissure) by typical arterial distribution of the latter. Enhancement doesn't occur until the 2nd week
5. **technetium brain scan:** process localized to temporal lobes
6. **brain biopsy:** false negatives may occur[73]
   A. **indications:** reserved for questionable cases. May not be necessary in patients with fever, encephalopathy, compatible CSF findings, focal neuro findings (focal seizure, hemiparesis, or cranial nerve palsy), and supporting evidence of at least one of the following: focal EEG, CT, MRI or technetium brain scan abnormality
   B. should be performed within ≤ 48 hrs of starting acyclovir (otherwise false negatives may occur)
   C. anterior inferior temporal lobe is preferred site
      1. the side chosen for biopsy is the one showing maximal involvement based on clinical information (e.g. localizing seizures), EEG and/or imaging studies[74]
      2. 10 **x** 10 **x** 5 mm deep specimen obtained from anterior portion of the inferior temporal gyrus with NO COAGULATION on specimen side (cut surface with #11 blade, then cauterize pial surface on <u>non</u>-specimen side)
      3. 2nd specimen obtained from beneath surface specimen with fenestrated pituitary biopsy forceps
   D. virus isolation is the most specific (100%) and sensitive (96-97%) test for HSE. Other findings (less accurate): perivascular cuffing, lymphocytic infiltration, hemorrhagic necrosis, neuronophagia, intranuclear inclusions (present in 50%)
   E. if electron microscopy (EM) or immunohistofluorescence is available,

70% may be diagnosed within ≈ 3 hrs of biopsy

F. biopsy tissue handling

1. avoid macerating specimens for histology
2. tissue for EM: placed in glutaraldehyde
3. tissue for permanent histology: placed in formalin
4. tissue for culture:
   a. handling: specimen is placed in sterile specimen container and sent directly to virology lab. If lab is closed, tissue may be:
      i. placed in regular refrigerator for up to 24 hrs
      ii. placed in –70° C freezer for indefinite time (virus remains viable for up to 5 yrs)
      iii. DO NOT place in regular freezer (destroys virus)
   b. cultures generally take at least 1 week to become positive
   c. cultures checked for 3 weeks before being declared negative

G. biopsy results: of 432 brain biopsies meeting the above criteria, 45% had HSE, 22% had identifiable but non HSE pathology (e.g. vascular disease, other viral infection, adrenal leukodystrophy, bacterial infection…), and 33% remained without a diagnosis[75]

TREATMENT

General supportive measures: to control elevated ICP from edema, includes: elevate HOB, mannitol, hyperventilation (dexamethasone unproven efficacy) (also see *Treatment measures for elevated ICP*, page 876). Phenytoin is used for seizure prophylaxis.

Antiviral medications

Ganciclovir is gaining favor over acyclovir.

acyclovir (Zovirax®) **DRUG INFO**

***Rx* Adult**: 30 mg/kg/day, in divided q 8 hr doses in minimum volume of 100 ml IV fluid over 1 hr (caution: this fluid load may be hazardous, especially since cerebral edema is already usually problematic) for 14-21 days (some relapses have been reported after only 10 days of treatment).

***Rx* Children** > 6 mos age: 500 mg/m^2 IV q 8 hrs **x** 10 days.

***Rx* Neonatal**: 10 mg/kg IV q 8 hrs for 10 days.

vidarabine (Vira-A®) **DRUG INFO**

Outcome

Six month mortality following treatment with acyclovir was influenced by:

- age (6% under age 30, 36% over age 30)
- Glasgow coma score **(GCS)** at time of treatment initiation (25% for GCS ≤ 10, 0% for GCS > 10)
- duration of disease before therapy (0% for initiating therapy within 4 days, 35% if after 4 days)

16.8.2. Multifocal varicella-zoster leukoencephalitis

Caused by the herpes varicella-zoster virus **(VZV)** which is responsible for varicella (chickenpox), herpes zoster **(HZ)** (shingles), and post-herpetic neuralgia (*see* *page 564*). VZV is a herpesvirus that is distinct from the *herpes simplex virus*.

Symptomatic zoster-related encephalitis occurs in < 5% of immunocompromised patients (including AIDS patients) with cutaneous zoster[76]. It typically follows cutaneous HZ by a short time (average: 9 days) although cases have been reported where many months have lapsed[77].

Manifestations include: altered level of consciousness, headache, photophobia, meningismus. Although focal neurologic deficits may occur, these are uncommon.

MRI may show multiple, discrete, round and oval lesions with minimal edema (best seen on T2WI) and minimal enhancement.

Unlike herpes simplex virus, VZV is difficult to isolate in culture. On brain biopsy, look for multiple discrete lesions within grey and white matter, with Cowdry type A intranuclear inclusion bodies in oligodendrocytes, astrocytes, and neurons, and a positive direct fluorescent antibody test directed against VZV.

There is a case report of VZV encephalitis treated with IV acyclovir[76].

16.9. Creutzfeldt-Jakob disease

Key concepts

- an invariably fatal encephalopathy characterized by rapidly progressive dementia, ataxia and myoclonus
- death usually occurs within 1 yr of onset of symptoms
- 3 forms: 1) transmissible (possibly via prions), 2) autosomal dominant inherited, 3) sporadic
- characteristic EEG finding: bilateral sharp wave (0.5-2 per second)
- pathology: status spongiosus without inflammatory response

Creutzfeldt-Jakob disease **(CJD)** is one of 4 known rare human diseases associated with transmissible spongiform encephalopathy agents, also called prions (proteinaceous infectious particles). Although sometimes also referred to as a "slow virus", these agents contain no nucleic acids and are also resistant to processes that inactivate conventional viruses (*see Table 16-12*). Prions do not provoke an immune response. The protease-resistant protein associated with disease is designated PrP^{res} or PrP^{Sc}, and is an isoform of a naturally occurring protease-sensitive protein designated PrP^{sen} or PrP^{C}.

Annual incidence of CJD: 0.5-1.5 per million population[78]. Over 200 people die of CJD in the U.S. each year. CJD occurs in 3 forms: transmissible, inherited and sporadic.

Acquired prion diseases: Natural route of infection is unknown and virulence appears low, with lack of significant dissemination by respiratory, enteric, or sexual contact. There is no increased incidence in spouses (only a single conjugal pair of cases has been verified), physicians or laboratory workers. There is no evidence of transplacental transmission. The only known cases of horizontal transmission of CJD have occurred iatrogenically (*see below*). Kuru has been transmitted via handling and ingestion of infected brains in ritualistic funereal cannibalism practiced among the Fore (pronounced: "foreay") linguistic group in the eastern highlands of Papua, New Guinea[79], a practice which was generally abandoned in the 1950's. Kuru is a subacute, uniformly fatal disease involving cerebellar degeneration (the word "kuru" means "to tremble" in the local language[80 (p 6)]).

Most noniatrogenically transmitted cases of CJD occur in patients > 50 yrs old, and is rare in age < 30. The incubation period can range from months to decades. The onset of symptoms following direct inoculation is usually faster (common range: 16-28 mos), but still may be much longer (up to 30 years with corneal transplant[81], and 4-21 yrs with hGH transmission).

Inherited CJD: 5-15% of cases of CJD occur in an autosomal dominant inheritance pattern with abnormalities in the amyloid gene[82] on chromosome 20 with a penetrance of 0.5683. Since familial CJD is dominantly inherited, analysis for the PrP gene is not indicated unless there is a history of dementia in a first degree relative.

Sporadic CJD: In ≈ 90% of cases of CJD, no infectious or familial source can be identified[82], and these cases are considered sporadic. 80% occur in persons 50-70 yrs old[78]. Sporadic cases show no abnormality in the PrP gene.

New variant CJD: Cases of atypical CJD are well-recognized. A new variant of CJD **(vCJD)** was identified in 10 cases of unusually young individuals (median age at death: 29 yrs) during 1994-95 in the United Kingdom[84], and has been strongly linked to the 1980s epidemic of bovine spongiform encephalopathy **(BSE)**, dubbed "mad cow" disease by the lay press. None of the vCJD patients had periodic spikes on EEG characteristic of classic CJD, the clinical course was atypical (having prominent psychiatric symptoms and early cerebellar ataxia, some-what similar to kuru), and brain plaques showed unusual features also reminiscent of amyloid plaques seen in kuru. A comparison of vCJD to sporadic CJD is shown in *Table 16-11*.

Table 16-11 Comparison of vCJD to sporadic CJD[78]

Characteristic	vCJD	sporadic
mean age at onset (yr)	29	60
mean duration of disease (mo)	14	5
most consistent and prominent early signs	psychiatric abnormalities, sensory symptoms	dementia, myoclonus
cerebellar signs (%)	100	40
periodic complexes on EEG (%)	0	94
pathological changes	diffuse amyloid plaques	sparse plaques in 5-10%

Iatrogenic transmission of CJD

Described only in cases of direct contact with infected organs, tissues or surgical instruments. Has been reported with: corneal transplants[81, 87], intracerebral EEG electrodes sterilized with 70% alcohol and formaldehyde

vapor after use on a CJD patient[88], operations in neurosurgical O.R.s after procedures on CJD patients, in recipients of pituitary-derived[A] human growth hormone **(hGH)**[89], and dural graft with cadaveric dura mater (Lyodura®). Recommended sterilization procedures for suspected CJD tissues and contaminated materials appear in *Table 16-12*.

A. there is no longer a risk of CJD with growth hormone in the U.S. since distribution of pituitary derived hGH was halted in 1985 and current hGH is obtained from recombinant DNA technology

Pathology

The typical form of CJD produces the classic histologic triad of neuronal loss, astrocytic proliferation, and cytoplasmic vacuoles in neurons and astrocytes (**status spongiosus**), all in the absence of an inflammatory response. There is a predilection for cerebral cortex and basal ganglia, but all parts of the CNS may be involved. In 5-10% of cases, these changes are accompanied by the deposition of amyloid plaques. Immunostaining for PrP^{res} is definitive.

Table 16-12 Operating room sterilization procedures for CJD[85]

• Fully effective (recommended) procedures A. steam autoclaving for 1 hr at 132°C, or B. immersion in 1N sodium hydroxide (NaOH) for 1 hr at room temperature
• Partially effective procedures A. steam autoclaving at either 121° C or 132° C for 15-30 mins, or B. immersion in 1N NaOH for 15 mins, or lower concentrations (< 0.5N) for 1 hr at room temp, or C. immersion in sodium hypochlorite (household bleach) undiluted or up to 1:10 dilution (0.5%) for 1 hr[86]
• ✖ Ineffective procedures: boiling, UV or ionizing radiation, ethylene oxide, ethanol, formalin, beta-propiolactone, detergents, quaternary ammonium compounds, Lysol®, alcoholic iodine, acetone, potassium permanganate, routine autoclaving

Presentation

One third initially express vague feelings of fatigue, sleep disorders, or reduced appetite. Another third have neurologic symptoms including memory loss, confusion, or uncharacteristic behavior. The last third have focal signs including cerebellar ataxia, aphasia, visual deficits (including cortical blindness), or hemiparesis.

The typical course is inexorable, progression of dementia, often noticeably worse week by week, with subsequent rapid development of pyramidal tract findings (limb weakness and stiffness, pathologic reflexes), and late

extrapyramidal findings (tremor, rigidity, dysarthria, bradykinesia) and myoclonus (often stimulus triggered). Clinical signs of sporadic CJD are shown in *Table 16-13*.

Supranuclear gaze palsy is an occasional finding, also usually late[83]. In early stages, CJD may resemble Alzheimer's disease **(SDAT)**. 10% of cases present as ataxia without dementia or myoclonus. Cases with pre-dominant spinal cord findings may be initially mistaken for ALS.

Myoclonus subsides in the terminal phases, and akinetic mutism ensues.

Table 16-13 Major clinical signs in sporadic CJD[78]

Sign	Freq (%)
cognitive deficits*	100
myoclonus	> 80
pyramidal tract signs	> 50
cerebellar signs	> 50
extrapyramidal signs	> 50
cortical visual deficits	> 20
abnormal extraocular movements	> 20
lower motor-neuron signs	< 20
vestibular dysfunction	< 20
seizures	< 20
sensory deficits	< 20
autonomic abnormalities	< 20

* dementia, psychiatric and behavioral abnormalities

Diagnosis

The complete "diagnostic triad" (dementia, myoclonus and periodic EEG activity) may be absent in up to 25% of cases. Diagnostic criteria have been published[90] as shown in *Table 16-14*. No patients in their series with a diagnosis other than CJD fulfilled the criteria for clinically definite CJD. The most common condition other than CJD fulfilling the criteria for clinically probable CJD was SDAT (especially difficult to distinguish in the early stages). There is a *CSF* immunoassay for the 14-3-3 brain protein (*see below*).

Differential diagnosis

CSF examination to exclude infections such as tertiary syphilis or SSPE is recommended. Toxicity from bismuth, bromides and lithium must be ruledout. Myoclonus is usually more prominent early in toxic/metabolic disorders than in CJD, and seizures in CJD are usually late[78].

Table 16-14 Diagnostic criteria* of CJD[90]

• **Pathologically confirmed** (with unequivocal spongiform changes) A. clinically: requires brain biopsy (*see text*) B. found at autopsy					
Clinical criteria	Mental deterio-ration	Myo-clo-nus	1-2 Hz pe-riodic EEG complexes	Any move-ment disorder or periodic EEG activity	Duration of illness (months)
clinically definite	+	+	+		< 12
clinically probable	+	+ OR	+		< 18
clinically possible	+			+	< 24

* in patients with normal metabolic status and spinal fluid. If there are early cerebellar or visual symptoms and then muscular rigidity, or if another family member has died of pathologically verified CJD, then upgrade the degree of certainty to the next higher category

Diagnostic tests

- **imaging**: no characteristic CT or MR finding. These studies are frequently normal, but are essential to rule-out other conditions (e.g. herpes-simplex encephalitis, recent stroke…). Diffuse atrophy may be present, especially late. MRI may show increased intensity on T2WI in areas typically involved (basal ganglion, striatum) in up to 79% of cases (retrospectively)[91]. This is nonspecific but may help differentiate CJD from SDAT[92]
- **blood tests**: serum assays for S-100 protein are so insensitive and nonspecific[93] that it can only be used as an diagnostic adjunct
- **CSF**:
    - A. routine labs: usually normal, although protein may occasionally be elevated
    - B. abnormal proteins:
        1. abnormal proteins (130 & 131) have been identified in the CSF of patients with CJD[94], but the assay is technically difficult
        2. proteins 130/131 were identified as the <u>normal</u> neuronal protein 14-3-3, and a relatively simple immunoassay for this was developed for use on as little as 50 µl of CSF[95]. Detection of the 14-3-3 protein in the CSF has 96% sensitivity and specificity for

CJD among patients with dementia. False positives may occur in other conditions involving extensive neuronal destruction including: acute CVA, herpes encephalitis, multi-infarct dementia, primary CNS lymphoma and rarely SDAT (most cases of SDAT test negative). Requires CSF (cannot be done on blood)

- **EEG**: characteristic finding of bilateral, symmetrical, periodic bi- or triphasic synchronous sharp-wave complexes, AKA **periodic spikes**, AKA pseudoperiodic sharp-wave complexes (0.5-2 per second) have ≈ 70% sensitivity and 86% specificity[96]. They resemble PLEDs (*see page 266*), but are responsive to noxious stimulus (may be absent in familial CJD[83] and in the recent UK variant (*see above*))
- **SPECT scan**: may be abnormal in vCJD even when EEG is normal[97], however the findings are not specific for vCJD
- **brain biopsy**: *see below*
- **tonsillar biopsy**: patients with variant CJD (vCJD) may have detectable levels of variant type 4 of the abnormal prion protein (PrPSc) in their lymphoreticular system, which may be accessed by a 1 cm wedge-biopsy of one palatine tonsil (using careful aseptic precautions)[98]

Brain biopsy

Due to lack of an effective treatment and the potential for iatrogenic infection in surgery, biopsy is reserved for cases where establishing the diagnosis is deemed important, or as part of a research study[74], or when diagnostic tests are equivocal and other potentially treatable etiologies are suspected.

Technique: to prevent aerosolization of the infectious agent, a manual saw is recommended over a power craniotome, and every effort should be made to avoid cutting the dura with the saw. Recommended decontamination procedures should be followed (*see Table 16-12 and references*). Specimens should be clearly labeled as being from suspected CJD patients to alert laboratory personnel to the hazard. Tissue should be fixed in a saturated 15% phenolized formalin (15 g of phenol per dl of 10% neutral buffered formalin with the undissolved phenol layering at the bottom of the solution)[99].

Treatment and prognosis

Given the lack of demonstrated infectivity (with tissues other than brain or CSF), isolation precautions such as gowns or masks are felt to be unnecessary[78].

There is no known treatment. The disease is rapidly progressive. Median survival is 5 months, and 80% of patients with sporadic CJD die within 1 year of diagnosis[78].

16.10. Neurologic manifestations of AIDS

TYPES OF NEUROLOGIC INVOLVEMENT

40-60% of all patients with acquired immunodeficiency syndrome **(AIDS)** will develop neurologic symptoms, with one third of these presenting initially with their neurologic complaint[100, 101]. Only ≈ 5% of patients that die with AIDS have a normal brain on autopsy. One study found the CNS complications of AIDS shown in *Table 16-15*.

The most common conditions producing focal CNS lesions in AIDS[103]:

1. toxoplasmosis
2. primary CNS lymphoma
3. progressive multifocal leukoencephalopathy **(PML)**
4. cryptococcal abscess

Manifestations of CNS toxoplasmosis

1. mass lesion (toxoplasmosis abscess): the most common lesion causing mass effect in AIDS patients (70-80% of cerebral mass lesions in AIDS[104]) (*see below* for CT/MRI findings)
2. meningoencephalitis
3. encephalopathy

CNS toxoplasmosis occurs late in the course of HIV infection, usually when CD4 counts are < 200 cells/mm^3.

Primary CNS lymphoma (PCNSL)

Occurs in ≈ 10% of patients with AIDS[105]. PCNSL is associated with the Epstein-Barr virus (*see page 673*).

Table 16-15 CNS complications of AIDS (320 patients[100])

Complication	%
viral syndromes	
subacute encephalitis*	17
atypical aseptic meningitis	6.5
herpes simplex encephalitis	2.8
★ progressive multifocal leukoencephalopathy **(PML)**	1.9†
viral myelitis	0.93
varicella zoster encephalitis	0.31
non-viral infections	
★ *Toxoplasma gondii*	> 32
Cryptococcus neoformans	13
Candida albicans	1.9
coccidiomycosis	0.31
Treponema pallidum	0.62
atypical *Mycobacteria*	1.9
Mycobacterium tuberculosis	0.31
Aspergillus fumigatus	0.31
bacteria (*E. coli*)	0.31
neoplasms	
★ primary CNS lymphoma	4.7
systemic lymphoma with CNS involvement	3.8
Kaposi's sarcoma (including brain mets)	0.93
CVA (stroke)	
infarct	1.6
intracerebral hemorrhage	1.2
miscellaneous/unknown	7.8

* CMV encephalitis occasionally occurs

† more recent estimate[102] of the incidence of PML in AIDS: 4%

Features of PML

1. caused by a ubiquitous polyomavirus (a subgroup of papova virus, small nonenveloped viruses with a closed circular double DNA-stranded

genome) called “JC virus[A]” **(JCV)**. 60-80% of adults have antibodies to JCV[106]

2. frequently manifests in patients with suppressed immune systems, including
   A. AIDS: currently the most common underlying disease associated with PML
   B. prior to AIDS, the most common associated diseases were chronic lymphocytic leukemia & lymphoma
   C. allograft recipients: due to immunosuppression[107]
   D. chronic steroid therapy
   E. PML also occurs with other malignancies, and with autoimmune disorders (e.g. SLE)
3. pathologic findings: focal myelin loss (demyelination, ∴ affects white matter) with sparing of axon cylinders, surrounded by enlarged astrocytes and bizarre oligodendroglial cells with eosinophilic intranuclear inclusion bodies. EM can detect the virus. Sometimes occurs in brainstem and cerebellum
4. clinical findings: mental status changes, blindness, aphasia, progressive cranial nerve, motor, or sensory deficits and ultimately coma. Seizures are rare
5. imaging findings: *see below*
6. clinical course: usually rapidly progressive to death within a few months, occasionally longer survival occurs inexplicably[108]. There is no effective treatment. Some promise initially with anti-retroviral therapy[109]
7. definitive diagnosis requires brain biopsy (sensitivity: 40-96%) although it is infrequently employed. JCV has been isolated from brain and urine. Polymerase chain reaction (PCR) of JCV DNA from CSF has been reported, and is specific but not sensitive for PML

A. named after the initials of the patient in whom it was first discovered, not to be confused with Jakob-Creutzfeldt (a prion disease) nor with Jamestown Canyon virus (also confusingly called JC virus, (a single-stranded RNA virus that occasionally causes *encephalitis* in humans)

Primary effects of AIDS infection

Neurologic involvement with infection with the Human Immunodeficiency Virus **(HIV)** (aside from opportunistic infection and tumors caused by the

immunodeficient state) includes:

1. **AIDS encephalopathy**: the most common neurologic involvement, occurs in ≈ 66% of patients with AIDS involving the CNS
2. AIDS dementia AKA HIV dementia complex
3. aseptic meningitis
4. cranial neuropathies: including "Bell's palsy" (occasionally bilateral)
5. AIDS related myelopathy: vacuolization of spinal cord (see *Myelopathy*, page 1185)
6. peripheral neuropathies

Neurosyphilis

1. AIDS patients can develop neurosyphilis as little as 4 mos from infection[110] (unlike the 15-20 yrs usually required in non-immunocompromised patients)
2. neurosyphilis can develop in spite of what would otherwise be adequate treatment for early syphilis with benzathine PCN[110, 111]
3. the CDC recommends treating patients having symptomatic or asymptomatic neurosyphilis for at least 10 days with probenecid 500 mg PO QID plus either aqueous crystalline PCN-G, 2-4-million units IV q 4 hrs (total of 12-24-million units/d), or aqueous procaine PCN-G 2.4-million units IM q d. This 10 day regimen should be followed by benzathine PCN 2.4-million units IM q week **x** 3 weeks. Benzathine PCN is NOT recommended initially[112]

Neuroradiologic findings in AIDS

A series of 200 consecutive AIDS patients[113] with neurologic symptoms followed to biopsy, autopsy, or for 2 yrs showed the following on initial CT:

- 81 patients (40%) had initially normal CT, only 5% of which went on to develop progression of neurologic abnormalities or developed CT abnormalities
- 75 patients (38%) showed only diffuse cerebral atrophy; 5 of these subsequently developed focal CT findings shown to be *Toxoplasma gondii* infection
- 44 patients (22%) had ≥ 1 focal lesion

See *Table 16-16* for a comparison of neuroradiologic findings in

toxoplasmosis, PCNSL and PML.

CT/MRI findings in toxoplasma abscess

1. most common findings: large area (low density on CT) with mild to moderate edema, ring enhancement with IV contrast in 68% compatible with abscess (of those that did not ring enhance, many showed hypodense areas with less mass effect with slight enhancement adjacent to lesion), well circumscribed margins[114]
2. most commonly located in basal ganglia, are also often subcortical
3. often multiple (typically > 5 lesions[115]) and bilateral
4. usually with little to moderate mass effect[103] (in BG, may compress third ventricle and sylvian aqueduct causing obstructive hydrocephalus)
5. most patients with toxoplasmosis had evidence of cerebral atrophy

Table 16-16 Comparison of neuroradiologic lesions in AIDS*

Feature	Toxo	PCNSL	PML
Multiplicity	usually > 5	multiple but < 5	may be multiple
Enhancement	ring	homogeneous	none
Location	basal ganglia and grey-white junction	subependymal	usually limited to white matter
Mass effect	mild-moderate	mild	none-minimal
Miscellaneous	lesions surrounded by edema	may extend across corpus callosum	high signal on T2WI, low on T1WI

* abbreviations: Toxo = toxoplasmosis, PCNSL = primary CNS lymphoma, PML = progressive multifocal leukoencephalopathy

CT/MRI findings in PML (*see Table 16-16*)

Note: the appearance of PML may differ in AIDS patients from non-AIDS patients.

1. CT: diffuse areas of low density. MRI: high intensity on T2WI
2. normally involves only white matter (spares cortex), however in AIDS patients gray matter involvement has been reported
3. no enhancement (on either CT or MRI), unlike most toxoplasmosis lesions
4. no mass effect
5. no edema
6. lesions may be solitary on 36% of CTs and on 13% of MRIs

7. borders are usually more ill-defined than in toxoplasmosis[114]

CT/MRI findings in primary CNS lymphoma (PCNSL) (*see Table 16-16*)

NB: the appearance of PCNSL may differ in AIDS patients from non-AIDS patients.

1. multiple lesions with mild mass effect and edema that tend to ring-enhance on CT, or appear as areas of hypointensity surrounding central area of high intensity (target lesion) targets onT2WI MRI (unlike non-AIDS cases which tend to enhance homogeneously[116])
2. there is a greater tendency to multicentricity in AIDS patients than in the nonimmunosuppressed population[117]

Imaging recommendations

MR with gadolinium is recommended as the initial screening procedure of choice for AIDS patients with CNS symptoms (lower false negative rate than CT[103]).

MANAGEMENT OF INTRACEREBRAL LESIONS

Neurosurgical consultation is often requested for biopsy in an AIDS patient with questionable lesion(s). The diagnostic dilemma is usually for low density lesions on CT, and in the United States is primarily between the following:

- toxoplasmosis: treated with pyrimethamine and sulfadiazine (*see below*)
- PML: no proven effective treatment (antiretroviral therapy may help[109])
- CNS lymphoma: usually treated with RTX (see *CNS lymphoma*, page 672)
- TB: tends to be unlikely except in Haitian population
- note: cryptococcus is more common than PML or lymphoma, but usually manifests as cryptococcal meningitis (and not as a ring enhancing lesion) (*see page 374*)

RECOMMENDATIONS

PML can usually be identified radiographically. However, radiographic imaging alone cannot reliably differentiate toxoplasmosis from lymphoma or from some other concurrent conditions (patients with toxoplasmosis may have other simultaneous diseases). Therefore, the following recommendations are

made:

1. obtain baseline toxoplasmosis titer on all known AIDS patients (NB: 50% of the general population have been infected by toxo and have positive titer by age 6 years, 80-90% will be positive by middle adulthood). The chances of toxo are higher with serum antibodies > 1:16115 (most are > 1:256)
2. multiple enhancing lesions with basal ganglion involvement in a patient whose toxo titer changes from negative to positive have a high probability of being toxo
3. primary CNS lymphoma **(PCNSL)**
   A. with <u>single</u> lesions, lymphoma is more likely than toxo
   B. if possibility of PCNSL is strong
      1. consider LP (contraindicated in presence of mass effect)
         a. high volume LP for cytology: PCNSL can be diagnosed in ≈ 10-25% of cases using ≈ 10 ml of CSF (*see page 674* for more details)
         b. or send CSF for polymerase chain reaction **(PCR)** amplification of viral DNA of Epstein-Barr virus or JC-virus[118] (the agents responsible for AIDS-related PCNSL and PML, respectively)
      2. some recommend early biopsy[A] to identify PCNSL cases to avoid delaying RTX for 3 weeks while assessing response to antibiotics[103]
4. in patient with possible toxoplasmosis (i.e. positive toxo titer and CT findings not atypical for toxo) even if other conditions have not been excluded:
   A. empirically start: pyrimethamine (Daraprim®) (200 mg loading dose, then 75-100 mg/d), sulfadiazine (75 mg/kg PO loading dose, then 25 mg/kg q 6 hrs), folic acid (5-40 mg/d, usually 10 mg with each dose of pyrimethamine)
   B. if sulfa allergy develops (which commonly occurs), change sulfadiazine to clindamicin 400-600 mg PO or 600 mg IV q 6 hrs
   C. alternatives for complete intolerance:
      1. spiramycin (Rovamycine®) 3-4 gms/d (peds: 50-100 mg/kg/d **x** 3-4 wks)
      2. atovaquone
   D. there should be a clinical and radiographic response within 2-3 weeks[119]

E. if response is good, reduce dosage after 6-12 weeks to 50% of the above doses and maintain for life

F. if these drugs are continued, it should be possible to maintain control for remainder of patient's life (cure is not generally possible)

G. if no response to therapy after 3 weeks (some recommend 7-10 days[120]), then consider biopsy[A]

5. perform biopsy in the following settings:

A. in patient with a negative toxo titer (note: patients occasionally have negative titer because of anergy)

B. accessible lesion(s) atypical for toxo (i.e. non-enhancing, sparing basal ganglia, periventricular location)

C. in the presence of extraneural infections or malignancies that may involve the CNS

D. lesion that could be either lymphoma or toxo (e.g. single lesion, *see 3. A.*)

E. in patients who have lesions not inconsistent with toxo but fail to respond to appropriate anti-toxo medications in the recommended time (*see above*)

F. the role of biopsy for <u>non-enhancing</u> lesions is less well defined as the diagnosis does not influence therapy (most are PML or biopsies are non-diagnostic), it may be useful only for prognostic purposes[120]

G. note: the risk of open biopsy in AIDS patients may be higher than nonimmunocompromised patients. Stereotactic biopsy may be especially well suited, with up to 96% efficacy, fairly low morbidity (major risk: significant hemorrhage, ≈ 8% incidence) and low mortality[121, 122]

6. stereotactic biopsy guidelines:

A. if multiple lesions are present, choose the most accessible lesion in the least eloquent brain area, or the lesion not responding to treatment

B. biopsy the center of non-enhancing lesions, or the enhancing portion of ring-enhancing lesions

C. recommended studies on biopsy: histology; immunoperoxidase stain for *Toxoplasma gondii*; stains for TB and fungus; culture for TB, fungi, pyogens

A. instead of biopsy, a few centers advocate empiric radiation treatment (for possible lymphoma)

PROGNOSIS

Patients with CNS toxo have a median survival of 446 days, which is similar to that with PML but longer than AIDS-related PCNSL[115]. Patients with CNS lymphoma in AIDS survive on average a shorter time than similarly treated CNS lymphoma in nonimmunosuppressed patients (3 months vs. 13.5 mos). Median survival is < 1 month with no treatment. CNS lymphoma in AIDS tends to occur late in the disease, and patients often die of unrelated causes (e.g. *Pneumocystis carinii* pneumonia)[120].

16.11. Lyme disease - neurologic manifestations

Lyme disease **(LD)** is a complex multisystem disease caused by various species of Borrelia spirochetes (in North America: *Borrelia burgdorferi*) transmitted to humans by the *Ixodes scapularis* or *pacificus* ticks (the American dog tick is not involved). It was first recognized in Lyme, Connecticut in 1975, and is now the most common arthropod-borne infection in the U.S.[123].

CLINICAL FINDINGS

There are 3 clinical stages which can overlap or occur separately.

Stage 1 (early localized disease, erythema migrans and flu-like illness)

Systemic signs of infection usually begin with a flu-like illness within days to weeks of infection, symptoms include: fever, chills, malaise, fatigue or lethargy, backache, headache, arthralgia, and myalgia. Regional or generalized lymphadenopathy may occur.

The hallmark of LD is **erythema chronicum migrans (ECM)** (classically a “bullseye rash”) which begins 3-30 days after the tick bite, and occurs in 60-75% of patients. ECM usually begins in the thigh, inguinal region, or axilla, and consists of an expanding macular rash with bright red borders and central clearing and induration that usually fades without scarring in 3-4 weeks. Within 30 days of the tick bite, spirochetes may be demonstrated in acellular spinal fluid.

Stage 2 (early disseminated disease)

Several weeks to months after infection, untreated patients develop more serious organ involvement. Cardiac and neurologic involvement may occur. Manifestations include:

1. cardiac: occurs in 8%. Conduction defects (usually A-V block, generally brief and mild) and myopericarditis
2. ocular: panophthalmitis, ischemic optic atrophy, and interstitial keratitis occur rarely
3. neurologic: occurs in 10-15% of patients with stage 2 disease
   A. the clinical triad of neurologic manifestations of Lyme disease is[124]:
      - cranial neuritis (especially that mimicking Bell's palsy: Lyme disease is the most common cause of bilateral "Bell's palsy" (facial diplegia) in endemic areas)
      - meningitis
      - radiculopathy

   B. other possible neurologic involvement includes: encephalitis, myelitis, peripheral neuritis

Neurologic findings are frequently migratory, and ≈ 60% of patients have multiple neurologic findings simultaneously. In Europe, **Bannwarth's syndrome** (chronic lymphocytic meningitis, peripheral neuropathy, and radiculopathy) is the most common manifestation, and primarily affects the peripheral nervous system[125]. Neurologic symptoms usually resolve gradually.

Stage 3 (late disease)

Arthritis and chronic neurologic syndromes may occur in this stage. Arthralgias are common in stage 1, but true *arthritis* usually does not begin for months to years after infection, and is seen in ≈ 60% of cases[126]. When arthritis occurs, it may affect the knee (89%), hip (9%), shoulder (9%), ankle (7%) and/or elbow (2%)[127]. Neurologic involvement includes[128]:

1. encephalopathy[A]
2. encephalomyelitis[A]
3. peripheral neuropathy[A]
4. ataxia
5. dementia
6. sleep disorder

7. neuropsychiatric disease and fatigue syndromes

A. these conditions are chronic, and their manifestation may be subtle

DIAGNOSIS

There is no test indicative of active infection. The spirochete is difficult to culture from infected humans. Diagnosis is easy if a history of travel to endemic areas, tick bite, and ECM are identified. *Table 16-17* shows the CDC criteria for diagnosis.

Serology

It takes 7-10 days from initial infection to develop antibodies to *B. burgdorferi*, but it takes ≈ 2-3 wks before antibodies can reliably be detected in un-treated patients (antibiotics can reduce the immune response)[130]. If the first serum test is negative, it should be repeated in 4-6 weeks if the clinical suspicion of LD is strong (seroconversion from negative to positive is supportive of *B. burgdorferi* infection). False positives can occur with other borrelial and treponemal infections (e.g. syphilis, however, VDRL test will differentiate the two).

Enzyme-linked immunosorbent assay **(ELISA)** detects IgM or IgG. Antibodies to *B. burgdorferi* is the usual test method. IgM is elevated acutely, and IgG gradually rises and is elevated in almost all patients at 4-6 weeks and is usually highest in patients with arthritis[123]. Western blot may help identify false-positive ELISA results (more sensitive and specific than ELISA, however, results may vary between labs). Amplification of *B. burgdorferi* DNA by polymerase chain reaction **(PCR)** yields a more very sensitive test that may have significant false positives, and can be positive even if the DNA is from dead organisms.

Table 16-17 CDC criteria for diagnosis of Lyme disease[129]

In endemic area: • erythema chronicum migrans **(ECM)** • antibody titer ≥ 1:256 by IFA* and involvement of ≥ 1 organ system†
In non-endemic area: • ECM with antibody titer ≥ 1:256 • ECM with involvement of ≥ 2 organ systems†

• antibody titer ≥ 1:256 by IFA* and involvement of ≥ 1 organ system

* IFA = immunofluorescence antibody

† either musculoskeletal, neurologic or cardiac

CSF

Elevated CSF IgG antibody titer to *B. burgdorferi* may occur with neurologic involvement[131]. CSF findings in late disease are usually compatible with aseptic meningitis. Oligoclonal bands and increased ratio of IgG to albumin may occur[132].

Treatment[128, 133, 134]

Antibiotic therapy is more effective early in the illness.

16.12. Parasitic infections of the CNS

Many parasitic infections may involve the central nervous system. Immunosuppression (including HIV) increases the susceptibility[135]. CNS parasitic infections include (those that potentially involve neurosurgical intervention have a dagger (†):

1. cysticercosis†: see *Neurocysticercosis* below
2. toxoplasmosis†: may occur as a congenital TORCH infection, or in the adult usually with AIDS (see *Neurologic manifestations of AIDS*, page 364). *Toxoplasma gondii* is an obligate intracellular protozoan that is ubiquitous but does not cause clinical infection except in immunocompromised hosts. Histologic features: necrosis containing 2-3 nm tachyzoites (cysts)
3. echinococcus†: *see page 373*
4. amebiasis†: ≈ exclusively *Naegleria fowleri* (*see page 375*)
5. schistosomiasis
6. malaria
7. African trypanosomiasis

† parasitic infections with a dagger are those that are more likely to come to neurosurgical attention

16.12.1. Neurocysticercosis

Key concepts:

- intracranial encystment of larva of *Taenia solium* (pork tapeworm)
- the most common parasitic infection of the CNS
- neurological symptoms: seizures or progressive intracranial hypertension
- occurs from ingesting the parasite's *eggs*, not from eating infested meat
- characteristic imaging finding: low density cysts with eccentric punctate high density (the scolex = tapeworm head). Hydrocephalus is common
- medical treatment: all patients get steroids. Start antihelmintic drugs (praziquantel or albendazole) when no signs of intracranial hypertension
- biopsy sometimes needed for diagnosis. Surgery: may be required for spinal, intraventricular or subarachnoid cysts (more refractory to medical therapy) or for giant cysts (> 50 mm) when intracranial hypertension persists despite steroids

Cysticercosis is the most common parasitic infection involving the CNS[136] and is the most common cause of acquired epilepsy in low-income countries[137]. It is caused by *Cysticercus cellulosae*, the larval stage of the pork tapeworm *Taenia solium*, which has a marked predilection for neural tissue. Cysticercosis is endemic in areas of Mexico, Eastern Europe, Asia, Central and South America, and Africa. The incidence of neurocysticercosis (encystment of larva in the brain) may reach 4% in some areas[138]. The incubation period varies from months to decades, but 83% of cases show symptoms within 7 years of exposure.

Life cycle of T. solium

There are 3 stages to the life cycle: larva, embryo (or oncosphere) and adult. *T. solium* can infect man in two different ways: as the adult worm or as the larva.

Infection with the adult worm (taeniasis - a parasitic infection)

Human intestinal tapeworm infection (taeniasis) results from eating undercooked infested (measly) pork. The encysted larvae are released in the small bowel and can then mature within the intestine into an adult over about 2 months. The scolex (head) of the segmented adult worm attaches by means of

four suckers and two rows of hooklets to the wall of the small intestine where the worm absorbs food directly through its cuticle. Man is the only known definitive host for the adult tapeworm, for which the GI tract is the sole habitat. Proglottids (mature segments, each containing reproductive organs) produce eggs which are liberally excreted along with gravid proglottid segments in the feces.

Infection with the larva

The disease cysticercosis occurs when animals or humans become an intermediate host for the *larval* stage by ingesting viable eggs produced by the proglottid. The most common routes of ingestion of viable eggs are:

1. food (usually vegetables) or water contaminated with human feces containing eggs or gravid proglottids (this is the means whereby pigs acquire the disease)
2. fecal-oral autoinoculation in an individual harboring the adult form of the tape-worm due to lack of good sanitary habits or facilities
3. autoinfection by reverse peristalsis of gravid proglottids from the intestine into the stomach (unproven theoretical possibility)

In the duodenum of man and pig, the shell of the ova dissolves and the thusly hatched embryos (oncospheres) burrow through the small bowel wall to enter the lymphatics or systemic circulation and gain access to:

- brain: involved in 60-92% of cases of cysticercosis. Latency from ingestion of eggs to *symptomatic* neurocysticercosis: 2-5 years[139]
- skeletal muscle
- eye: immunologically privileged, like brain
- subcutaneous tissue
- heart

Once in the tissue of the intermediary host, embryos develop a cyst wall in ≈ 2 months (immature cyst) which matures in ≈ 4 months to a larva. Larval cysts are usually rapidly eliminated by the immune system. Many larvae die naturally within 5-7 yrs or with cysticidal therapy producing an inflammatory reaction with collapse of the cyst (**granular nodular stage**), these sometimes calcify (nodular calcified stage). In pigs, the larva lie dormant in the muscle, “waiting” to be eaten after which the cycle repeats.

Types of neurologic involvement

Spinal cord and peripheral nerves involvement is rare.

Giant cysts: definition: cyst with diameter > 50 mm[140].

Two types of cysts tend to develop in the brain[141]:

1. **cysticercus cellulosae**: regular, round or oval thin-walled cyst, ranging in size from ≈ 3 to 20 mm tending to form in the parenchyma or narrow subarachnoid spaces. This cyst contains a scolex (head), is usually static, and produces only mild inflammation during the active phase
2. **cysticercus racemosus**: larger (4-12 cm), grows actively producing grape-like clusters in the basal subarachnoid spaces and produces intense inflammation. There are no larvae in these cysts. These cysts usually degenerate in 2-5 years, in which the capsule thickens and the clear cyst contents are replace by a whitish gel which undergoes calcium deposition with concomitant shrinkage of the cyst

Location of the cysts tends to fall into 1 of 4 groups:

1. meningeal: found in 27-56% of cases with neural involvement. Cysts are adherent or free-floating and are located either in:
   - dorsolateral subarachnoid space: usually C. cellulosae type, causing minimal symptoms
   - basal subarachnoid space: usually the expanding C. racemosus form producing arachnoiditis and fibrosis comprising a chronic meningitis with hypoglycorrhachia. Can obstruct foramina of Luschka and Magendie producing hydrocephalus, or can cause entrapment of basal cisterns → cranial neuropathies (including visual disturbance). Extremely high mortality with this form
2. parenchymal: found in 30-63%; focal or generalized seizures occurs in ≈ 50% of cases (up to 92% in some series)
3. ventricular: found in 12-18%, possibly gaining access via the choroid plexus. Pedunculated or free floating cysts occur, can block CSF flow and cause hydrocephalus with intermittent intracranial hypertension (Brun syndrome). There may be adjacent ependymal enhancement (ependymitis)
4. mixed lesions: found in ≈ 23%

Clinical

Presentation: seizures, signs of elevated ICP, focal deficits related to the location of the cyst, and altered mental status are the most common findings. Increased ICP may be due to hydrocephalus or to giant cysts. Symptoms may also be produced by the immunologic reaction to the infestation (cysticercotic

encephalitis). Cranial nerve palsies can occur with basal arachnoiditis. Subcutaneous nodules may sometimes be felt.

DIAGNOSIS

Diagnosis is usually made by imaging studies and confirmatory serologic tests.

LABORATORY EVALUATION

Mild peripheral eosinophilia can occur, but is inconsistent and thus unreliable.

CSF may be normal. Eosinophils are seen in 12-60% of cases and suggests parasitic infection. Protein may be elevated.

Stool: less than 33% of cases have *T. solium* ova in the stool.

Serology

Most centers use enzyme-linked immunoelectrotransfer blot **(EIBT)** against glycoprotein *antigens* (western blot) which is ≈ 100% specific and 98% sensitive[142], although sensitivity is less (70%) in cases with a solitary cyst[143]. May be used on serum or CSF. EIBT has effectively superseded ELISA where titer is considered significant at 1:64 in serum, and 1:8 in the CSF; checking for titer exceeding these thresholds in the serum produces a test that is more sensitive and in the CSF is more specific for cysticercosis. False negative rates are higher in cases without meningitis.

RADIOGRAPHIC EVALUATION

Soft-tissue x-rays may show calcifications in subcutaneous nodules, and in thigh and shoulder muscles.

Skull x-rays show calcifications in 13-15% of cases with neurocysticercosis. May be single or multiple. Usually circular or oval in shape.

CT

The following findings on brain CT have been described (modified[141, 144]):

1. ring enhancing cysts of various sizes representing living cysticerci. Little inflammatory response (edema) occurs as long as larva is alive. Characteristic finding: small (< 2.5 cm) low density cysts with eccentric punctate high density that may represent the scolex

2. low density with ring enhancement seen as an intermediate stage between living cyst and calcified remnant representing intermediate stage in granuloma formation. Resultant inflammatory reaction can cause edema, and basal arachnoiditis in cysts located in basal subarachnoid space. Often ring enhancing
3. intraparenchymal punctate calcifications (granuloma) sometimes with, but usually without surrounding enhancement, seen with dead parasites
4. hydrocephalus. Sometimes with intraventricular cysts which may be isointense with CSF on plain CT[145] and may require contrast CT ventriculography[146] or MRI to be demonstrated

MRI

Early findings: nonenhancing cystic structure(s) with eccentric T1WI hyperintensity (scolex) with no inflammatory response. Lesions may be seen in parenchyma, ventricle, and subarachnoid space. The cyst collapses in later stages of parasitic evolution, with initial edema that gradually resolves with time.

TREATMENT

Combination of:

1. antihelmintic medication: antiparasitic and/or cysticidal regimens
2. antiepileptics: to treat seizures, which may sometimes be medically refractory
3. steroids (*see below*)
4. surgery:
   A. surgical resection of lesions when appropriate
   B. ventricular CSF diversionary procedures

Steroids

Corticosteroids should be used in all patients. May temporarily relieve symptoms, and may help decrease edema that tends to occur initially during treatment with anti-helmintic drugs. If possible, start 2-3 d before antihelmintics (e.g. dexamethasone 8 mg q 8 hours[140]), on day 3 decrease to 4 mg q 8 hours, on day 6 change to prednisone 0.4 mg/kg per day divided TID. Taper steroids after antihelmintics are discontinued. In patients with symptoms of intracranial hypertension: antihelmintic treatment is started after symptoms subside (usually after 3 doses). ✖ Any cysticercocidal drug may cause irreversible damage when

used to treat ocular or spinal cysts, even with corticosteroid use.

Antiepileptics

Seizures usually respond to a single AED. However, the risk of seizures may be lifelong. Risk factors for recurrent seizures: calcified brain lesions, multiple seizures, multiple brain cysts[147].

Antihelmintic drugs

Praziquantel (Biltricide®) is an antihelmintic with activity against all known species of schistosomas. Several regimens have been published:

- 50 mg/kg/d divided in 3 doses (same dose for pediatrics) for 15 days (doses of 100 mg/kg/d have been recommended[140] because steroids reduce serum concentration by 50%[148]). Produces a significant reduction in symptoms and in number of cysts seen on CT[136]
- 10-100 mg/kg/d **x** 3-21 days
- high dose single day regimen: 25-30 mg/kg q 2 hrs **x** 3 doses
- for intestinal infestation: single oral dose of 5-10 mg/kg

Albendazole (Zentel®) 15 mg/kg per day divided in 2-3 doses, taken with a fatty meal to enhance absorption (same dose for pediatrics), may be given for 3 months[149, 150], can be stopped sooner if imaging shows resolution[140]. More parasiticidal than praziquantel and may have fewer side effects.

Niclosamide (Niclocide® and others) may be given orally to treat adult tapeworms in the GI tract. ***Rx*** 1 gm (2 tablets) chewed PO, repeated in 1 hour (total = 2 gm).

Intraventricular disease: There is no consensus on the efficacy of medical treatment for intraventricular cysts[140, 151, 152].

Surgery

Surgery may sometimes be necessary to establish the diagnosis. Stereotactic biopsy may be well suited for some cases, especially with deep lesions.

CSF diversion is necessary for patients with symptomatic hydrocephalus, although tubing may become obstructed by granulomatous inflammatory debris[153].

Surgery may be indicated for spinal cysts[138] and for intraventricular cysts which may be less responsive to medical therapy. The latter may sometimes be

dealt with using stereotactic techniques and/or endoscopic instrumentation[146], however, shunting and antihelmintics may suffice[152]. Surgery may also be needed for giant cysts when intracranial hypertension does not respond to steroids[140]. Antihelmintics may be required even after complete surgical removal because of possibility of relapse[140].

Follow-up

CT or MRI scan every 6 months until lesions disappear or calcify[140].

Contacts

Both patients with cysticercosis and their personal contacts should be screened for tapeworm infection since a single dose of niclosamide or praziquantel will eliminate the tapeworm[154]. Close contacts of persons with tapeworms should have screening by medical history and serologic testing for cysticercosis; if suggestive of cysticercosis a neurologic exam and CT or MRI should be done.

16.12.2. Echinococcosis

AKA **hydatid (cyst) disease**. Caused by encysted larvae of the dog tapeworm *Echinococcus granulosa* in endemic areas (Uruguay, Australia, New Zealand…). The dog is the primary definitive host of the adult worm. Intermediate hosts for the larval stage include sheep and man. Ova are excreted in dog feces and contaminate herbage eaten by sheep. After ingestion, the embryos hatch and the parasite burrows through the duodenal wall to gain hematogenous access to multiple organs (liver, lungs, heart, bone, brain). Dogs eat these infested organs and the parasite enters the intestine where it remains.

Man is infected either by eating food contaminated with ova, or by direct contact with infected dogs. CNS involvement occurs in only ≈ 3%. Produces cerebral cysts that are confined to the white matter. Primary cysts are usually solitary, secondary cysts (e.g. from embolization from cardiac cysts that rupture or from iatrogenic rupture of cerebral cysts) are usually multiple. The CT density of the cyst is similar to CSF, it does not enhance (although rim enhancement may occur if there is an inflammatory reaction), and there is little surrounding edema. It contains germinating parasitic particles called “hydatid sand” containing ≈ 400,000 scoleces/ml. The cyst enlarges slowly (rates of ≈ 1 cm per year are

quoted, but this is variable and may be higher in children), and usually does not present until quite large with findings of increased ICP, seizures, or focal deficit. Patients often have eosinophilia and may have positive serologic tests for hydatid disease.

Treatment

Treatment is surgical removal of the intact cyst. Every effort must be made to avoid rupturing these cysts during removal, or else the scoleces may contaminate the adjacent tissues with possible recurrence of multiple cysts or allergic reaction. May use adjunctive medical treatment with albendazole (Zentel®) 400 mg PO BID (pediatric dose: 15 mg/kg/d) **x** 28 days, taken with a fatty meal, repeated as necessary[150].

The Dowling technique is recommended[155]:

1. the head is positioned so that the cyst points straight up towards the ceiling when the OR table is 30° head up
2. drilling burr holes and performing craniotomy must be done very carefully to avoid rupturing the cyst or tearing the dura which is thin and under tension
3. do not coagulate with anything but low-power bipolar (to avoid cyst rupture)
4. open the dura circumferentially away from the dome of the cyst as it may be adherent to the dura
5. keep the surface of the cyst moist to prevent desiccation and rupture
6. open the thinned overlying cortex gently, separating it from the cyst with irrigation and cottonoids. The cortical opening need only be ≈ 3/4 the cyst diameter but no less
7. insert a soft rubber catheter between the cyst and the brain, and gently irrigate with saline as the head of the OR table is slowly lowered 45° while the surgeon supports the adjacent cortex with his/her fingers
8. continue irrigating more saline and float the cyst out and into a saline filled receptacle
9. if the cyst is ruptured during the procedure, immediately place a sucker in the cyst to aspirate the contents, remove the capsule, and wash the cavity with saline for 5 minutes. Change instruments and gloves. Placing 10% formalin soaked cottonoids on the cavity for a few minutes is controversial[156 (p 3750)]

16.13. Fungal infections of the CNS

Most are medically treated conditions that do not require neurosurgical intervention. They tend to present either with chronic meningitis or brain abscess. Some of the more common ones or those of particular relevance to neurosurgery include:

1. cryptococcosis: *see below*
   A. cryptococcal meningitis
   B. cryptococcoma (mucinous pseudocyst): rare
2. candidiasis: the most common fungal infection of the CNS, but rarely diagnosed before autopsy. Very rare in healthy individuals. Most are *C. albicans*
   A. candidal meningitis: the most common CNS infection (*see page 345* for Rx)
   B. parenchymal infection: candida brain abscesses are rare
   C. following ventricular shunt placement: almost all fungal VP shunt infections are due to *Candida spp.*[16] (*see page 346*)
3. aspergillosis: may be associated with cerebral abscess in organ transplant patients (*see page 351*)
4. coccidiomycosis: caused by the dimorphic fungus *Coccidioides immitis*. Endemic in southwestern U.S., Mexico, and Central America. Usually presents as meningitis, with rare reports of parenchymal lesions[157]
5. mucormycosis (phycomycosis): usually occurs in diabetics (*see page 836*)

CRYPTOCOCCAL INVOLVEMENT OF THE CNS

CNS involvement is diagnosed more frequently in living patients than any other fungal disease. Occurs in healthy or immunocompromised patients. In HIV, *Cryptococcus neoformans* is the typical agent.

1. cryptococcoma (mucinous pseudocyst): a parenchymal collection which occurs almost exclusively in AIDS patients. Much less common than cryptococcal meningitis. No enhancement of the lesion or the meninges. Usually 3-10 mm in diameter and are frequently located in the basal ganglia (due to spread by small perforating vessels)
2. cryptococcal meningitis:
   A. occurs in 4-6% of patients with AIDS[158]. Typical symptoms: fever,

malaise and H/A[159]. Meningeal signs (nuchal rigidity, photophobia…) occur in only ≈ 25%. Encephalopathic symptoms (lethargy, altered mentation…) usually from increased ICP occur in a minority

B. can also occur without AIDS: *gatti* variety can infect the brain of immuno-competent hosts[160]

C. may be associated with increased ICP (with or without hydrocephalus on CT/MRI), decreased visual acuity, and/or cranial nerve deficits. Dilation of Virchow-Robbins spaces may be seen on imaging; on MRI the signal is similar to CSF on T1WI & T2WI but will be higher signal on FLAIR

D. late deterioration in the absence of documented infection may respond to decadron 4 mg q 6 hrs transitioned to prednisone 25 mg p.o. q d[161]

Diagnosis

LP: should be done at the time of diagnosis, with OP measured in the lateral decubitus position[162]. CSF cryptococcal antigen titer is invariably high with cryptococcal meningitis or meningoencepahlitis. OP is usually elevated, and is > 20 cm H_2O in up to 75%.

Serum cryptococcal Ag: almost always elevated with CNS involvement[162].

Management

2009 CDC guidelines for CNS cryptoccal infection in HIV-infected adolescents/adults[162]:

1. antifungal agents: the recommended initial standard treatment[162] is amphotericin B deoxycholate (Amphocin®) 0.7 mg/kg IV q d, plus fluconazole (an oral triazole) 100 mg/kg po q d in 4 divided doses
2. patients with clinical signs of increased ICP (confusion, blurred vision, papilledema, LE clonus…) should have LP to measure ICP
3. management of intracranial hypertension **(ICHT)** (OP ≥ 25 cm H_2O) with or without hydrocephalus:[A]
   A. daily LPs: drain enough CSF to reduce ICP by 50% (typically 20-30 ml)[164]
   B. daily LPs may be suspended when pressures are normal for several consecutive days
   C. lumbar drain: occasionally needed for extremely high OPs (> 40 cm

H_2O) when frequent LPs are required to or fail to control symptoms[163]

D. **CSF shunt**: considered when daily LPs are no longer tolerated or when signs and symptoms of ICHT are not being relieved (neither dissemination of infection through the distal shunt nor creation of a nidus of infection refractory to medical therapy has been described[165]). Options:
   1. lumboperitoneal shunt
   2. VP or VA shunt[166, 167]

4. antifungal treatment is continued for ≥ 2 weeks if renal function is normal[B]
5. after 2 weeks of treatment, repeat the LP to look for clearance of the organism from the CSF. Positive CSF cultures after 2 weeks of treatment are predictive of future relapse and are associated with worse outcome
6. treatment failures: defined as lack of clinical improvement after 2 weeks of appropriate therapy including management of ICHT, or relapse after an initial response, defined as either a positive CSF culture and/or rising CSF cryptococcal Ag titer with a compatible clinical picture. Management:
   A. optimal management has not been defined
   B. trials with alternative antifungals (e.g flucytosine) or higher doses of fluconazole
7. maintenance therapy (secondary prophylaxis): HIV patients who have completed 10 weeks of treatment should be maintained on fluconazole 200 mg q d until immune reconstitution occurs, otherwise lifetime treatment is indicated[162]
8. the risk of recurrence is low for patient who remain asymptomatic after a complete course of therapy and have sustained increase (> 6 months) of CD4+ counts to ≥ 200 cells/μL. Some experts perform an LP to document negative CSF culture and antigen before stopping maintenance therapy

---

A. corticosteroids, acetazolamide and mannitol have not been shown to be effective[163]

B. most immunocompetent patients will be successfully treated with 6 weeks of therapy[163]

16.14. Amebic infections of CNS

Naegleria fowleri: the only ameba known to cause CNS infection in humans → primary amebic meningoencephalitis **(PAM)**: diffuse encephalitis with hemorrhagic necrosis and prurulent meningitis involving brain and spinal cord. Rare (only 95 cases in the U.S. as of 2002, and ≈ 200 cases worldwide as of 2004). Typically occurs ≤ 5 days of exposure, usually from diving in warm freshwater. The ameba gains entry to the CNS by invading nasal olfactory mucosa.

Associated cerebral edema may cause increased ICP and, ultimately, herniation. Fatal in ≈ 95% usually within 1 week.

CSF: cloudy and often hemorrhagic, ↑ leukocytes, ↑ protein, normal or ↓ glucose, Gram stain negative (no bacteria or fungi), wet prep → motile trophozoites (may be confused with WBCs).

Treatment

Drug of choice: amphotericin B (lipid preparations (Abelcet®) achieve higher MICs than other amphotericin preparations). Miconazole may be synergistic.

Surgical intervention: ventriculostomy with CSF drainage may be indicated when findings are suggestive of increased ICP. In one survivor, surgical drainage of a brain abscess was performed in addition to treatment with a 6-week course of amphotericin B, rifampicin, and chloramphenicol.

16.15. Spine infections

Spine infections may be divided into the following major categories:

1. vertebral osteomyelitis (spondylitis): *see page 380*
    A. pyogenic
    B. nonpyogenic, granulomatous
        1. tuberculous spondylitis
        2. brucellosis
        3. aspergillosis
        4. blastomycosis
        5. coccidiomycosis
        6. infection with *Candida tropicalis*
2. discitis: *see page 383*, usually associated with vertebral osteomyelitis (spondylodiscitis) *see page 380*

A. spontaneous
B. post-operative/post-procedure

3. spinal epidural abscess (*see below*)
4. spinal subdural empyema
5. meningitis
6. spinal cord abscess

MRI experience suggests that patients with infectious spondylitis will develop an associated epidural abscess if untreated, and that epidural empyema is unusual in the absence of vertebral osteomyelitis[168]. Thus, the discovery of one of these conditions should prompt a search for the other.

16.15.1. Spinal epidural abscess

Key concepts:

- should be considered in a patient with back pain, fever, and spine tenderness
- major risk factors: diabetes, IV drug abuse, chronic renal failure, alcoholism
- may produce progressive myelopathy, sometimes with precipitous deterioration
- fever, sweats or rigors are common, but normal WBC and temperature can occur
- classical presentation of a skin boil (furuncle) occurs in only ≈ 15%
- treatment: controversial. Many patients improve with antibiotics alone. Early surgery is advocated by some even if no neuro deficit because of risk of precipitous deterioration

Epidemiology

Incidence: 0.2-1.2 per 10,000 hospital admissions annually[169], possibly on the rise[170]. Average age: 57.5 ± 16.6 years[171].

Thoracic level is the most common site (≈ 50%), followed by lumbar (35%) then cervical (15%)[171]. 82% were posterior to the cord, and 18% anterior in one series[169]. SEA may span from 1 to 13 levels[172].

Spinal epidural abscess **(SEA)** is often associated with vertebral osteomyelitis (in one series of 40 cases, osteomyelitis occurred in all cases of anterior SEA, in 85% of circumferential SEA, and no cases of posterior SEA)

and intervertebral discitis.

CO-MORBID CONDITIONS

Chronic diseases associated with compromised immunity were identified in 65% of 40 cases[173]. Associated conditions included diabetes mellitus (32%), IV drug abuse (18%), chronic renal failure (12%), alcoholism (10%), and the following in only 1 or 2 patients: cancer, recurrent UTI, Pott's disease, and positivity for HIV. Chronic steroid use and recent spinal procedure or trauma (e.g. GSW) are also risk factors[172]. Also, skin infection.

CLINICAL FEATURES

Usually presents with excruciating pain localized over spine, tender to percussion. Radicular symptoms follow with subsequent distal cord findings, often beginning with bowel/bladder disturbance, abdominal distension, weakness progressing to para- and quadriplegia. Average time is 3 days from back pain to root symptoms; 4.5 days from root pain to weakness; 24 hrs from weakness to paraplegia.

Fever, sweats or rigors are common, but are not always present[172].

A furuncle may be identified in 15%.

Patients may be encephalopathic. This may range from mild to severe and may further delay diagnosis. Meningismus with a positive Kernig's sign may occur.

Patients with post-operative SEA may demonstrate surprisingly few signs or symptoms (including lack of leukocytosis, lack of fever) aside from local pain[174].

Pathophysiology of spinal cord dysfunction

Although some cord symptoms may be due to mechanical compression (including that due to vertebral body collapse), this is not always found[175]. A vascular mechanism has also been postulated, and various combinations of arterial and venous pathology have been described[169] (one autopsy series showed little arterial compromise, but did show venous compression and thrombosis, thrombophlebitis of epidural veins, and venous infarction and edema of the spinal cord[176]). Occasionally, there may be infection of the spinal cord itself, possibly by extension through the meninges.

Differential diagnosis

SEA should be considered in any patient with backache, fever, and spine tenderness[177]. Also see *Differential diagnosis, Myelopathy* on page 1185.

Differential diagnosis

1. meningitis
2. acute transverse myelitis (paralysis is usually more rapid, radiographic studies are normal)
3. intervertebral disc herniation
4. spinal cord tumors
5. post-op SEA may appear similar to pseudomeningocele[174]

Source site of infection

- hematogenous spread is the most common source (26-50% of cases) either to the epidural space or to the vertebra with extension to epidural space. Reported foci include:
  - A. skin infections (most common): furuncle may be found in 15% of cases
  - B. parenteral injections, especially with <u>IV drug abuse</u>[178]
  - C. bacterial endocarditis
  - D. UTI
  - E. respiratory infection (including otitis media, sinusitis, or pneumonia)
  - F. pharyngeal or dental abscess
- direct extension from:
  - A. decubitus ulcer
  - B. psoas abscess: *see below*
  - C. penetrating trauma, including: abdominal wounds, neck wounds, GSW
  - D. pharyngeal infections
  - E. mediastinitis
  - F. pyelonephritis with perinephric abscess
- following spinal procedures (3 of 8 of these patients had readily identified perioperative infections of periodonta, UTI, or AV-fistula[173])
  - A. open procedures: especially lumbar discectomy (incidence[174] ≈ 0.67%)
  - B. closed procedures: e.g. epidural catheter insertion for spinal epidural

anesthesia[179-181], lumbar puncture[182]…
- a history of recent back trauma is common (in up to 30%)
- no source can be identified in up to 50% of patients in some series[183]

Psoas abscess

1. psoas muscle:
   A. one of 2 heads of the iliopsoas muscle (the other head is iliacus)
   B. origin: inner surface of ilium, base of sacrum, and transverse processes, vertebral bodies **(VB)** and intervertebral discs of spinal column starting from the inferior margin of T12 VB, extending to the upper part of L5 VB. Insertion: lesser trochanter of the femur. Psoas is the primary hip flexor
   C. innervation: branches of L2-4 nerve roots proximal to the formation of the femoral nerve
   D. susceptibility to infection
      1. rich vascular supply makes it vulnerable to hematogenous spread
      2. proximity to structures that may be a source of infection: sigmoid colon, jejunum, vermiform appendix, ureters, aorta, renal pelvis, pancreas, iliac lymph nodes and spine
2. may be primary (no identifiable underlying disease) or secondary in which it may be associated with one of the conditions shown in *Table 16-18*
3. risk factors: IV drug abuse, HIV/AIDS, age > 65 years, DM, immunosuppression, renal failure
4. physical findings: signs of iliopsoas inflammation include:
   A. active: pain on flexing the hip against resistance
   B. passive: with the patient lying on the unaffected side, hyperextension of the affected hip stretches the psoas muscle and produces pain
5. diagnostic tests:
   A. routine infection work-up: WBC (often elevated), blood cultures, U/A + C&S (pyuria may be seen)
   B. AP abdominal x-ray: psoas shadow may be obliterated
   C. CT: sensitivity is 80-100% (MRI is not better)[185]. Enlargement of psoas muscle on affected side best seen inside iliac wing
6. treatment often includes drainage of the psoas abscess either surgically or percutaneously with CT-guidance
7. mortality rates with psoas abscess: 2.4% with primary, 19% with

secondary[186]

Table 16-18 Conditions associated with secondary psoas abscess[184]

Organ system	Condition
gastrointestinal	diverticulitis, appendicitis, Crohn's disease, colorectal cancer
genitourinary	UTI, cancer
musculoskeletal infections	vertebral osteomyelitis, infectious sacroiliitis, septic arthritis
other	endocarditis, femoral artery catheterization, infected abdominal aortic aneurysm graft, hepatocellular Ca, intrauterine contraceptive device, trauma, sepsis, dialysis (peritoneal or long-term hemodialysis)

ORGANISMS

Operative cultures are most useful in identifying the responsible organism, these cultures may be negative (possibly more common in patients previously on antibiotics) and in these cases blood cultures may be positive. No organism may be identified in 29-50% of cases.

1. *Staph. aureus*: the most common organism (cultured in > 50%) possibly due to its propensity to form abscesses, its ubiquity, and its ability to infect normal and immunocompromised hosts (these facts help explain why many SEA arise from skin foci)
2. aerobic & anaerobic streptococcus: second most common
3. *E.coli*
4. *Pseudomonas aeruginosa*
5. *Diplococcus pneumoniae*
6. *Serratia marcescens*
7. Enterobacter
8. chronic infections:
   A. TB is the most common of these, and although it has become less wide-spread in the U.S. it is still responsible for 25% of cases of SEA[187], it is usually associated with vertebral osteomyelitis (Pott's disease) (see *Tuberculous vertebral osteomyelitis*, page 381)
   B. fungal: cryptococcosis, aspergillosis, brucellosis
   C. parasitic: Echinococcus
9. multiple organisms in ≈ 10%
10. anaerobes cultured in ≈ 8%

Laboratory tests

CBC: leukocytosis common in acute group (average WBC = 16,700/mm^3), but usually normal in chronic (ave. WBC = 9,800/mm^3)[169].

ESR elevated in most[70], usually > 30[173].

LP: performed cautiously in suspected cases at a level distant to the clinically suspected site (C1-2 puncture may be needed to do myelogram) with constant aspiration while approaching thecal sac to detect pus (danger of transmitting infection to subarachnoid space); if pus is encountered, stop advancing, send the fluid for culture, and abort the procedure. CSF protein & WBC usually elevated; glucose normal (indicative of parameningeal infection). 5 of 19 cases grew organisms identical to abscess.

Blood cultures: may be helpful in identifying organism in some cases.

Anergy battery: (e.g. mumps and Candida) to assess immune system.

Radiographic studies

Plain films: Usually normal unless there is osteomyelitis of adjacent vertebral bodies (more common in infections anterior to dura). Look for lytic lesions, demineralization, and scalloping of endplates (may take 4-6 weeks after onset of infection).

MRI: Imaging study of choice. Differentiates other conditions (especially transverse myelitis or spinal cord infarction) better than myelo/CT, and doesn't require LP.

Typical findings: T1WI → hypo- or isointense epidural mass, vertebral osteomyelitis shows up as reduced signal in bone. T2WI → high intensity epidural mass that often enhances with gadolinium (3 patterns of enhancement: 1) dense homogeneous, 2) inhomogeneous with scattered areas of sparse or no uptake, and 3) thin peripheral enhancement[188]) but may show minimal enhancement in the acute stage when comprised primarily of pus with little granulation tissue. Vertebral osteomyelitis shows up as increased signal in bone, associated discitis produces increased signal in disc and loss of intranuclear cleft. Unenhanced MRI may miss some SEA[189], gadopentetate dimeglumine enhancement may slightly increase sensitivity[190].

Myelogram: Usually shows findings of extradural compression (e.g. "paintbrush appearance" when complete block is present). In the event of complete block, C1-2 puncture is needed to delineate upper extent (unless post-myelographic CT shows dye above the lesion). See cautions above regarding LP.

CT scan: Intraspinal gas has been described on plain CT[191]. Post-myelographic CT is more sensitive.

TREATMENT

Controversial. Some advocate early surgical evacuation combined with antibiotics as the treatment of choice. Argument: although there are reports of management with antibiotics alone[192-194] ± immobilization[168], rapid and irreversible deterioration has occurred even in patients treated with appropriate antibiotics who were initially neurologically intact[171, 173]. 86% of those who deteriorated were initially treated it with antibiotics alone[172]. Therefore it is recommended that nonsurgical management be reserved for the following patients (reference[192] modified[172]):

1. those with prohibitive operative risk factors
2. involvement of an extensive length of the spinal canal
3. complete paralysis for > 3 days

Surgery

Goals are establishing diagnosis and causative organism, drainage of pus and debridement of granulation tissue, and bony stabilization if necessary. Most SEA are posterior to dura and are approached with extensive laminectomy. For posteriorly located SEA and no evidence of vertebral osteomyelitis, instability will usually not follow simple laminectomy and appropriate postoperative antibiotics[183]. Closure is performed with limited wire sutures. Post-op drainage is not necessary in cases with only granulation tissue and no pus. For recurrent infections, reoperation and post-op suction-irrigation may be needed[195].

Patients with vertebral osteomyelitis may develop instability after laminectomy alone[196] especially if significant bony destruction is present. Thus for anterior SEA, usually with osteomyelitis (especially Pott's disease), a posterolateral extracavitary approach is utilized whenever possible (to avoid transabdominal or transthoracic approach in these debilitated patients) with removal of devitalized bone usually followed by posterior instrumentation and fusion. Strut grafting with autologous bone (rib or fibula) can be done acutely in Pott's disease with little risk of graft infection. With purulent osteomyelitis, metal hardware is not contraindicated but bone grafting risks continuation of infection.

Specific antibiotics

If organism and source unknown, *S. aureus* most likely. Empiric antibiotics:

1. 3rd generation cephalosporin, e.g. cefotaxime (Claforan®)

PLUS

2. vancomycin: until methicillin resistant *S. aureus* **(MRSA)** can be ruled out. Once MRSA is ruled out switch to synthetic penicillin (e.g. nafcillin or oxacillin)

PLUS

3. rifampin PO

Modify antibiotics based on culture results or knowledge of source (e.g. IV drug abusers have a higher incidence of Gram-negative organisms).

Duration of treatment

For SEA, 3-4 weeks of IV antibiotics followed by 4 weeks of oral antibiotics usually suffices. 6-8 weeks of IV antibiotics are suggested if there is documented concomitant vertebral osteomyelitis[197] (although some argue that osteomyelitis is present pathologically in most cases even if not demonstrated radiographically, and therefore there should be no treatment difference between these groups[198]). Serial ESRs may also guide duration (failure to reduce suggests residual infection[170]). Immobilization for at least 6 weeks during antibiotic therapy is recommended.

OUTCOME

Fatal in 4-31%[199] (the higher end of the range tends to be in older patients and in those paralyzed before surgery[173]). Patients with severe neurologic deficit rarely improve, even with surgical intervention within 6-12 hrs of onset of paralysis, although a few series have shown a chance for some recovery with treatment within 36 hrs of paralysis[177, 198]. Reversal of paralysis of caudal spinal cord segments if present for more than a few hours is rare (exception: Pott's disease has 50% return). Mortality is usually due to original focus of infection or as a complication of residual paraplegia (e.g. pulmonary embolism).

16.15.2. Vertebral osteomyelitis

Key concepts:

- presentation and risk factors similar to spinal epidural abscess (*see page 376*)
- percutaneous needle biopsy for C&S and to rule-out tumor. Can be done by neurosurgeon or interventional radiologist
- treatment: most cases can be managed nonsurgically with long-term antibiotics
- surgery is considered for instability, and infrequently for severe resistance to Abx

For differential diagnosis, *see Destructive lesions of the spine*, page 1232. Often associated with discitis, which may be grouped together under the term *spondylodiscitis*. VO has features similar to spinal epidural abscess **(SEA)** (*see page 376*).

Vertebral body collapse and kyphotic deformity may occur with possible retropulsion of necrotic bone and disc fragments, compressing the spinal cord or cauda equina.

Epidemiology

Vertebral osteomyelitis **(VO)** comprises 2-4% of all cases of osteomyelitis[200]. Incidence is 1:250,000 in general population. Incidence appears to be rising. Male:female ratio is 2:1. Incidence increases with age, most patients are > 50 years old. The lumbar spine is the most common site, followed by thoracic, cervical and sacrum[201]. Thoracic VO may → empyema.

Risk factors

1. IV drug abuse[202]
2. diabetes mellitus: susceptible to unusual bacterial infections and even fungal osteomyelitis
3. hemodialysis: a diagnostic challenge since radiographic changes of osteomyelitis can occur even in the absence of infection (see *Destructive lesions of the spine*, page 1232)
4. immunosuppression
   A. AIDS
   B. chronic corticosteroid use
   C. ethanol abuse
5. infectious endocarditis

6. following spinal surgery or invasive diagnostic or therapeutic procedures
7. may occur in elderly patients with no other identifiable risk factors[203]

Complications that may accrue

1. spinal epidural abscess
2. subdural abscess
3. meningitis
4. bony instability
5. progressive neurologic impairment
6. unique to cervical spine involvement: pharyngeal abscess
7. unique to thoracic spine involvement: mediastinitis

Clinical

Signs/symptoms: localized pain (90%), fever (52%, with fever spikes and chills being rare), weight loss, paraspinal muscle spasm, radicular symptoms (50-93%) or myelopathy. VO sometimes produces few systemic effects (e.g. WBC and/or ESR may be normal). ≈ 17% of patients with VO have neurologic symptoms. The risk of paralysis may be higher in the older patient, in cervical VO (vs. thoracic or lumbar), in those with DM or rheumatoid arthritis, and in those with VO due to *S. aureus*[196]. Neurologic findings are uncommon initially, which may delay the diagnosis[204]. Sensory involvement is less common than motor and long-tract signs because compression is primarily anterior.

Pathogenesis

Source of infection

Sources of spontaneous VO: UTI (the most common), respiratory tract, soft-tissues (e.g. skin boils, IV drug abuse…), dental flora, blunt trauma to the spine. In 37% of cases a source is never identified[205].

Potential routes of spread

Three main routes (arterial, venous, and direct extension):

1. hematogenous: hematogenously disseminated spondylodiscitis in adults usually involves bone initially, and once infection is established in the subchondral space, spread is to the adjacent disc and thence to the next

VB[206]

A. arterial

B. via spinal epidural venous plexus (Batson's plexus[207])

2. direct extension (e.g. following surgery/LP, trauma, or local infection)

Organisms

1. *Staphylococcus aureus is* the most common pathogen (> 50%) as in SEA
2. *E. coli* is a distant second
3. organisms associated with some primary infection sites[208]:
   A. IV drug abusers: *Pseudomonas aeruginosa* is common
   B. urinary tract infections: *E. coli* & *Proteus spp.* are common
   C. respiratory tract infections: *Streptococcus pneumoniae*
   D. alcohol abuse: *Klebsiella pneumoniae*
   E. endocarditis:
      1. acute endocarditis: *Staph. aureus*
      2. subacute endocarditis: *Streptococcus spp.*
4. tuberculous VO: *Mycobacterium tuberculosis* (*see below*)
5. unusual organisms include: nocardia (*see page 356*)
6. *Mycobacterium avium complex (M. Avium* and *M. intracellulare*) **(MAC)** can cause pulmonary disease in nonimmunocompromised patients (usually elderly or on chronic steroids), but can cause VO similar to TB[209] as part of disseminated disease which usually occurs in HIV patients
7. rarely (< 2.5%) pyogenic infections are polymicrobial

Tuberculous vertebral osteomyelitis: AKA tuberculous spondylitis, AKA **Pott's disease**. More common in third world countries. Typically symptomatic for many months. Usually affects more than one level. The most common levels involved are the lower thoracic and upper lumbar levels. Has a predilection for the vertebral body, sparing the posterior elements. Psoas abscess is common (the psoas major muscle attaches to the bodies and intervertebral discs from T12-L5). Sclerosis of the involved vertebral body may occur. Definitive diagnosis requires the identification of acid fast bacilli on culture or Gram stain of biopsy material (may be done percutaneously).

Neurologic deficit develops in 10-47% of patients[210], and may be due to medullary and radicular inflammation in most cases. The infection itself rarely extends into the spinal canal[211], however, epidural granulation tissue or fibrosis or a kyphotic bony deformity may cause cord compression[210].

The role of surgical debridement and fusion with TB is controversial, and good results may be obtained with either medical treatment or surgery. Surgery may be more appropriate when definite cord compression is documented or for complications such as abscess or sinus formation[212].

DIAGNOSTIC TESTS

Laboratories

WBC: elevated in only ≈35% (rarely > 12,000), associated with poor prognosis.

ESR: elevated in almost all. Usually > 40 mm/hr. Mean: 85.

CRP: may be more sensitive than ESR, and may tend to normalize more quickly with appropriate treatment[213]. For normal values *see page 387*.

Cultures/biopsy

Culture: blood (positive in ≈ 50%), urine and any focal suppurative process.

Needle biopsy with cultures: can usually be done percutaneously via transpedicular approach with CT or fluoroscopic guidance. May be helpful even if blood cultures are positive (different organisms retrieved in 15%[214]) ∴ an attempt at direct culture from the involved site should be made. Ideally, cultures should be done before antibiotics are started. The yield of needle biopsy cultures ranges from 60-90%. Open biopsy is more sensitive, but morbidity is higher.

IMAGING

A comparison of sensitivities and specificities of various imaging modalities is shown in *Table 16-19*. NB: MRI and CT may be negative if done too early in the course.

MRI: T1WI → confluent low signal in vertebral bodies and intervertebral disc space. T2WI → increased intensity of involved VBs and disc space[215]. Contrast: enhancement of VB and disc, also look for paraspinal and epidural mass.

Plain x-ray: changes take from 2-8 weeks from the onset of infection to develop. Earliest changes are loss of cortical endplate margins and loss of disc space height.

Bone scan: three phase bone scan (*see page 140*) has reasonably good sensitivity and specificity. Gallium scan (*see page 141*) has better accuracy, findings include increased uptake in the 2 adjacent VBs with loss of intervening

disc[216]. Indium-111 labeled WBC scan: low sensitivity for vertebral osteomyelitis.

Table 16-19 Accuracy of various imaging modalities for vertebral osteomyelitis[215]

Modality	Sensitivity	Specificity	Accuracy
plain x-rays	82%	57%	73%
bone scan	90%	78%	86%
gallium scan	92%	100%	93%
bone scan + gallium scan	90%	100%	94%
MRI	96%	92%	94%

Work-up

In patients with suspected vertebral osteomyelitis (VO) (see text above for details):

1. clinical: history of IV drug abuse, DM, skin boil
2. physical exam: R/O radiculopathy & myelopathy, point tenderness over spine
3. diagnostic tests:
   A. bloodwork: WBC, ESR (a normal ESR is almost incompatible with VO), blood cultures
   B. imaging: MRI without and with contrast. Bone scan is used when suspicion is high and MRI is contraindicated
   C. percutaneous needle biopsy with cultures: usually by radiologist. Cultures should include: fungal, aerobic and anaerobic bacterial, and TB

Table 16-20 Candidates for non-surgical treatment in pyogenic spontaneous spondylodiscitis[208]

• organism identified
• antibiotic sensitivity
• single disc space involvement with little VB involvement
• minimal or no neurologic deficit
• minimal or no spinal instability

Treatment

90% of cases can be managed non-surgically with antibiotics and immobilization. Characteristics of potential candidates for non-surgical treatment are listed in *Table 16-20*. Must also take into account level(s) involved

and patient's condition.

In cases with high suspicion for VO, antibiotics may be started as soon as biopsy has been performed (some treat even earlier). For details of antimicrobials, see *Treatment*, page 379 (under spinal epidural abscess).

Improvement on imaging can lag behind clinical response and ESR/CRP.

Indications for neurosurgical[A] intervention:

1. progression of disease despite adequate best-case antibiotic therapy
2. spinal instability
3. spinal epidural abscess: *see* *page 376*
4. chronic infection refractory to medical management

For patients not being treated surgically:

1. percutaneous biopsy to obtain ID & sensitivity of organism
2. antibiotics:
   A. IV antibiotics for at least **6 weeks**[B] (longer, e.g. 12 weeks, if ESR not normalizing or if extensive bone involvement and paravertebral infection)
   B. followed by 6-8 weeks of oral agents[208]
3. pain medication as appropriate for pain
4. TLSO brace: to reduce pain (due to movement at involved site) and to reduce stress on weakened bone until healing
5. check upright films in the TLSO to verify stability in the brace
6. follow-up at approximately 8 and 12 weeks with x-rays in brace, then consider discontinuing brace if infection and pain are under control

Surgical treatment

Decompression of neural elements, removal of inflammatory tissue and infected bone to decrease bioburden. Use of instrumented fusion is not contraindicated even for pyogenic infections. Use of bone morphogenic protein (rhBMP-2) in 14 patients undergoing circumferential fusion for refractory infections did not produce complications[217].

16.15.3. Discitis

An uncommon primary infection of the nucleus pulposus. May start in cartilaginous endplate and spread to disc and vertebral body **(VB)**. Can occur following a number of procedures (see *Epidemiology*, page 386) or may be

"spontaneous" (the latter being more common). Often a benign, self-limited disease. Similar to vertebral osteomyelitis, except osteomyelitis primarily involves the VB and spreads secondarily to the disc space. Features and management common to spontaneous and postoperative discitis are discussed in the "general" section below, followed by sections describing characteristics unique to each (see *Spontaneous discitis*, page 386 or *Postoperative discitis* on page 386).

Many radiographic features of spondylodiscitis and tumor (metastatic and primary) are similar, but tumors rarely involve the disc space, whereas most infections begin in, or before too long, involve the disc space (for more details, see *Differentiating factors*, page 1233).

DISCITIS IN GENERAL

CLINICAL

1. symptoms:
   A. pain (the primary symptom)
      1. local pain, moderate to severe, exacerbated by virtually any motion of the spine, usually well localized to the level of involvement
      2. radiating to abdomen[218], hip, leg, scrotum, groin, or perineum
      3. radicular symptoms: in 50%[219] to 93%[220] depending on the series
   B. fever and chills (only 30-50% are febrile)
2. signs:
   A. tenderness
   B. paravertebral muscle spasm
   C. limitation of movement

A. intervention by a general surgeon may be indicated for empyema, psoas abscess…

B. the rate of treatment failure is increased when IV antibiotics are given for < 4 weeks[208]

WORK-UP (SEE TEXT FOR DETAILS)

1. MRI: also evaluates for epidural spread
2. blood tests
   A. WBC

B. ESR & CRP

C. blood cultures

3. echocardiogram: rule-out endocarditis or valvular vegetations
4. percutaneous needle biopsy

RADIOGRAPHIC EVALUATION

A characteristic radiographic finding that helps distinguish infection from meta-static disease is that destruction of the disc space is highly suggestive of infection, whereas in general, tumor does not cross the disc space (see *Differentiating factors*, page 1233).

PLAIN X-RAYS

Usually not helpful for early diagnosis. Sequence of changes on plain films:

- earliest changes: interspace narrowing with some demineralization of the VB. Not seen < 2-4 wks following onset of clinical symptoms, nor later than 8 wks
- sclerosis (eburnation) of adjacent cortical margins with increased density of adjacent areas of VB representing new bone formation, starting 4-12 weeks following onset of clinical symptoms
- irregularity of the adjacent vertebral endplates, with sparing of the pedicles (except for tuberculosis, which may involve the pedicles)
- in 50% of cases, the infection remains confined to the disc space, in the other 50% it spreads to adjacent VB
- a late finding is widening (ballooning) of the disc space with erosion of the VB
- circumferential bone formation may lead to exuberant spur formation between VBs 6-8 months into course of illness
- spontaneous fusion of the VB may occur

MRI

Demonstrates involvement of disc space and of VBs. MRI can R/O paravertebral or epidural spinal abscess but is poor in assessing bony fusion. As sensitive as radionuclide bone scan. Characteristic finding: decreased signal from the disc and adjacent portion of VBs on T1WI, and increased signal from these structures on T2WI. Characteristic findings may occur 3-5 days after onset of symptoms. MRI also rules-out other causes of postop pain (epidural abscess, recurrent/residual disc herniation…).

The triad of gadolinium enhancement shown in *Table 16-21* is strongly suggestive of discitis (some asymptomatic patients may have some of these

findings, but they rarely have all)[221].

Table 16-21 Gadolinium enhancement in discitis

Location of gadolinium enhancement	Number (out of 15 patients without discitis)	Number (out of 7 patients with discitis)
1. vertebral bone marrow	1	7
2. disc space	3	5
3. posterior annulus fibrosus	13	7

CT

May also R/O paravertebral or epidural spinal abscess, and is better for assessing bony fusion. With the addition of water soluble intrathecal contrast, also assesses the spinal canal for compromise.

Diagnostic criteria

Three basic changes on CT[222] (if all 3 are present, pathognomonic for discitis; if only the 1st 2 are present, then only 87% specific for discitis):

1. endplate fragmentation
2. paravertebral soft-tissue swelling with obliteration of fat planes
3. paravertebral abscess

Spine polytomograms

For postoperative discitis **(POD)**: performed through level of previous discectomy. Otherwise, center tomograms on painful level.

Scintigrams

Very sensitive for discitis and vertebral osteomyelitis (85% sensitivity), but may be negative in up to 85% of patients with Pott's disease. Uses either technetium-99 (abnormal as early as 7 days following onset of clinical symptoms) or gallium-67 (abnormal within 14 days). A positive scan shows focal increased uptake in adjacent endplates, and may be differentiated from osteomyelitis which will involve only one endplate. A positive scan is not specific for infection, and may also occur with neoplasms, fractures, and degenerative changes.

Laboratory studies

ESR: In non-immunocompromised patients, ESR will be elevated in almost all

cases with an average of 60 mm/hr (although it can rarely occur, a normal ESR should call the diagnosis into question). Interpreting ESR may be more problematic in post-op discitis (*see page 387*). ESR may be useful to follow as an indicator of response to treatment.

C-reactive protein: *See C-reactive protein* on page 387.

WBC: Peripheral WBC is often normal, and rarely is elevated above 12,000.

PPD: Applied to help R/O Pott's disease (see *Tuberculous vertebral osteomyelitis*, page 381), may be negative in 14% of cases[223].

Cultures: An attempt should be made to obtain direct cultures from the involved disc space. These may be obtained percutaneously with CT or other radiographic guidance (reported up to 60% positive culture rate; if available, a nucleotome provides a higher yield than e.g. Craig needle biopsy), or from intraoperative specimen (NB: surgery for open biopsy alone is usually not indicated). Staining for TB must be done in all cases.

Blood cultures may be positive in ≈ 50% of cases, and are helpful in guiding choice of antimicrobial agent when positive.

PATHOGENS

Staphylococcus aureus is the most common organism when direct cultures are obtained, followed by *S. albus* and *S. epidermidis* (*S. epidermidis* is the most common pathogen in POD). Gram negative organisms may also be found, including *E. coli* and Proteus species. Enteric flora in post-op discitis may due to undetected breach of the anterior longitudinal ligament with bowel perforation.

Pseudomonas aeruginosa may be more common in IV drug abusers.

H. flu is common in juvenile discitis (*see below*).

Tuberculous spondylitis (Pott's disease) may also occur.

TREATMENT

Outcome is generally good, and antibiotics together with immobilization are adequate treatment in ≈ 75% of cases. Occasionally surgery is required. Also see *Management*, page 387 under postoperative discitis for other aspects of management.

IMMOBILIZATION

Probably does not affect final outcome, but generally affords earlier pain relief, and may allow return to activity at an earlier time.

Most patients are started on strict bed rest, and are fitted for a plastic-type body jacket in which they are allowed to ambulate, and in which they remain for 6-8 weeks on the average. Alternative forms of immobilization include spica cast (provides better immobilization) and a corset-type brace.

ANTIBIOTICS

Current thinking is that most patients should receive antibiotics, guided by the results of the direct cultures when positive. In the 40-50% of cases where no organism is isolated, broad spectrum antibiotics should be used.

Two alternative treatment plans suggested:

1. treat with IV antibiotics for an arbitrary period of time, usually ≈ 4-6 weeks, followed with oral antibiotics for an additional 4-6 weeks
2. treat with IV antibiotics until the ESR normalizes, then change to PO

SURGERY

Required in only ≈ 25% of cases. Debridement may be done through the previous laminectomy site. However, if there has been significant bone loss and instability, then an anterior discectomy and fusion through a retroperitoneal approach may be required.

Surgery is reserved for:

1. situations where the diagnosis is uncertain, especially when neoplasm is a strong consideration (CT guided needle biopsy may help here)
2. decompression of neural structures, especially with associated spinal epidural abscess or compression by reactive granulation tissue. Ascending numbness, weakness, or onset of neurogenic bladder herald cauda equina syndrome
3. drainage of associated abscess, especially septated abscesses that might be recalcitrant to CT guided percutaneous needling
4. rarely, to fuse an unstable spine. Poorly endorsed in the face of active infection, especially since most go on to spontaneous fusion

Approaches

1. anterior discectomy and corpectomy removes the offending infected tissue, with strut graft using iliac crest (or, in the thoracic region, a posterolateral approach, with the strut made from the resected rib if large enough)

2. posterior laminectomy may be adequate for emergent decompression, but does not allow access to the site of pathology in cervical or thoracic regions

SPONTANEOUS DISCITIS

No recent history of surgery or instrumentation. Higher incidence of neurologic deficits and radiculopathy than with postoperative discitis **(POD)**.

Two distinct types:

1. juvenile: more common; age usually < 20 yrs (*see below*)
2. adult: usually occurs in susceptible patients (diabetics, IV drug abusers)

JUVENILE DISCITIS

Age usually < 20 yrs, with a peak between 2-3 years. Probably due to the presence of primordial feeding arteries that nourish the nucleus pulposus and which involute at ≈ 20-30 yrs age. Lumbar spine is more commonly involved than thoracic or cervical. Common presentation: refusal to walk or stand progressing to refusal to sit in young children. Back pain is most common in children > 9 yrs age. Low grade fever may be present. ESR is usually 2-3 **x** normal. WBC is sometimes elevated. *H. flu* is a more commonly seen pathogen in this group.

In most cases, there is complete resolution in 9-22 weeks without recurrence in long-term follow-up studies[210 (p 365-71)]. Surgery is reserved for the rare case that progresses in spite of antibiotics, for spinal instability, or for recurrent cases.

Most authors reserve antibiotics for patients with[210 (p 365-71)]:

1. positive cultures (blood cultures or biopsy cultures)
2. elevated WBC count, constitutional symptoms, or high fever
3. poor response to rest or immobilization
4. neurologic sequelae (very rare)

Antibiotics should be given for a total of 4-6 weeks. Start with IV antibiotics, and when clinical symptoms improve convert to PO for the remainder of therapy.

POSTOPERATIVE DISCITIS

Unless otherwise specified, the following is based on a series of 27 post-op cases identified retrospectively at Duke[224].

Epidemiology

Incidence after lumbar discectomy[225]: 0.2-4% (realistic estimate is probably at the lower end of this range). May also occur after LP, myelogram, cervical laminectomy, lumbar sympathectomy, chemonucleolysis[226], discography (*see page 436*), fusions and other procedures. Very rare after ACDF. Risk factors include: advanced age, obesity, immuno-suppression, systemic infection at the time of surgery.

Pathophysiology

There is some controversy as to whether some cases of post-op discitis are not infectious[227], an autoimmune process has been implicated in some of these so-called "avascular" or "chemical" or "aseptic" discitis cases. These cases are less common than infectious ones. ESR and CRP abnormalities may be less pronounced in these patients, and biopsy of the disc space fails to grow organisms or show signs of infection (infiltrates of lymphocytes or PMNS) on microscopy[227].

In septic cases, various mechanisms for infection have been proposed: direct inoculation at the time of surgery, infection following aseptic necrosis of disc material…

Clinical

1. interval from operation to onset of symptoms: 3 days to 8 mos (most commonly 1-4 wks post-op, usually after an initial period of pain relief and recovery from surgery). 80% present by 3 wks
2. symptoms:
   A. moderate to (usually) severe back pain at the site of operation was the most common symptom, exacerbated by virtually any motion of the spine, often accompanied by paraspinal muscle spasms. Back pain is usually out of pro-portion to the findings
   B. fever (> 38° C in 9 patients; literature reports only 30-50% are febrile) and chills
   C. pain radiating to hip, leg, scrotum, groin, abdomen or perineum (true sciatica is uncommon)
3. signs: all had paravertebral muscle spasm and limited range of motion of the spine. 13 were virtually immobilized by pain. Point tenderness over infected spine occurred in 9, expressible pus in 2 (literature reports 0-8%). No new neurologic deficits were noted. Only 10-12% have associated

wound infection[219]

4. lab findings:
   - ESR: 26/27 had ESR > 20 mm/hr (60 = ave.; > 40 in 17 patients; > 100 in 5 patients; the single patient < 20 was on steroids). ESR increases after un-complicated discectomy, peaking at 2-5 days, and can fluctuate for 3-6 weeks before normalizing[228]. A n elevated ESR that never decreases after surgery is a strong indicator of discitis. NB: ESR in anemic patients is un-reliable and no reference range can be established (use CRP in these cases)
   - C-reactive protein **(CRP)**[228]: an acute phase protein synthesized by hepatocytes that because of rapid decomposition may be a more specific indicator of post-op infection than ESR. Values vary from lab to lab, but CRP is normally not detectable in the blood (i.e. < 0.6 mg/dL = 6 mg/L). After uncomplicated discectomy (i.e. in the absence of discitis), CRP peaks ≈ 2-3 days post-op (to 4.6 ± 2.1 mg/dL after lumbar microdiscectomy, 9.2 ± 4.7 after conventional lumbar discectomy, 7.0 ± 2.3 after anterior lumbar fusion, and 17.3 ± 3.9 after PLIF), and returns to normal between 5-14 days post op
   - WBC: elevated > 10,000 in only 8/27 (prevalence in literature: 18-30%)

Radiographic evaluation

Also, see *Radiographic evaluation*, page 384 under *Discitis in general*.

In postoperative discitis **(POD)**, the average time from surgery to changes on plain x-ray is 3 mos (range: 1-8 mos). Changes are detectable earlier on polytomograms (3 wks to 2 mos). Average time from first change to spinal fusion: 2 yrs.

Pathogens

See Table 16-22. Most studies report *S. aureus* as the most commonly identified organism, accounting for ≈ 60% of positive cultures[225], followed by other staph species. Also reported: Gram-negative organisms (including *E. coli*), *Strep viridans*, *Streptococcus species* anaerobes, TB and fungi.

Blood cultures were positive in 2 of 6 (both *S. aureus*).

For culture techniques, *see below*.

Table 16-22 Culture results (14 patients, Craig needle biopsy)

Organism	No. of patients
Staphylococcus epidermidis	4

S. aureus	3
No growth	7

MANAGEMENT

1. admitting labs (in addition to routine): ESR, C-reactive protein, CBC, blood cultures
2. analgesics + muscle relaxants (e.g. diazepam (Valium®) 10 mg PO TID)
3. antibiotics:
   - IV antibiotics for 1-6 wks (or until ESR decreases), then PO for 1-6 mos (typically 6 weeks)
   - most start with anti-staphylococcal antibiotics (initial empiric therapy: vancomycin + PO rifampin) and a broad spectrum antibiotic (e.g. Cefizox), modify based on sensitivities if positive cultures are obtained
4. activity restriction (one of the following used, usually until significant pain relief):
   - spinal immobilization with spica cast or plastic body jacket
   - strict bed rest
   - activity with corset
5. some authors recommend steroid therapy initially to assist pain relief
6. cultures: performed if radiographs suspicious, usually performed utilizing percutaneous CT-guided technique
   A. sites
      1. disc aspiration if evidence of disc space involvement
      2. needling of paraspinal mass if present
   B. send cultures for the following:
      1. stains
         a. Gram stain
         b. fungal stain
         c. AFB stain
      2. culture
         a. routine cultures: aerobic and anaerobic
         b. fungal culture: this is not only helpful for fungus, but since these cultures are kept for longer period and any growth that occurs will be further characterized, fastidious or indolent bacterial organisms may sometimes be identified
         c. TB culture
7. 3 patients in Duke series underwent anterior discectomy and fusion after

unsuccessful medical therapy

OUTCOME

9 patients developed bony bridging in 12-18 mos; 10 developed bony fusion in 18-24 mos.

All patients eventually become pain free (or significantly improve). This is not the case in all series, where some report 60% were pain free at F/U, others found slight back pain in most patients, and yet others report severe chronic LBP in 75%[225]. 67-88% return to their previous work, and 12-25% received disability pension; these numbers are similar to the outcome from disc surgery in general.

No difference in outcome was found for the various activity restrictions specified, except for earlier pain relief with first two types listed above.

17. Seizures

17.1. Seizure classification

Definition of a seizure: an abnormal paroxysmal cerebral neuronal discharge that results in alteration of sensation, motor function, behavior or consciousness. Seizures may be classified by type, etiology, and by epileptic syndromes.

Classification of major seizure types[1-3]

1. primary **generalized**: bilaterally symmetrical and synchronous involving both cerebral hemispheres at the onset, no local onset, consciousness lost from the start. Represents ≈ 40% of all seizures
   A. generalized tonic-clonic **(GTC)** (née: grand-mal seizure): generalized seizure that evolves from tonic to clonic motor activity. This is a specific type and does <u>NOT</u> include partial seizures that generalize secondarily
   B. clonic seizures: fairly symmetric, bilateral synchronous semirhythmic jerking of the UE & LE, usually with elbow flexion and knee extension
   C. tonic seizures: sudden sustained increased tone with a characteristic guttural cry or grunt as air is forced through adducted vocal cords
   D. **absence** (née: petit-mal seizure): impaired consciousness with mild or no motor involvement (*see below*)
      1. typical absences
      2. atypical absences: more heterogeneous with more variable EEG pattern then typical absence. Seizures may last longer
   E. myoclonic seizures: shock-like body jerks (1 or more in succession) with generalized EEG discharges
   F. atonic seizures (AKA astatic seizures or “drop attacks”): sudden brief loss of tone that may cause falls
2. **partial** (née focal seizure): implies one hemisphere involved at onset. About 57% of all seizures. A new onset of partial seizure represents a

structural lesion until proven otherwise

A. simple partial seizure (no impairment of consciousness)
    1. with motor signs (including Jacksonian)
    2. with sensory symptoms (special sensory or somatosensory)
    3. with autonomic signs or symptoms
    4. with psychic symptoms (disturbance of higher cerebral function)

B. complex partial seizure (many used to be classified as psychomotor seizure, often attributed to temporal lobe but they can arise from any cortical area): any alteration of consciousness, usually LOC or automatisms (including lip smacking, chewing, or picking with the fingers) with autonomic aura (usually an epigastric rising sensation)
    1. simple partial onset followed by impairment of consciousness (may have premonitory **aura**)
        a. without automatisms
        b. with automatisms
    2. with impairment of consciousness at onset
        a. without automatisms (impairment of consciousness only)
        b. with automatisms

C. partial seizure with secondary generalization
    1. simple partial evolving to generalized
    2. complex partial evolving to generalized
    3. simple partial evolving to complex partial evolving to generalized

3. unclassified epileptic seizures: ≈ 3% of all seizures

Classification by etiology (and some epileptic syndromes)

This list is not all inclusive (see reference[2, 3]).

1. **symptomatic** (AKA “secondary”): seizures of known etiology (e.g. CVA, tumor…)
    A. temporal lobe epilepsies:
        1. mesial temporal sclerosis: *see below*
2. **idiopathic** (AKA “primary”): no underlying cause. Includes:
    A. juvenile myoclonic epilepsy: *see below*
3. **cryptogenic**: seizures presumed to be symptomatic but with unknown etiology
    A. West syndrome (infantile spasms, Blitz-Nick-Salaam Krämpfe): *see below*

B. Lennox-Gastaut syndrome: *see below*

4. special syndromes: situation-related seizures

A. febrile seizures: *see page 402*

B. seizures occurring only with acute metabolic or toxic event: e.g. alcohol

KEY distinctions (having therapeutic implications)

In generalized tonic-clonic seizures: primary generalized vs. partial with secondary generalization (often, local onset may not be observed).

In staring spells: absence vs. complex partial.

Epilepsy

A disorder, not a single disease. Characterized by recurrent (2 or more), unprovoked seizures.

Absence seizure

Formerly called petit-mal seizure. Impaired consciousness with mild or no motor involvement (automatisms occur more commonly with bursts lasting > 7 secs). No post-ictal confusion. Aura rare. May be induced by hyperventilation **x** 2-3 mins. EEG shows **spike and wave** at exactly 3 per second.

Uncinate seizures

Obsolete term: "uncal fits". Seizures originating in the inferior medial temporal lobe, usually in the hippocampal region. May produce olfactory hallucinations (kakosmia or cacosmia: the perception of bad odors where none exist).

Mesial temporal sclerosis[4, 5]

The most common cause of intractable temporal lobe epilepsy. Specific pathologic basis: hippocampal sclerosis (cell loss in hippocampus on one side). Characteristics are shown in *Table 17-1*. For differential diagnosis, *see page 1228*.

Adult seizures are initially responsive to medical therapy but become more varied and refractory, and may respond to seizure surgery.

Juvenile myoclonic epilepsy[7]

Sometimes called bilateral myoclonus. 5-10% of cases of epilepsy. An

idiopathic generalized epilepsy syndrome with age-related onset consisting of 3 seizure types:

1. myoclonic jerks: predominantly after waking
2. generalized tonic-clonic seizures
3. absence

Table 17-1 Syndrome of mesial temporal-lobe epilepsy[6]

History
• higher incidence of complicated febrile seizures than in other types of epilepsy
• common family history of epilepsy
• onset in latter half of first decade of life
• auras in isolation are common
• infrequent secondarily generalized seizures
• seizures often remit for several years until adolescence or early adulthood
• seizures often become medically refractory
• common interictal behavioral disturbances (especially depression)
Clinical features of seizures
• most have aura (especially epigastric, emotional, olfactory or gustatory) **x** several secs
• CPS often begin with arrest & stare; oroalimentary & complex automatisms are common. Posturing of contralateral arm may occur. Seizure usually lasts 1-2 mins
• postictal disorientation, recent-memory deficit, amnesia of ictus and (in dominant hemisphere) aphasia usually lasts several mins
Neurologic and laboratory features
• neuro exam: normal except memory deficit
• MRI: hippocampal atrophy and signal alteration with ipsilateral dilatation of temporal horn of lateral ventricle
• unilateral or bilateral independent anterior temporal EEG spikes with maximal amplitude in basal electrodes
• external ictal EEG activity only with CPS, usually initial or delayed focal rhythmic onset pattern of 5-7 Hz, maximal in 1 basal temporal derivation
• interictal fluorodeoxyglucose PET scan: hypometabolism in temporal lobe and possibly ipsilateral thalamus and basal ganglia
• neuropsychological testing: memory dysfunction specific to involved temporal lobe
• Wada test: amnesia with contralateral amobarbital injection (*see page 421*)

EEG → polyspike discharges. Strong family history (some studies showing linkage to the HLA region on the short arm of chromosome 6). Most responsive to depakene.

WEST SYNDROME

This term is being used less frequently as it appears not to be a homogeneous group. Classically a seizure disorder that usually appears in first year of life, and consists of recurrent, gross flexion and occasionally extension of the trunk and limbs (massive myoclonus, AKA infantile spasms, AKA salaam seizures, AKA jackknife spasms). Seizures tend to diminish with age, often abating by 5 yrs. Usually associated with mental retardation. 50% may develop complex-partial seizures, some of the rest may develop Lennox-Gastaut syndrome (*see below*).

An associated brain lesion may be found in some.

EEG → the majority show either interictal **hypsarrhythmia** (huge spike/wave plus slow wave resembling muscle artifact) or modified hypsarrhythmia at some point.

Usually dramatic response of seizures and EEG findings to ACTH or corticosteroids.

LENNOX-GASTAUT SYNDROME

Rare condition that begins in childhood as atonic seizures ("drop attacks"). Often develops into tonic seizures with mental retardation. Seizures are often polymorphic, difficult to treat medically, and may occur as often as 50 per day. May also present with status epilepticus. Approximately 50% of patients have reduced seizures with valproic acid. Corpus callosotomy may reduce the number of atonic seizures.

TODD'S PARALYSIS

A post-ictal phenomena in which there is partial or total paralysis usually in areas involved in a partial seizure. More common in patients with structural lesions as the source of the seizure. The paralysis usually resolves slowly over a period of an hour or so. Thought to be due to depletion of neurons in the wake of the extensive electrical discharges of a seizure. Other similar phenomena include post-ictal aphasia and hemianopsia.

17.1.1. Factors that lower the seizure threshold

Factors that lower the seizure threshold (i.e. make it easier to provoke a seizure) in individuals with or without a prior seizure history include many items listed under *Etiologies* of *New onset seizures* (*see below*) as well as:

1. sleep deprivation
2. hyperventilation
3. photic stimulation (in some)
4. infection: systemic (febrile seizures, *see page 402*), CNS…
5. metabolic disturbances: electrolyte imbalance (especially profound hypoglycemia), pH disturbance (especially alkalosis), drugs… (*see below*)
6. head trauma: closed head injury, penetrating trauma (*see page 398*)
7. cerebral ischemia: CVA (*see below*)
8. "kindling": a concept that repeated seizures may facilitate the

development of later seizures

17.2. Special types of seizures

17.2.1. New onset seizures

The age adjusted incidence of new onset seizures in Rochester, Minnesota was 44 per 100,000 person years[8].

Etiologies: In patients presenting with a first-time seizure, etiologies include (modified[9]):

1. following neurologic insult: either acutely (i.e. < 1 week) or remotely (> 1 week, and usually < 3 mos from insult)
   A. cerebrovascular accident (CVA, or stroke): 4.2% had a seizure within 14 days of a CVA. Risk increased with severity of stroke[10]
   B. head trauma: closed head injury, penetrating trauma (*see page 398*)
   C. CNS infection: meningitis, cerebral abscess, subdural empyema
   D. febrile seizures: *see page 402*
   E. birth asphyxia
2. underlying CNS abnormality
   A. congenital CNS abnormalities
   B. degenerative CNS disease
   C. CNS tumor: metastatic or primary
   D. hydrocephalus
   E. AVM
3. acute systemic metabolic disturbance
   A. electrolyte disorders: uremia, hyponatremia, hypoglycemia (especially profound hypoglycemia), hypercalcemia
   B. drug related, including:
      1. alcohol-withdrawal: *see page 399*
      2. cocaine toxicity: *see page 276*
      3. opioids (narcotics), principally associated with the following:
         a. propoxyphene (Darvon®)
         b. meperidine (Demerol®): may also cause delerium
         c. the street drug combination “T’s and blues” (pentazocine

(Talwin®) + the antihistamine tripelennamine)
4. phenothiazine antiemetics
5. with administration of flumazenil (Romazicon®) to treat benzodiazepine **(BDZ)** overdose (especially when BDZs are taken with other seizure lowering drugs such as tricyclic antidepressants or cocaine
6. phencyclidine **(PCP)**: originally used as an animal tranquilizer
7. cyclosporine: can affect Mg^{++} levels

C. eclampsia

4. idiopathic

In 166 pediatric patients presenting to an emergency department with either a chief complaint of, or a discharge diagnosis of a first-time seizure[11]:

1. 110 were found to actually have either a recurrent seizure or a nonictal event
2. of the 56 patients actually thought to have had a first-time seizure
   A. 71% were febrile seizures
   B. 21% were idiopathic
   C. 7% were "symptomatic" (hyponatremia, meningitis, drug intoxication…)

In a prospective study of 244 patients with a new-onset unprovoked seizure, only 27% had further seizures during follow-up[9, 12]. Recurrent seizures were more common in patients with a family seizure history, spike-and-waves on EEG, or a history of a CNS insult (CVA, head injury…). No patient seizure-free for 3 years had a recurrence. Following a second seizure, the risk of further seizures was high.

EVALUATION

Adults

A new-onset seizure in an adult in the absence of obvious cause (e.g. alcohol withdrawal) should prompt a search for an underlying basis (the onset of idiopathic seizures, i.e. epilepsy, is most common before or during adolescence). A CT or MRI (without and with enhancement) should be performed. A systemic work-up should be done to identify the presence of any factors listed previously (*see above*). If all this is negative, then an MRI should be performed if not already done. If this is negative also, a repeat study (CT or MRI) should be done

in ≈ 6 months and at 1 and possibly 2 years to rule-out a tumor which might not be evident on the initial study.

Pediatrics

Among pediatric patients with first-time seizures, laboratory and radiologic evaluations were often costly and not helpful[11]. A detailed history and physical exam were more helpful.

Management

Management of an adult with the new onset of idiopathic seizures (i.e. no abnormality found on CT or MRI, no evidence of drug withdrawal) is controversial. In one study, an EEG was performed, which if normal was followed by a sleep deprived EEG with the following observations[13]:

1. there is substantial interobserver variation in interpreting such EEGs
2. if both EEGs were normal, the 2-yr recurrence rate of seizures was 12%
3. if one or both EEGs showed epileptic discharges, the 2-yr recurrence rate was 83%
4. the presence of nonepileptic abnormalities in one or both EEGs had a 41% 2-yr recurrence rate
5. the recurrence rate with focal epileptic discharges (87%) was slightly higher than for generalized epileptic discharges (78%)

The conclusion is that EEGs thus obtained have moderate predictive value, and may be factored into the decision of whether or not to treat such seizures with AEDs.

17.2.2. Posttraumatic seizures

Key concepts:

- 2 categories: early (≤ 7 days) and late (> 7 days) after head trauma
- anticonvulsants **(AEDs)** may be used to prevent early posttraumatic seizures **(PTS)** in patients at high risk for seizures (*see text*)
- prophylactic AEDs do NOT reduce the frequency of late PTS
- discontinue AEDs after 1 week except for cases meeting specific criteria (*see text*)

Posttraumatic seizures **(PTS)** are often divided (arbitrarily) into: early (occurring within 1 week of injury) and late (thereafter)[14]. There may be justification for a third category: "immediate", i.e. within minutes to an hour or so.

Early PTS (≤ 7 days after head trauma)

30% incidence in severe head injury ("severe" defined as: LOC > 24 hrs, amnesia > 24 hrs, focal neuro deficit, documented contusion, or intracranial hematoma) and ≈ 1% in mild to moderate injuries. Occurs in 2.6% of children < 15 yrs age with head injury causing at least brief LOC or amnesia[15].

Early PTS may precipitate adverse events as a result of elevation of ICP, alterations in BP, changes in oxygenation, and excess neurotransmitter release[16].

Late onset PTS (> 7 days after head trauma)

Estimated incidence 10-13% within 2 yrs after "significant" head trauma (includes LOC > 2 mins, GCS < 8 on admission, epidural hematoma…) for all age groups[17, 18]. Relative risk: 3.6 times control population. Incidence in severe head injury >> moderate > mild[15].

The incidence of early PTS is higher in children than adults, but late seizures are much less frequent in children (in children who have PTS, 94.5% develop them within 24 hrs of the injury[19]). Most patients who have not had a seizure within 3 yrs of penetrating head injury will not develop seizures[20]. Risk of late PTS in children does not appear related to the occurrence of early PTS (in adults: only true for mild injuries). Risk of developing late PTS may be higher after repeated head injuries.

Penetrating trauma

The incidence of PTS is higher with penetrating head injuries than with closed head injuries (occurs in 50% of penetrating trauma cases followed 15 yrs[21]).

TREATMENT

A prospective double blind study of patients at high risk of PTS (excluding penetrating trauma) showed a 73% reduction of risk of early PTS by administering 20 mg/kg loading dose of PHT within 24 hrs of injury and maintaining high therapeutic levels; but after 1 week there was no benefit in

continuing the drug (based on intention to treat)[22]. Carbamazepine (Tegretol®) has also been shown to be effective in reducing the risk of early PTS, and valproic acid is currently being studied[16].

Phenytoin has adverse cognitive effects when given long-term as prophylaxis against PTS[23].

TREATMENT GUIDELINES

Based on available information (*see above*) it appears that:

1. no treatment studied effectively impedes epileptogenesis
2. in high-risk patients (*see Table 17-2*), AEDS reduces the incidence of early PTS
3. however, no study has shown that reducing early PTS improves outcome[24]
4. once epilepsy has developed, continued AEDs reduces the recurrence of seizures

The following are therefore offered as guidelines.

Initiation of AEDs

AEDs may be considered for short term use especially if a seizure could be detrimental[A]. Early posttraumatic seizures were effectively reduced when phenytoin was used for 2 weeks following head injury with no significant increased risk of adverse effects[25].

A. acutely, seizures may elevate ICP, and may adversely affect blood pressure and oxygen delivery, and may worsen other injuries (e.g. spinal cord injury in the setting of an unstable cervical spine)[16]

Option: begin AEDs (usually phenytoin or carbamazepine) within 24 hrs of injury in the presence of any of the high risk criteria shown in *Table 17-2* (modified[16, 19, 22, 26]). When using PHT, load with 20 mg/kg and maintain high therapeutic levels (*see page 409*). Switch to phenobarbital if PHT not tolerated.

Table 17-2 High risk criteria for PTS

1. acute subdural, epidural, or intracerebral hematoma
2. open-depressed skull fracture with parenchymal injury
3. seizure within the first 24 hrs after injury
4. Glasgow Coma Scale score < 10

5. penetrating brain injury
6. history of significant alcohol abuse
7. ± cortical (hemorrhagic) contusion on CT

Discontinuation of AEDs

1. taper AEDs after 1 week of therapy except in the following:
   A. penetrating brain injury
   B. development of late PTS (i.e. a seizure > 7 days following head trauma)
   C. prior seizure history
   D. patients undergoing craniotomy[27]
2. for patients not meeting the criteria to discontinue AEDs after 1 week (*see above*):
   A. maintain ≈ 6-12 mos of therapeutic AED levels
   B. recommend EEG to rule-out presence of a seizure focus before discontinuing AEDs (predictive value) for the following:
      1. repeated seizures
      2. presence of high risk criteria shown in *Table 17-2*.

17.2.3. Alcohol withdrawal seizures

Also, see *Alcohol withdrawal syndrome*, page 273. The withdrawal syndrome may begin hours after the EtOH peak (*see page 274* for prevention and treatment). Ethanol withdrawal seizures are classically seen in up to 33% of habituated drinkers within 7-30 hours of cessation or reduction of ethanol intake. They typically consist of 1-6 tonic-clonic generalized seizures without focality within a 6 hour period[28]. Seizures usually occur before delerium develops. They may also occur during intoxication (without withdrawal).

The seizure risk persists for 48 hrs (risk of delerium tremens **(DTs)** continues beyond that), thus a single loading dose of PHT is frequently adequate for prophylaxis. However, since most EtOH withdrawal seizures are single, brief, and self-limited, PHT has not been shown to be of benefit in uncomplicated cases and is thus usually not indicated. Chlordiazepoxide (Librium®) or other benzodiazepines administered during detoxification reduces the risk withdrawal seizures[29] (*see page 274*).

Evaluation

The following patients should have a CT scan of the brain, and should be admitted for further evaluation as well as for observation for additional seizures or for DTs:

1. those with their first EtOH withdrawal seizure
2. those with focal findings
3. those having more than 6 seizures in 6 hrs
4. those with evidence of trauma

Other causes of seizure should also be considered, e.g. a febrile patient may require an LP to R/O meningitis.

Treatment

A brief single seizure may not warrant treatment, except as outlined below. A seizure that continues beyond 3-4 minutes may be treated with diazepam or lorazepam, with further measures used as in status epilepticus (*see page 402*) if seizures persist. Loading with phenytoin (18 mg/kg = 1200 mg/70 kg, *see page 409*) and long-term treatment is indicated for:

1. a history of previous alcohol withdrawal seizures
2. recurrent seizures after admission
3. history of a prior seizure disorder unrelated to alcohol
4. presence of other risk factors for seizure (e.g. subdural hematoma)

17.2.4. Nonepileptic seizures

AKA pseudoseizures (some prefer not to use this term since it may connote voluntary feigning of seizures), with the term psychogenic seizures being preferred for nonepileptic seizures **(NES)** with a psychologic etiology (psychogenic seizures are real events and may not be under voluntary control)[30].

The hazard of NES is that patients may end up needlessly taking AEDs, which in some cases may worsen NES. Possible etiologies of NES are given in *Table 17-3*. Most NES are psychogenic.

DDx for seizures:

1. psychogenic: 20-90% of patients with intractable seizures referred to epilepsy centers. These patients carry the diagnosis of seizures from 5-7 years. Up to 50% of these may have legitimate seizures at some time as

well[31].

2. tic: can be suppressed, is not repetitive (if repetitive, may be hemifacial spasm)
3. movement disorder: myoclonus (can be epileptic or non-epileptic)
   A. cataplexy: e.g. with narcolepsy often provoked by laughter or other emotional stimulus (can rarely be caught on EEG, when it is it shows REM intrusion into wakefulness)
   B. parasomnia: a sleep movement disorder (occurs during sleep). Includes: night terrors (occurs in slow wave sleep, vs. nightmare which occurs in REM), sleep walking, REM behavior disorders (usually occurs in older men, and there is a high prob-ability they will go on to have degenerative brain disease (used to be called paroxysmal nocturnal PNT). Head banging is a benign parasomnia
4. syncope: 90% of the time people who faint have myoclonic jerks or shaking[32]
5. TIA

Table 17-3 Differential diagnosis of nonepileptic seizures[30]

1. psychologic disorders (psychogenic seizure) A. somatoform disorders: especially conversion disorder B. anxiety disorders: especially panic attack and posttraumatic stress disorder C. dissociative disorders D. psychotic disorders E. impulse control disorders F. attention-deficit disorders* G. factitious disorders: including Munchausen's syndrome
2. cardiovascular disorders A. syncope B. cardiac arrhythmias C. transient ischemic attacks D. breath-holding spells*
3. migraine syndromes A. complicated migraines* B. basilar migraines
4. movement disorders A. tremors B. dyskinesias C. tics*, spasms D. other (including shivering)
5. parasomnias & sleep-related disorders A. night terrors*, nightmares*, somnambulism* B. narcolepsy, cataplexy C. rapid eye movement behavior disorder D. nocturnal paroxysmal dystonia
6. gastrointestinal disorders A. episodic nausea or colic*

	B. cyclic vomiting syndrome*
7. other	
	A. malingering
	B. cognitive disorders with episodic behavioral or speech symptoms
	C. medication effects or toxicity
	D. daydreams*

* usually encountered in children

DIFFERENTIATING NES FROM EPILEPTIC SEIZURES

Distinguishing between epileptic seizures **(ES)** and NES is a common clinical dilemma. There are unusual seizures that may fool experts[33]. Some frontal lobe and temporal lobe complex partial seizures may produce bizarre behaviors that do not correspond to classic ES findings and may not produce discernible abnormalities with scalp-electrode EEG (and therefore may be misdiagnosed even with video-EEG monitoring, although this is more likely with partial seizures than with generalized). A multidisciplinary team approach may be required.

History: Attempt to document: prodromal symptoms, precipitating factors, time and environment of Sz, mode and duration of progression, ictal and postictal events, frequency and stereotypy of manifestations. Determine if patient has history of psychiatric conditions, and if they are acquainted with individuals who have ES.

Psychological testing: May help. Differences occur in ES and NES on the Minnesota Multiphasic Personality Inventory **(MMPI)** scales in hypochondriasis, depression hysteria, and schizophrenia[34].

Table 17-4 contrasts some features of true seizures vs. NES, and *Table 17-5* lists some features often associated with NES, however, no characteristics are definitively diagnostic of NES since a number of them may also occur with ES.

Features common to both true seizures and NES: verbal unresponsiveness, rarity of automatisms and whole-body flaccidity, rarity of urinary incontinence. Reminder: some seizures can be bizarre and can resemble NES (sometimes called pseudo-pseudoseizures). 10% of patients with psychogenic seizures actually have epilepsy.

Table 17-4 Features of ES vs. NES[31]

Feature	Epileptic seizure	NES
% males	72%	20%

Clonic UE movement		
inphase	96%	20%
out-of-phase	0	56%
Clonic LE movement		
inphase	88%	16%
out-of-phase	0	56%
Vocalizations		
none	16%	56%
start of seizure	24%	44%
middle	60% "epileptic cry"	0
types	only sounds of tonic or clonic respiratory muscle contraction	moans, screams, grunts, snorts, gagging, retching, understandable statements, gasps
Head turning		
unilateral	64%	16%
side-to-side	8% (slow, low amplitude)	36% (violent, high amplitude)

Features suggestive of non-epileptic seizures:

1. arching of the back: 90% specific for NES
2. asynchronous movement
3. stop & go: seizures usually build and then gradually subside
4. forced eye closing during entire seizure
5. provoked with stimuli that would not cause a seizure (e.g. tuning fork to the head, alcohol pad to the neck, IV saline…)
6. bilateral shaking with preserved awareness. Exception: supplementary motor area seizures (mesial frontal area) these seizures are usually tonic (not clonic)
7. weeping (whining): highly specific
8. multiple or variable seizure types (ES is usually stereotypical), fluctuating level of consciousness, denial of correlation of Sz with stress

If any two of the following are demonstrated, 96% of time this will be NES:

1. out-of-phase clonic UE movement
2. out-of-phase clonic LE movement
3. no vocalization or vocalization at start of event

Lateral tongue laceration is very specific for seizures.

Table 17-5 Features often associated with NES[30]

• frequent seizures despite therapeutic AEDs
• multiple different-physician visits
• lingering prodrome or gradual ictal onset (over minutes)
• prolonged duration (> 5 mins)
• manifestations altered by distraction
• suggestible or inducible seizures
• intermittent arrhythmic and out-of-phase activity
• fluctuating intensity and severity during Sz
• side-to-side rolling, pelvic thrusting, wild movements
• bilateral motor activity with preserved consciousness
• nonphysiologic spread of neurologic signs
• absence of labored breathing or drooling after generalized convulsion
• expression of relief or indifference
• crying or whimpering
• no postictal confusion or lethargy
• disproportionate postictal mental status changes
• absence of stereotypy

Prolactin levels after seizures

Transient elevations in human serum prolactin **(HSP)** levels occur following 80% of generalized motor, 45% of complex partial, and only 15% of simple partial seizures[35]. Peak levels are reached in 15-20 minutes, and gradually return to baseline over the subsequent hour[36-38]. It has been suggested that drawing a serum prolactin level shortly after a questionable seizure may be helpful in differentiating NES (which may have elevated cortisol levels but normal HSP levels[39]).

Repetitive seizures are associated with progressively smaller HSP elevations[40], and no rise follows absence seizures or status epilepticus (whether convulsive or absence)[41]. Greater than twofold HSP elevations consistently follow seizures that produce intense widespread high frequency mesial temporal lobe discharges; whereas such elevations do not occur in seizures not involving these limbic structures[42].

Furthermore, there may be higher baseline HSP levels in cases with right-sided interictal EEG discharges compared to those with left-sided[43], and the presence of psycho-pathology may affect postictal HSP elevations[44].

Therefore, the presence of HSP peaks may be strongly indicative of true

seizures, but the absence may be due to a variety of complex phenomena[45]. The overall classification accuracy is ≈ 72%[38].

17.2.5. Febrile seizures

Definitions[46]

febrile seizure	a seizure in infants or children associated with fever with no defined cause and unaccompanied by acute neurologic illness (includes seizures during vaccination fevers)
complex febrile seizure	a convulsion that lasts longer than 15 minutes, is focal, or multiple (more than one convulsion per episode of fever)
simple febrile seizure	not complex
recurrent febrile seizure	more than one episode of fever associated with seizures

Epidemiology[46]

Febrile convulsions are the most common type of seizure. Excluding children with pre-existing neurologic or developmental abnormalities, the prevalence of febrile seizures is ≈ 2.7% (range: 2-5% in U.S. children aged 6 mos-6 yrs). The risk for developing epilepsy after a simple febrile seizure is ≈ 1%, and for a complex febrile seizure is 6% (9% for prolonged seizure, 29% for focal seizure). An underlying neurological or developmental abnormality or a family history of epilepsy increases the risk of developing epilepsy.

Treatment

In one study, the IQ in the group treated with phenobarbital was 8.4 points lower (95% confidence interval) than the placebo group, and there remained a significant difference several months after discontinuing the drug[47]. Furthermore, there was no significant reduction in seizures in the phenobarbital group. And yet, no other drug really appears well suited to treating this entity: carbamazepine and phenytoin appear ineffective, valproate may be effective but has serious risks in the < 2 yrs age group. Given the low incidence (1%) of

having *afebrile* seizures (i.e. epilepsy) after a simple febrile seizure and the fact that AEDs probably do not prevent this development, there is little support for prescribing anticonvulsants in these cases. The recurrence rate of febrile seizures in children with a history of one or more febrile seizure can be reduced by administering diazepam 0.33 mg/kg PO q 8 hrs during a febrile episode (temp > 38.1° C) and continuing until 24 hrs after the fever subsides[48].

17.3. Status epilepticus

Key concepts:

- definition: Sz > 5 mins, or persistent Sz after 1st & 2nd line AEDs
- morbidity and mortality are high in untreated status epilepticus **(SE)**
- most common etiology: patient with known Sz disorder with low AED levels
- de novo SE in acute illness is considered a manifestation of the illness which should be treated at the same time as the SE
- see *Table 17-6*, page 405 for treatment measures

Definition: a seizure lasting > 5 minutes or persistent seizure activity after sequential administration of appropriate first and second-line AEDs[49].

Features important to management

- seizures that do not cease in 5-10 mins are less likely to terminate[50]
- in patients with no prior Sz history, status epilepticus **(SE)** is usually a manifestation of illness-related cortical irritation or injury[49] and treatment of the underlying disorder (in addition to treating the SE) is critical
- a relapse of Sz. in a patient with a known Sz. disorder and subtherapeutic AED levels usually responds to a bolus of the maintenance AEDs. However, SE should be treated by the standard protocol[49]
- most cases of convulsive status in adults start as partial seizures that generalize
- the choice of 1st and 2nd-line AEDs is arbitrary, and the dose is the more important determinant of success in aborting SE[49]

Types of status epilepticus

• generalized status

1. convulsive: generalized convulsive tonic-clonic status epilepticus **(SE)** is the most frequent type[51]. A medical emergency
2. absence[A]
3. secondarily generalized: accounts for ≈ 75% of generalized SE
4. myoclonic
5. atonic (drop attack): especially in Lennox-Gastaut syndrome (*see page 396*)

• partial status (usually related to an anatomic abnormality)

1. simple (AKA **epilepsy partialis continuans**)
2. complex[A]: most often from frontal lobe focus. Urgent treatment is required
3. secondarily generalized

A. in status, these may present in **twilight state**

Epidemiology

Incidence is ≈ 150,000 new cases/year in the U.S. in the outpatient setting[49]. Most cases occur in young children (among children, 73% were < 5 yrs old[52]), the next most affected group is patients > 60 yrs age. In > 50% of cases, SE is the patient's first seizure[51]. One out of six patients presenting with a first time seizure will present in SE

Etiologies

1. the most common etiology is a patient with a known seizure disorder having low AED levels for any reason (non-compliance, intercurrent infection preventing PO intake of meds, drug-drug interactions → lowering effectiveness of AEDs…)
2. febrile seizures: a common precipitator in young patients. 5-6% of patients presenting with SE have a history of prior febrile seizures
3. cerebrovascular accidents: the most commonly identified cause in the elderly
4. CNS infection: in children, most are bacterial, the most common organisms were *H. influenza* and *S. pneumoniae*

5. idiopathic: accounts for ≈ one-third (in children, usually associated with fever)
6. epilepsy: is present or is subsequently diagnosed in ≈ 50% of patients presenting with SE. About 10% of adults ultimately diagnosed as having epilepsy will present in SE
7. **electrolyte imbalance**: hyponatremia (most common in children, usually due to water intoxication[52]), hypoglycemia, hypocalcemia, uremia, hypomagnesemia…
8. illicit drug intoxication: especially cocaine, amphetamines
9. precipitous drug withdrawal: barbiturates, benzodiazepines, alcohol or narcotics
10. proconvulsant drugs, including: ß-lactam antibiotics (penicillins, cephalosporins), certain antidepressants (bupropion), clonazapine, bronchodilators, immunosuppressants
11. traumatic brain injury: acute as well as old
12. hypoxia/ischemia
13. tumor

In children < 1 yr age, 75% had an acute cause: 28% were secondary to CNS infection, 30% due to electrolyte disorders, 19% associated with fever[52]. In adults, a structural lesion is more likely. In an adult, the most common cause of SE is subtherapeutic AED levels in a patient with a known seizure disorder.

Morbidity and mortality from SE

Mean duration of SE in patients without neurologic sequelae is 1.5 hrs (therefore, proceed to pentobarbital anesthesia before ≈ 1 hour of SE). Recent mortality: < 10-12% (only ≈ 2% of deaths are directly attributable to SE or its complications; the rest are due to the underlying process producing the SE). Mortality in lowest amongst children (≈ 6%[52]), patients with SE related to subtherapeutic AEDs, and patients with unprovoked SE[53]. The highest mortality occurs in elderly patients and those with SE resulting from anoxia or CVA[53]. 1% of patients die during the episode itself.

Morbidity and mortality is due to[54]:

1. CNS injury from repetitive electric discharges: irreversible changes begin to appear in neurons after as little as 20 minutes of convulsive activity. Cell death is very common after 60 mins
2. systemic stress from the seizure (cardiac, respiratory, renal, metabolic)

3. CNS damage by the acute insult that provoked the SE

17.3.1. General treatment measures for status epilepticus

Treatment is directed at stabilizing the patient, stopping the seizure, and identifying the cause (determining if there is an acute insult to the brain) and if possible also treating the underlying process. Treatment often must be initiated prior to the availability of test results to confirm the diagnosis.

- CPR if needed
- neurologic exam
- "ABC's"
  - **A** irway: oral airway if feasible. Turn patient on their side to avoid aspiration
  - **B** reathing: O_2 by nasal cannula or bag-valve-mask. Consider intubation if respirations compromised or if seizure persists > 30 min
  - **C** irculation: large bore proximal IV access (2 if possible): start with NS KVO
- monitor: EKG & baseline vital signs. Pulse oximeter. Frequent blood pressure checks
- bloodwork: STAT capillary blood (fingerstick) glucose (to R/O hypoglycemia), electrolytes (including glucose), CBC, LFTs, Mg^{++}, Ca^{++}, AED levels, ABG
- head CT (usually without contrast)
- correct any electrolyte imbalance (SE due to electrolyte imbalance responds more readily to correction than to AEDs[52])
- if CNS infection is a major consideration, perform LP for CSF analysis (especially in febrile children) unless contraindicated (*see page 201*). WBC pleocytosis up to 80 x 106/L can occur following SE (benign postictal pleocytosis), and these patients should be treated with antibiotics until infection can be ruled out by negative cultures
- <u>general</u> meds for unknown patient:
  1. glucose:
     A. in patients with poor nutrition (e.g. alcoholics): giving glucose in thiamine deficiency can precipitate Wernicke's encephalopathy (*see page 275*) ∴ prior to glucose bolus give thiamine 50-100 mg IV
     B. if fingerstick glucose can be obtained immediately and it shows hypoglycemia, or if no fingerstick glucose can be done: give 25-50 ml

of D50 IV push for adults (2 ml/kg of 25% glucose for peds). If at all possible, draw blood for definitive serum glucose first

2. naloxone (Narcan®) 0.4 mg IVP (in case of narcotics)
3. ± bicarbonate to counter acidosis (1-2 amps depending on length of seizure)
4. for neonate < 2 years: consider pyridoxine 100 mg IV push (pyridoxine-dependent seizures constitute a rare autosomal recessive condition that generally presents in the early neonatal period[50])

- administer specific anticonvulsants for seizures lasting > 5-10 mins (*see below*)
- EEG monitor if possible
- if paralytics are used (e.g. to intubate), use short acting agents and be aware that muscle paralysis alone may stop visible seizure manifestations, but does not stop the electrical seizure activity in the brain, which can lead to permanent neurologic damage if prolonged (*see above*)

17.3.2. Medications for generalized convulsive status epilepticus

There are no randomized trials for refractory status epilepticus, although there is published data regarding specific treatment options. Numerous protocols exist. *Table 17-6* shows a summary of medications for a status epilepticus protocol that is outlined in further detail below (modified management scheme[49]). Items below in boxes are considered treatment of choice. "Adult" refers to patients > 16 yrs of age. Drugs should be given IV (do not use IM route). If IV access is impossible, diazepam solution (not suppository) or Diastat® (diazepam rectal) can be given rectally or intranasal, buccal[55] or rectal midazolam (Versed®) can be given.

Rapid treatment is indicated as delays are associated with neuronal injury and reduced response to medications.

Table 17-6 Summary of initial steps for status epilepticus (adult) (*see text* for details)

ABC's. Start O_2. Turn patient on their side. Check VS. Do a neuro exam
Monitor/labs: Pulse oximetry. EKG/telemetry. ✔ Fingerstick glucose. Blood tests (do not wait for results to begin Rx): ✔ electrolytes, ✔ CBC, ✔ ABG, ✔ AED levels, ✔ LFTs, ✔ Mg^{++}, ✔ Ca^{++}, ✔ head CT
Large bore IV X 2. Start IV fluids

• **thiamine** 100 mg IV and/or 50 ml of 50% dextrose (if needed)
First-line AED: • **lorazepam** (Ativan®) 0.1 mg/kg IV @ < 2 mg/min
Second-line AED: (may be given simultaneously with first-line drug or 1 minute after end of lorazepam bolus if Sz persist) • **phenytoin***/fosphenytoin 20 mg/kg IV loading dose starting at 25 mg/min for phenytoin, or 75 mg/min for fosphenytoin • then, titrate phenytoin/fosphenytoin infusion up to max* as tolerated
✔ phenytoin level ≈ 10 min after PHT loading dose
± 3rd line AED. NB: only 7% chance of stopping Sz with 3rd line drugs. (Consider: skipping 3rd line and intubate & start CIT below). Select one: • phenobarbital: up to 20 mg/kg IV (start infusing @ < 100 mg/min • sodium valproate 15-30 mg/kg IV bolus (max rate: 6 mg/kg/min) • levetiracetam 20mg/kg IV bolus of over 15 minutes
CIT: If seizures continue > 30 mins or if skipping 3rd line drugs: intubate in ICU and begin continuous infusion therapy **(CIT)** of midazolam, pento-barbital or propofol (*see text*). If Sz persist, ensure that correctable conditions have been ruled-out and/or treated; continue to following steps
alternative CIT: carbamazepine, oxcarbazepine, topiramate, lamotrigine…
novel therapeutic options (not systematically studies): shock therapy…

* maximum rate for phenytoin IV is 50 mg/min; for fosphenytoin it is 150 mg PE/min (*see page 411*) if BP stable

Protocol for status epilepticus (SE) in <u>adult</u>[49]

Prehospital phase:

1. impending SE: may be heralded by a crescendo in Sz. A 1-3 d course of lorazepam may preempt the development of SE
2. SE treatment may be initiated with buccal midazolam or rectal diazepam

Hospital phase:

Start IV drugs at half the maximal rate, and titrate up to maximal rate if VS stable.

1. First line drugs
   A. benzodiazepine[56] (main side effect: respiratory depression in ≈ 12%; be prepared to intubate). Onset of action is rapid (1-2 mins):

• **lorazepam** (Ativan®) **0.1 mg/kg** (about 4 mg for average adult) IV @ rate < 2 mg/min (range: 0.02-0.12 mg/kg)

OR diazepam (Valium®) 0.1 mg/kg (7 mg average adult dose) IV @ rate < 50 mg/min. IV diazepam redistributes rapidly and SE may recur within a few minutes. Rectal dose (usually absorbed in ≈ 10 mins): 0.5 mg/kg of diazepam solution up to 20 mg max, or

Diastat® 0.2 mg/kg

OR midazolam (Versed®) 0.05 mg/kg IV @ < 0.01 mg/min, or 10 mg buccal

- Wait 1 minute for response. If Sz continue, given additional doses of lorazepam up to a maximum of 9 mg (adult)

2. Second line drugs: either start simultaneously with 1st line drugs, or give if Sz persist 1 minute after first-line benzodiazepine dose
   A. in second IV site: load with phenytoin (Dilantin®) **(PHT)**[57] as follows (do not worry about acutely overdosing, but do follow dosing rates, monitor BP for hypotension and EKG for arrhythmias). Conventional phenytoin can only be given in NS to prevent precipitation. After giving the following loading dose, start on maintenance (*see page 409*)

      1. **phenytoin** load with **20 mg/kg** (if not already on PHT): (1400 mg for 70 kg adult) (use 15 mg/kg for elderly patients), maximum rate for phenytoin **< 50 mg/min** (fosphenytoin max rate is 150 mg PE/min)
      2. if on PHT and a recent level is known: a rule of thumb is giving 0.74 mg/kg to an adult raises the level by ≈ 1 μg/ml
      3. if on PHT and level not known: adult: give 500 mg @ < 50 mg/min[A]

3. Third line drugs: only 7% of patients who have not responded to the above will respond to a 3rd line drug[56]. Therefore, third line drugs may be skipped and one may proceed directly to CIT (*see below*)
   A. PHT additional doses of 5 mg/kg @ < 50 mg/min up to a total of 30 mg/kg
   B. one of the following[B]

      - phenobarbital: up to 20 mg/kg IV (1400 mg for 70 kg) (start infusing @ < 100 mg/min until seizures stop), takes 15-20 min to work, watch BP (a myocardial depressant).
        Peds: 5-10 mg/kg/dose q 20-30 min to max total 30-40 mg/kg.

        Phenobarbital may be preferred to PHT in patients with PHT hypersensitivity, cardiac conduction abnormality, and in neonates and young children. Maintenance phenobarbital therapy should be instituted with 24 hours of the loading dose (*see page 413*), OR
      - sodium valproate 15-30 mg/kg IV bolus (max rate of 6 mg/kg/min), followed by maintenance dose of 500 mg TID, OR

• levetiracetam 20mg/kg IV bolus of over 15 minutes, followed by maintenance dose of 1500 mg BID

C. initiate EEG monitoring in the ICU

4. Continuous infusion therapy **(CIT)**: if seizures continue > 30 minutes, intubate and begin any one of the following:

• midazolam: load with 0.2 mg/kg slow IV bolus, maintenance 0.1-0.4 mg/kg/hr, titrate up to a maximum of 2.0 mg/kg/hr

• propofol: loading dose: 1-2 mg/kg IV at 10 mg/min, maintenance 2-10 mg/kg/h, maximum dose: 15 mg/kg/h (varies according to institution)

• pentobarbital: load with 3 mg/kg IV at a rate of 25 mg/min, maintenance 0.3-3 mg/kg/hr. Monitor BP, for hypotension give fluids and dopamine (*see page 884* for additional measures such as PA catheter)

5. if seizures continue: additional drugs that may be tried include carbamazepine, oxcarbazepine, topiramate, levetiracetam, lamotrigine, gabapentin…

6. novel treatments: lidocaine infusion, inhalational anesthesia, direct brain stimulation, transcranial magnetic stimulation, electroconvulsive therapy (shock therapy), surgical intervention if a seizure focus is identified

---

A. the risk of acute phenytoin toxicity in the hospital setting is lower than that of continued SE, the therapeutic levels used for drugs is based on chronic treatment in the outpatient setting[49]

B. using both phenobarbital and a benzodiazepine (e.g. diazepam) is discouraged because of increased risk of respiratory depression

---

Efficacy

Diazepam stops seizures within 3 mins in 33%, within 5 mins in 80%. PHT stops seizures in 30% after 400 mg has been given. 63% of generalized tonic-clonic SE respond to benzodiazepine + PHT. PHT is slower to control status than diazepam, but lasts longer.

Lorazepam

Among benzodiazepines, lorazepam **(LZP)** is preferred (diazepam **(DZP)** redistributes rapidly in fatty tissues[58], and seizures may recur within 10-20 minutes), but causes longer sedation. LZP aborts SE in 97% of cases, vs. 68% for DZP[59]. Also, less respiratory depression than with DZP. As with all

benzodiazepines:

1. respiratory depression and hypotension are exacerbated when used with other depressants (including barbiturates…)
2. effectiveness in SE is reduced by prior maintenance on other benzodiazepines (e.g. clonazepam), but is not affected by the presence of other anticonvulsants
3. tachyphylaxis may develop so that subsequent doses are less effective[60]

Medications to avoid in status epilepticus

1. narcotics
2. phenothiazines: including promethazine (Phenergan®)
3. neuromuscular blocking agents without AED therapy: seizures may continue and cause neurologic injury but would not be clinically evident (*see page 404*)

17.3.3. Miscellaneous status epilepticus

Myoclonic status

Treatment: valproic acid (drug of choice). Place NG, give 20 mg/kg per NG loading dose. Maintenance: 40 mg/kg/d divided (*see page 412*).

Can add lorazepam (Ativan®) or clonazepam (Klonopin®) to help with acute control.

Absence status epilepticus

Almost always responds to diazepam.

17.4. Antiepileptic drugs (AEDs)

The goal of AEDs is seizure control (a contentious term, usually taken as reduction of seizure frequency and severity to the point to permit the patient to live a normal lifestyle without epilepsy-related limitations) with minimal or no drug toxicity. ≈ 75% of epileptics can achieve satisfactory seizure control with medical therapy[61].

17.4.1. Classification of AEDs

AEDs can be grouped as shown in *Table 17-7*.

The following agents are considered "broad spectrum" (treat a variety of seizure types):

1. valproic acid
2. lamotrigine (Lamictal®)
3. levetiracetam (Keppra®)

These agents are not considered broad spectrum:

1. phenytoin (Dilantin® and others)
2. carbamazepine (Tegretol®)

Agents that interfere with platelet function and may ↑ the risk of bleeding complications:

1. valproic acid
2. phenytoin (Dilantin® and others)

17.4.2. Choice of antiepileptic drug

Antiepileptic drugs (AED) for various seizure types

Boldface drugs are drug of choice **(DOC)**.

1. primary generalized
   A. GTC (generalized tonic-clonic):
      1. **valproic acid** (VA): if no evidence of focality some studies show fewer side effects and better control than PHT (*see page 412*)
      2. carbamazepine: *see page 411*
      3. **phenytoin** (PHT): *see page 409*
      4. phenobarbital (PB): *see page 413*
      5. primidone (PRM): *see page 413*

   B. absence:
      1. **ethosuximide**
      2. **valproic acid** (VA)
      3. clonazepam
      4. methsuximide: *see page 414*

   C. myoclonic → benzodiazepines

D. tonic or atonic:
1. benzodiazepines
2. felbamate: *see page 414*
3. vigabatrin: *see page 417*

2. partial (simple or complex, with or without secondary generalization)[62] (VA may compare favorably with CBZ for secondarily GTC, but is less effective for complex partial seizures[63]):

A. **carbamazepine** (CBZ)	most effective, least side effects
C. phenobarbital (PB)	↓
B. **phenytoin** (PHT)	↓
D. primidone (PRM)	slightly less effective, more side effects

3. second line drugs for any of the above seizure types:
A. valproate
B. lamotrigine[A]: *see page 417*
C. topiramate[A]: *see page 417*

A. effective for many types of generalized seizures, but are not FDA approved for this yet

Table 17-7 Classification of AEDs

Drug	Indications*	Page
• Barbiturates		
pentobarbital (Nembutal®)	**status**	
phenobarbital	**status**, **GTC**, **partial Sz**, febrile Sz, neonatal Sz	413
primidone (Mysoline)®		413
• Benzodiazepines		
clonazepam (Klonopin®)	**Lennox-Gastaut**, **akinetic**, **myoclonic**	415
clorazepate (Tranxene-SD®)	**adj - partial Sz**	
diazepam (Valium®)	**status**	405
lorazepam (Ativan®)	**status**	405
• GABA analogues		
gabapentin (Neurontin®)	**adj - partial Sz**	416
tiagabine (Gabitril®)	**adj - partial Sz**	418
• Hydantoins		

fosphenytoin (Cerebyx®)	**status**, **Sz during neurosurgery**, **short-term replacement for oral PHT**	411
phenytoin (Dilantin®)	**GTC**, **CP**, **Sz during or after neurosurgery**	409
• Phenyltriazenes		
lamotrigine (Lamictal®)	**adj - partial Sz**, **adj - Lennox-Gastaut**	417
• Succinimides		
ethosuximide (Zarontin®)	**ABS**	414
methsuximide (Celontin®)	**ABS** refractory to other drugs	414
• Miscellaneous		
acetazolamide (Diamox®)		416
carbamazepine (Tegretol®, Carbatrol®)	**partial Sz + complex symptomology**, **GTC**, **mixed Sz**, ✖ not for absence	411
felbamate (Felbatol®)	use only with extreme caution - *see text*	414
levetiracetam (Keppra®)	**adj - partial Sz**	415
oxcarbazepine (Trileptal®)	**mono or adj - partial Sz**	412
topiramate (Topamax®)	**adj - partial Sz** or **primarily GTC**	417
valproate (Depakene®…)	**CP (alone or with other types)**, **ABS**, **adj - multiple Sz types**	412
zonisamide (Zonegran®)	**adj - partial Sz**	

* Indications for seizure types (does not include other uses, e.g. for chronic pain). FDA approved indications are in bold, off-label indications appear in plain text.
Abbreviations: ABS = absence, adj = adjunctive therapy, CP = complex partial, GTC = generalized tonic-clonic, PHT = phenytoin, Sz = seizure, status = status epilepticus

17.4.3. Anticonvulsant pharmacology[64]

GENERAL GUIDELINES

Monotherapy versus polytherapy

1. increase a given medication until seizures are controlled or side effects become intolerable (do not rely solely on therapeutic levels, which is only the range in which most patients have seizure control without side effects)
2. try monotherapy with a different drugs before resorting to two drugs together. 80% of epileptics can be controlled on monotherapy, however, failure of monotherapy indicates an 80% chance that the seizures will not be controllable pharmaco-logically. Only ≈ 10% benefit significantly from

the addition of a second drug[63]. When > 2 AEDs are required, consider nonepileptic seizures (*see page 400*)

3. when first evaluating patients on multiple drugs, withdraw the most sedating ones first (usually barbiturates and clonazepam)

Generally, dosing intervals should be less than one half-life. Without loading dose, it takes about 5 half-lives to reach steady state.

Many AEDs affect liver function tests **(LFTs)**, however, only rarely do the drugs cause enough hepatic dysfunction to warrant discontinuation. Guideline: discontinue an AED if the GGT exceeds twice normal.

SPECIFIC ANTICONVULSANTS

Table 17-8 Abbreviations

AED = antiepileptic drug; **ABS** = absence; **EC** = enteric coated; **DIV** = divided; **DOC** = drug of choice; **GTC** = generalized tonic-clonic seizure; **S/C-P** = simple or complex partial.
Pharmacokinetics: Unless otherwise specified, numbers are given for oral dosing form. $\mathbf{t_{1/2}}$ = half-life; $\mathbf{t_{PEAK}}$ = time to peak serum level; $\mathbf{t_{SS}}$ = time to steady state (approximately 5 **x** $t_{1/2}$); $\mathbf{t_{D/C}}$ = time to discontinue (recommended withdrawal period over which drug should be tapered); **MDF** = minimum dosing frequency. "Therapeutic level" is the average therapeutic range.

phenytoin (PHT) (Dilantin®) DRUG INFO

INDICATIONS

GTC, S/C-P, occasionally in ABS.

PHARMACOKINETICS

Pharmacokinetics are complicated: at low concentrations, kinetics are 1st order (elimination proportional to concentration), metabolism saturates near the therapeutic level resulting in zero-order kinetics (elimination at a constant rate). ≈ 90% of total drug is protein bound. Oral bioavailability is ≈ 90% whereas IV bioavailability is ≈ 95%; this small difference may be significant when patients are near limits of therapeutic range (due to zero-order kinetics).

$t_{1/2}$ (half-life)	t_{PEAK} (peak serum levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level*
≈ 24 hrs (range: 9-140 hrs)†	oral suspension: 1.5-3 hrs regular capsules: 1.5-3 hrs extended release capsules: 4-12 hrs	7-21 days	4 wks	10-20 µg/ml

* therapeutic level as measured in most labs: 10-20 µg/ml (NB: it is the free PHT that is the important moiety; this is usually ≈ 1% of total PHT, thus therapeutic free PHT levels are 1-2 µg/ml; some labs are able to measure free PHT directly).

† $t_{1/2}$ for phenytoin depends on serum concentration and metabolic autoinduction

Renal failure: dosage adjustment not needed. However, serum protein binding may be altered in uremia which can obfuscate interpretation of serum phenytoin levels. *Eq 17-1* may be used to convert serum PHT concentration in a uremic patient C (observed), to the expected PHT level in nonuremic patients C (nonuremic).

$$C\ (\text{nonuremic}) = \frac{C\ (\text{observed})}{0.1 \times \text{albumin} + 0.1} \qquad \textbf{Eq 17-1}$$

ORAL DOSE

***Rx* Adult**: usual maintenance dose= 300-600 mg/d divided BID or TID (MDF = q d, for single daily dosing, either the phenytoin-sodium capsules or the extended release form should be used). Oral loading dose: 300 mg PO q 4 hrs until 17 mg/kg are given. **Peds**: oral maintenance: 4-7 mg/kg/d (MDF = BID). **SUPPLIED**: (oral forms): 100 mg tablets of phenytoin-sodium (sodium-salt); 30 & 100 mg Kapseals® (extended release); 50 mg chewable Infatabs® (phenytoin-acid); oral suspension 125 mg/5-ml in 8 oz. (240 ml) bottles or individual 5 ml unit dose packs; pediatric suspension 30 mg/5-ml. Phenytek® 200 & 300 mg capsules.

Dosage changes

Because of zero-order kinetics, at near-therapeutic levels a small dosage change can cause large level changes. Although computer models are necessary for a high degree of accuracy, the dosing change guidelines in *Table 17-9* or the nomogram in *Figure 17-1*[65] may be used as a quick approximation.

GI absorption of phenytoin suspension or capsules may be decreased by up to 70% when given with nasogastric feedings of Osmolyte® or Isocal®[66, 67], and the sus-pension has been reported to have erratic absorption. Hold NG feeding for 2 hrs before and 1 hour after phenytoin dose.

Table 17-9 Guidelines for changing phenytoin dosage

Present level (mg/dl)	Change to make
< 6	100 mg/day
6-8	50 mg/day
> 8	25-30 mg/day

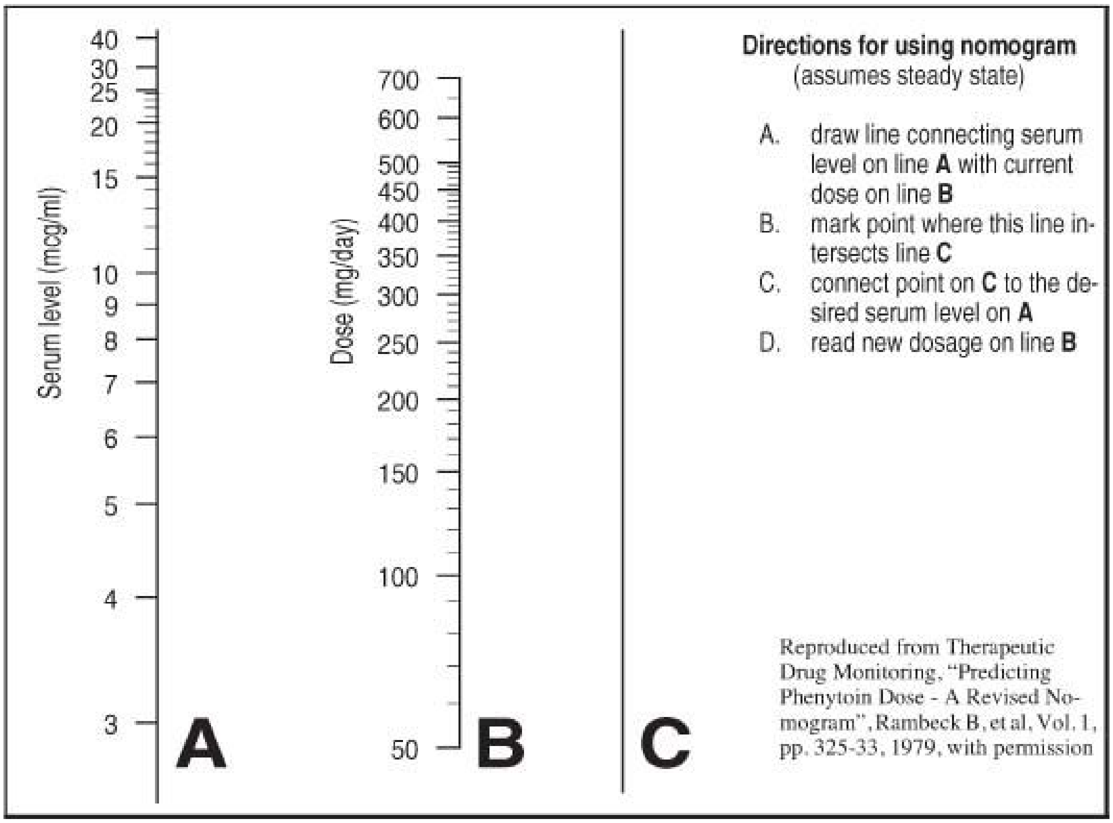

Figure 17-1 Nomogram for adjusting phenytoin dose

PARENTERAL DOSE

Phenytoin is a negative inotrope and can cause hypotension.

Conventional phenytoin may be given slow IVP or by IV drip (*see below*). The IM route should NOT be used (unreliable absorption, crystallization and sterile abscesses may develop). IV must be given slowly to reduce risk of arrhythmias and hypotension, viz. **Adult**: < 50 mg/min, **Peds**: < 1-3 mg/kg/min. The only compatible solution is NS, inject at site nearest vein to avoid precipitation.

Rx loading. Adult: 18 mg/kg slow IV. Peds: 20 mg/kg slow IV.

Rx maintenance. Adult: 200-500 mg/d (MDF = q d). Most adults have therapeutic levels on 100 mg PO TID. Peds: 4-7 mg/kg/d (MDF = BID).

Drip loading method:

Requires cardiac monitoring, and BP check q 5 minutes.

Rx Add 500 mg PHT to 50 ml NS to yield 10 mg/ml, run at 2 ml/min (20 mg/min) long enough to give 18 mg/kg (for 70 kg patient: 1200 mg over 60 mins). For more rapid administration, up to 40 mg/min may be used, or use fosphenytoin (*see below*). Decrease rate if hypotension occurs.

Fosphenytoin sodium injection

Fosphenytoin sodium **(FOS)** injection (Cerebyx®) is a newer formulation for administering IV phenytoin, and is indicated for short term use (≤ 5 days) when the enteral route is not usable. It is completely converted in vivo to phenytoin by organ and blood phosphatases with a conversion half-life of 10 minutes. Product labeling is given in terms of phenytoin equivalents **(PE)**. Safety in pediatric patients has not been established. **SUPPLIED**: 50 mg PE/ml in 2 & 10 ml vials (100 mg PE and 500 mg PE respectively).

Advantages of FOS (over conventional IV phenytoin):

1. less venous irritation (due to lower pH of 8.6-9 compared to 12 for phenytoin) resulting in less pain and IV extravasation
2. FOS is water soluble and therefore may be infused with dextrose or saline
3. tolerated by IM injection (IM route should not be used for status epilepticus)
4. does not come combined with propylene glycol (which can cause cardiac arrhythmias and/or hypotension itself)
5. the maximum administration rate is 3 **x** as fast (i.e. 150 mg PE/min)

SIDE EFFECTS OF PHENYTOIN

May interfere with cognitive function. May produce SLE-like syndrome, hepatic granulomas, megaloblastic anemia, cerebellar degeneration (chronic doses), hirsutism, gingival hypertrophy, hemorrhage in newborn if mother on PHT, toxic epidermal necrolysis (Stevens-Johnson variant). PHT antagonizes vitamin D → osteomalacia and rickets. Most hypersensitivity reactions occur within 2 months of initiating therapy[66]. In cases of maculopapular erythematous rash, the drug may be stopped and the patient may be re-challenged; often the rash will not recur the second time. Teratogenic (fetal hydantoin syndrome[68]).

Signs of phenytoin toxicity may develop at concentrations above 20 µg/ml (toxicity is more common at levels > 30 µg/ml) and include nystagmus (may also occur at therapeutic levels), diplopia, ataxia, asterixis, slurred speech, confusion, and CNS depression.

Drug-drug interactions: fluoxetine (Prozac®) results in elevated phenytoin levels (ave: 161% above baseline)[69]. Phenytoin may impair the efficacy of: corticosteroids, warfarin, digoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, vitamin D.

carbamazepine (CBZ) (Tegretol®) DRUG INFO

INDICATIONS

Partial seizures with or without secondary generalization. Trigeminal neuralgia. An IV form for use in e.g. status epilepticus is in development.

DOSE

***Rx* oral route. Adult** range: 600-2000 mg/d. **Peds**: 20-30 mg/kg/d. MDF = BID.

Before starting, check: CBC & platelet count (consider reticulocyte count) & serum Fe. Package insert says "recheck at frequent intervals, perhaps q week **x** 3 mos, then q month **x** 3 yrs."

Do not start CBZ (or discontinue it if patient already on CBZ) if: WBC < 4K, RBC < 3 **x** 10^6, Hct < 32%, platelets < 100K, reticulocytes < 0.3%, Fe > 150 µg%.

Start low and increment slowly: 200 mg PO q d **x** 1 wk, BID **x** 1 wk, TID **x** 1 wk. As an inpatient, dosage changes may be made every 3 days, monitoring for signs of side effects. As an outpatient, changes should be made only ≈ weekly, with levels after each change. **Carbatrol**® (extended release CBZ) is usually dosed BID.

SUPPLIED: oral form. Scored tabs 200 mg. Chewable scored tabs 100 mg. Suspension 100 mg/5-ml. IV form: not available in the U.S. at the time of this writing. Carbatrol® (extended release CBZ): 200 & 300 mg tablets.

Caveats with oral forms: oral absorption is erratic, and smaller more frequent doses are preferred[70]. Oral suspension is absorbed more readily, and also ✖ should not be administered simultaneously with other liquid medicinal agents as it may result in the precipitation of a rubbery, orange mass. ✖ May aggravate hyponatremia by SIADH-like effect.

PHARMACOKINETICS

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level (µg/ml)*
single dose: 20-55 hrs after chronic therapy: 10-30 hrs (adults), 8-20 hrs (peds)	4-24 hrs	up to 10 days†	4 wks	6-12

* may be misleading since the active metabolite carbamazepine-10,11-epoxide may cause toxicity and must be assayed separately

† t_{SS} may subsequently fall due to autoinduction which plateaus at 4-6 wks

CBZ induces hepatic enzymes that result in increased metabolism of itself (autoinduction) as well as other drugs over a period of ≈ 3-4 weeks.

SIDE EFFECTS

✖ Drug-drug interaction: caution, propoxyphene (Darvon®), cimetidine, erythromycin and isoniazid may cause dramatic elevation of CBZ levels due to inhibition of hepatic cytochrome oxidase that degrades CBZ[71]. Side effects include:

1. drowsiness and GI upset: minimized by slow dose escalation
2. relative leukopenia in many: usually does not require discontinuing drug
3. transient diplopia
4. ataxia
5. less effect on cognitive function than PHT
6. hematological toxicity: rare. May be serious → agranulocytosis & aplastic anemia
7. Stevens-Johnson syndrome
8. SIADH
9. hepatitis (occasionally fatal) reported

oxcarbazepine (Trileptal®) DRUG INFO

Very similar efficacy profile to carbamazepine with the following differences:

1. there is no autoinduction (C-P450 is not involved in metabolism) and therefore minimal drug-drug interactions
2. no blood testing is required since:
   A. there is no liver toxicity
   B. there is no hematologic toxicity
   C. there is no need to check drug levels
3. dosing is BID

4. kinetics are linear
5. more expensive

Dose

Rx: starting dose for pain control is 150 mg PO BID, for seizures it is 300 mg PO BID. Maximum dose 2400 mg/day total. **Supplied**: 150, 300 & 600 mg scored tablets. 300 mg/5 ml oral suspension.

valproate DRUG INFO

Available as valproic acid (Depakene®) and divalproex sodium (Depakote®).

Indications

Effective in primary GTC. Also useful in ABS with GTC, juvenile myoclonic epilepsy, and partial seizures (not FDA approved for latter). Also FDA approved for migraine prophylaxis. Note: severe GI upset and short half life make valproic acid much less useful than Depakote® (divalproex sodium).

Dose

Adult range: 600-3000 mg/d. **Peds** range: 15-60 mg/kg/d. MDF = q d.

Rx Start at 15 mg/kg/d, increment at 1 wk intervals by 5-10 mg/kg/d. Max recommended adult dose: 60 mg/kg/d. If daily dose > 250 mg is required, it should be divided. **Supplied**: Oral: capsules 250 mg. Syrup 250 mg/5-ml. **Depakote**® (enteric coated) tabs: 125, 250, & 500 mg; sprinkle capsules[125] mg. IV: **Depacon**® for I.V. injection 500 mg/5 ml vial.

Pharmacokinetics

$t_{1/2}$ (half-life)	t_{PEAK} (peak serum levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level (µg/ml)
8-20 hrs	(uncoated) 1-4 hrs	2-4 days	4 wks	50-100

Valproic acid **(VA)** is 90% protein bound. ASA displaces VA from serum proteins.

Side effects

Serious side effects are rare. Pancreatitis has been reported. Fatal liver failure has occurred especially if age < 2 yrs and in combination with other AEDs. Teratogenic (*see Contraindications* below). Drowsiness (temporary), minimal cognitive deficits, N/V (minimized with Depakote), liver dysfunction, hyperammonemia (even without liver dysfunction), weight gain, mild hair loss, tremor (dose related; similar to benign familial tremor; if severe and valproic acid is absolutely necessary, the tremor may be treated with beta blockers). May interfere with platelet function, caution with surgery on these patients.

CONTRAINDICATIONS

✖ Pregnancy: causes neural tube defects **(NTD)** in ≈ 1-2% of patients[72]. Since a correlation between peak VA levels and the risk of NTDs has been found, if VA must be used, some experts recommend changing from BID to TID dosing. ✖ Patients ≤ 2 yrs age (risk of hepatotoxicity).

phenobarbital **DRUG INFO**

INDICATIONS

Used as alternative in GTC and partial (not DOC). Had been DOC for febrile seizures, dubious benefit[47]. About as effective as PHT, but very sedating. Also used for status epilepticus (*see page 406*).

DOSE

Same dose PO, IV, or IM. MDF = q d[73, 74]. Start slowly to minimize sedation.

Rx **Adult** loading: 20 mg/kg slow IV (administer at rate < 100 mg/min). Maintenance: 30-250 mg/d (usually divided BID-TID). **Peds** loading: 15-20 mg/kg. Maintenance: 2-6 mg/kg/d (usually divided BID). **SUPPLIED**: tabs 15 mg, 30 mg, 60 mg, 100 mg; elixir 20 mg/5-ml.

PHARMACOKINETICS

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level
adult: 5 d (range: 50-160 hrs) peds: 30-70 hrs	PO & IM: 1-6 hrs	16-21 days (may take up to 30 days)	≈ 6-8 wks (reduce ≈ 25% per week)	15-30 µg/ml

Phenobarbital is a potent inducer of hepatic enzymes that metabolize other AEDs.

Side effects

Cognitive impairment (may be subtle and may outlast administration of the drug by at least several months[47]), thus avoid in peds; sedation; paradoxical hyperactivity (especially in peds); may cause hemorrhage in newborn if mother is on phenobarbital.

primidone (Mysoline®) DRUG INFO

Indications

Same as phenobarbital (not DOC). NB: when used in combination therapy, low doses (50-125 mg/day) may add significant seizure control to the primary AED with few side effects.

Dose

Rx **Adult**: 250-1500 mg/d. **Peds**: 15-30 mg/kg/d; MDF = BID.

Start at 125 mg/d **x** 1 wk, and inc. slowly to avoid sedation. **Supplied**: (oral only): scored tabs 50 mg, 250 mg; suspension 250 mg/5-ml.

Pharmacokinetics

Metabolites include phenylethylmalonamide (PEMA) and phenobarbital. Therefore always check phenobarbital level at same time as primidone level.

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level (µg/ml)
Primidone: 4-12 hrs derived phenobarbital: 50-160 hrs	2-5 hrs	up to 30 days	same as phenobarbital	primidone: 1-15 derived phenobarbital: 10-30

Side effects

Same as phenobarbital, plus: loss of libido, rare macrocytic anemia.

ethosuximide (Zarontin®) DRUG INFO

Indications

DOC in ABS.

Dose

***Rx* Adult**: 500-1500 mg/d. **Peds**: 10-40 mg/kg/d; MDF = q d. **Supplied**: oral only; capsules 250 mg; syrup 250 mg/5-ml.

Pharmacokinetics

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	Therapeutic level (µg/ml)
adult: 40-70 hrs peds: 20-40 hrs	1-4 hrs	adult: up to 14 days peds: up to 7 days	40-100

Side effects

N/V; lethargy; hiccups; H/A; rarely: eosinophilia, leukopenia, erythema multiforme, Stevens-Johnson syndrome, SLE-like syndrome. Toxic levels → psychotic behavior.

methsuximide (Celontin®) DRUG INFO

Indications

Indicated for absence seizures refractory to other drugs.

Dose

Rx optimum dose must be determined by trial. Start with 300 mg PO q d, increase by 300 mg PRN at weekly intervals up to 1200 mg/d. **Supplied**: 150 & 300 mg capsules.

felbamate (Felbatol®) DRUG INFO

✖ CAUTION: Due to an unacceptably high rate of aplastic anemia and hepatic failure, felbamate **(FBM)** should *not* be used except in those circumstances where the benefit clearly outweighs the risk; then, hematologic consultation is recommended by the manufacturer. See *Side effects* below (also for drug-drug interactions).

FBM is efficacious for monotherapy and adjunctive therapy for partial seizures (complex and secondary generalization), and reduces the frequency of atonic and GTC seizures in Lennox-Gastaut syndrome.

PHARMACOKINETICS

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	Therapeutic level
20-23 hrs	1-3 hrs	5-7 days	not established

DOSE

Rx: CAUTION *see above*. Felbamate is <u>not</u> to be used as a first-line drug. Patient or guardian should sign informed consent release. Start with 1200 mg/d divided BID, TID, or QID, and decrease other AEDS by one third. Increase felbamate biweekly in 600 mg increments to usual dose of 1600-3600 mg/d (max: 45 mg/kg/d). Slow down increments and/or reduce other AEDs further if side effects become severe. Administer at upper end of range when used as monotherapy. **SUPPLIED**: (oral only) 400 & 600 mg scored tablets; sus-pension 600 mg/5-ml.

Table 17-10 Effect of felbamate on other AED levels

AED	Change in level	Recommended dosing change
phenytoin	↑ 30-50%	↓ 20-33%
carbamazepine	↓ 30% total ↑ 50-60% epoxide	↓ 20-33%
valproic acid	↑ 25-100%	↓ 33%

SIDE EFFECTS

Felbamate has been associated with aplastic anemia (usually discovered after 5-30 wks of therapy) in ≈ 2-5 cases per million persons per yr, and hepatic failure (some fatal, necessitating baseline and serial LFTs every 1-2 wks). Other side effects: insomnia, anorexia, N/V, H/A. Felbamate is a potent metabolic inhibitor, thus it is necessary to reduce the dose of phenytoin, valproate or carbamazepine when used with felbamate[75] (*see Table 17-10*) (general rule: drop dose by one third).

levetiracetam (Keppra®) DRUG INFO

No identified drug-drug interactions. Less than 10% protein bound. Linear pharmakokinetics, no level monitoring needed.

Indications

Adjunctive therapy for partial onset Sz with secondary generalization in patients 4 years of age and older. Myoclonic seizures (juvenile myoclonic epilepsy). Generalized tonic-clonic.

Dose

Rx start with 500 mg PO BID. Increment by 1000 mg/d q 2 weeks PRN to a maximum of 3000 mg/d. Keppra XR: the same dose of levetiracetam can be converted to Keppra XR for q d dosing.

IV: 500-1500 mg diluted in 100 ml of diluent (LR, D5W, normal saline) infused over 15 minutes BID.

Supplied: 250, 500, 750 & 1000 mg scored film-coated tabs; 100 mg/ml oral solution. Keppra XR (extended release) 500 mg.

IV: 1 vial (5 ml) contains 500 mg.

Side effects

PO or IV: somnolence and fatigue in 15%. Dizziness in 9%. Asthenia 15% and infection 13% (nasopharyngitis and influenza may or may not have been related).

Keppra XR: somnolence 8%, irritability 6%.

clonazepam (Klonopin®) DRUG INFO

A benzodiazepine derivative.

Indications

✖ Not a recommended drug for seizures (*see below*).

Used for myoclonic, atonic, and absence seizures (in absence, less effective than valproate or ethosuximide, and tolerance may develop).

NB: clonazepam usually works very well for several months, and then tends to become less effective, leaving only the sedating effects. Also, many cases have been reported of patients having seizures during withdrawal, including status epilepticus (even in patients with no history of status). Thus, may need to taper this drug over 3-6 months.

DOSE

***Rx* Adult**: start at 1.5 mg/d DIV TID, increase by 0.5-1 mg q 3 d, usual dosage range is 1-12 mg/d (max 20 mg/d); MDF = q d. **Peds**: start at 0.01-0.03 mg/kg/d DIV BID or TID, increase by 0.25-0.5 mg/kg/d q 3 d; usual dosage range is 0.01-0.02 mg/kg/d; MDF = q d. **SUPPLIED**: oral only; scored tabs: 0.5 mg, 1 mg, 2 mg.

PHARMACOKINETICS

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	$t_{D/C}$ (discontinue)	Therapeutic level (μg/ml)
20-60 hrs	1-3 hrs	up to 14 days	≈ 3-6 months*	0.013-0.072

* CAUTION: withdrawal seizures are common, *see text* above

SIDE EFFECTS

Ataxia; drowsiness; behavior changes.

zonisamide (Zonegran®) DRUG INFO

INDICATIONS

Adjunctive therapy for partial Sz in adults.

acetazolamide (Diamox®) DRUG INFO

The anti-epileptic effect may be either due to direct inhibition of CNS carbonic anhydrase (also reduces CSF production) or due to the slight CNS acidosis that results.

INDICATIONS

Centricephalic epilepsies (absence, nonfocal seizures). Best results are in absence seizures; however benefit has also been observed in GTC, myoclonic jerk.

SIDE EFFECTS

Do not use in first trimester of pregnancy (may be teratogenic). The diuretic effect causes renal loss of HCO_3 which may lead to an acidotic state with long-

term therapy. A sulfonamide, therefore any typical reaction to this class may occur (anaphylaxis, fever, rash, Stevens-Johnson syndrome, toxic epidermal necrolysis…). Paresthesias: medication should be discontinued.

Dose

***Rx* Adult**: 8-30 mg/kg/d in divided doses (max 1 gm/d, higher doses do not improve control). When given with another AED, the suggested starting dose is 250 mg once daily, and this is gradually increased. **SUPPLIED**: tablets 125, 250 mg. Diamox sequels® are sustained release 500 mg capsules. Sterile cryodessicated powder is also available in 500 mg vials for parenteral (IV) use.

Although developed to be a GABA agonist, it does not interact at any known GABA

gabapentin (Neurontin®) DRUG INFO

receptor. Efficacious for primary generalized seizures and partial seizures (with or without secondary generalization). Ineffective for absence seizures. Very low incidence of known side-effects. No known drug interactions (probably because it is renally excreted). Also used for central pain

Dose

***Rx* Adult**: 300 mg PO **x** 1 day 1; 300 mg BID day 2; 300 mg TID day 3; then increase rapidly up to usual doses of ≈ 800-1800 mg per day. Doses of 1800-3600 may be needed in intractable patients. ✖ Dosage must be reduced in patients with renal insufficiency or on dialysis (see *Eq 3-1*, page 46 to estimate). **SUPPLIED**: 100, 300, 400, 600, 800 mg capsules. 50 mg/ml suspension.

Pharmacokinetics

Gabapentin is not metabolized, and 93% is excreted unchanged renally with plasma clearance directly proportional to creatinine clearance[76]. Does not affect hepatic microsomal enzymes, and does not affect metabolism of other AEDs. Antacids decrease bioavailablilty by ≈ 20%, therefore give gabapentin > 2 hrs after the antacid[77].

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	Therapeutic level
5-7 hrs*	2-3 hrs	1-2 days	not established

* with normal renal function

Side effects

Somnolence, dizziness, ataxia, fatigue, nystagmus; all reduce after 2-3 weeks of drug therapy. Increased appetite. Not known to be teratogenic.

lamotrigine (Lamictal®) DRUG INFO

Anticonvulsant effect may be due to presynaptic inhibition of glutamate release[76].

Efficacious as <u>adjunctive</u> therapy for partial seizures (with or without secondary generalization) and Lennox-Gastaut syndrome. Preliminary data suggest it may also be useful as an adjunct for refractory generalized seizures, or as monotherapy for newly diagnosed partial or generalized seizures[78]. Also FDA approved for bipolar disorder.

Side effects

Somnolence, dizziness, diplopia. ✖ Serious rashes requiring hospitalization and discontinuation of therapy have been reported (rash usually begins 2 weeks after initiating therapy and may be severe and potentially life-threatening, including Stevens-Johnson syndrome (more of a concern with simultaneous use of valproate), and rarely, toxic epidermal necrolysis **(TEN)**). Incidence of significant epidermal reaction may be decreased by a slow ramping-up of dosage. May increase seizure frequency in severe myoclonic epilepsy of infancy[79]. Metabolism of lamotrigine is affected by other AEDs.

Dose

***Rx* Adult**: In adults receiving enzyme-inducing AEDs (PHT, CBZ, or phenobarbital), start with 50 mg PO q d **x** 2 wks, then 50 mg BID **x** 2 wks, then ↑ by 100 mg/d q week until the usual maintenance dose of 200-700 mg/d (divided into 2 doses) is reached. For patients on valproic acid **(VA)** alone, the maintenance dose was 100-200 mg/d (divided into 2 doses), and VA levels drop by ≈ 25% within a few weeks of starting lamotrigine. For patients on both enzyme-inducing AEDs <u>and</u> VA, the starting dose is 25 mg PO qod **x** 2 wks, then 25 mg qd **x** 2 wks, then ↑ by 25-50 mg/d q 1-2 wks up to a maintenance of 100-150 mg/d (divided into 2 doses). Instruct patients that rash, fever or lymphadenopathy may herald a serious reaction and that a physician should be contacted immediately. **Peds**: not indicated for use in patients < 16 yrs old due to higher incidence of potentially life-threatening rash in the pediatric population[76].

Supplied: 25, 100, 150 & 200 mg tablets. 2, 5 & 25 mg chewable dispersible tablets.

Pharmacokinetics[78]

$t_{1/2}$ (half-life)	t_{PEAK} (peak levels)	t_{SS} (steady state)	Therapeutic level
24 hrs*	1.5-5 hrs	4-7 days	controversial[121]

* half-life is shortened to ≈ 15 hrs by PHT and CBZ, whereas valproic acid increases it to 59 hrs

vigabatrin DRUG INFO

Indications

Effective in treating partial seizures. Less so for generalized seizures.

Dose

***Rx* Adult**: 1500-3000 mg/d.

topiramate (Topamax®) DRUG INFO

May block voltage-sensitive sodium channels and enhance GABA activity at $GABA_A$ receptors and attenuate some glutamate receptors[76].

Indications[80]

As an oral adjunct to other drugs in treating refractory partial onset seizures.

Dose

***Rx* Adult**: start with 50 mg/d and increase slowly up to 200-400 mg/d[81], with no significant benefit noted at dosages > 600 mg/d[82]. **Supplied**: 25, 100, & 200 mg tabs.

Pharmacokinetics

30% is metabolized in the liver, the rest is excreted unchanged in the urine.

$t_{1/2}$ (half-life)	t_{SS} (steady state)	Therapeutic level

19-25 hrs	5-7 days	not established

SIDE EFFECTS

May increase phenytoin concentration by up to 25%. Levels of topiramate are reduced by other AEDs (phenytoin, carbamazepine, valproic acid and possibly others).

Cognitive impairment (word finding difficulty, problems with concentration…), weight loss, dizziness, ataxia, diplopia, paresthesias, nervousness and confusion have been troublesome. ≈ 1.5% incidence of renal stones which usually pass spontaneously[76]

Oligohidrosis (reduced sweating) and hyperthermia, primarily in children in association with elevated environmental temperatures and/or vigorous physical activity.

tiagabine (Gabitril®) **DRUG INFO**

A GABA uptake inhibitor, with cognitive problems of a similar frequency to that with topiramate[83].

Rx **Adult**: start with 4 mg/d, increase weekly by 4-8 mg to a maximum of 32-56 mg (divided BID to QID). **SUPPLIED**: 4, 12, 16 & 20 mg tablets.

lacosamide (Vimpat®) **DRUG INFO**

Enhances slow inactivation of voltage gated sodium channels, affecting only neurons that are depolarized of active over a prolonged period (as in a seizure).

INDICATIONS

Partial onset seizures. Painful diabetic neuropathy.

DOSE

Rx **Adult**: 200-400 mg. **SUPPLIED**: 50, 100, 150 & 200 mg tabs. 10 mg/ml IV solution.

17.4.3.1. Withdrawal of antiepileptic drugs

Most seizure recurrences develop during the first 6 months after AED withdrawal[84].

Indications for AED withdrawal

There is no agreement on how long a patient should be seizure-free before withdrawal of anticonvulsants, nor is there agreement on the prognostic value of EEGs and on the best time period over which to withdraw AEDs.

The following is based on a study of 92 patients with idiopathic epilepsy, who had been free of seizures for two years[85]. Generalization, e.g. to posttraumatic seizures, may not be appropriate. Taper was by 1 "unit" q 2 weeks (where a unit is defined as 200 mg for CBZ or valproic acid, or 100 mg for PHT). Follow-up: mean = 26 mos (range: 6-62).

Table 17-11 EEG class and seizure relapse rate

Class	– – EEG description – –		Re-lapse rate	No. of relapses/ patients at risk
	Before treatment	Before with-drawal		
1	normal	normal	34%	11/31
2	abnormal	normal	11%	4/35
3	abnormal	improved	50%	2/4
4	abnormal	unchanged	74%	14/19

31 patients (34%) relapsed, with the average time to relapse being 8 mos (range: 1-36). Using actuarial methods, the risk for recurrence is 5.9%/month for 3 months, then 2.7%/month for 3 months, then 0.5%/month for 3 months. Factors found to affect the likelihood of relapse include:

1. seizure type: 37% relapse rate for generalized seizures; 16% for complex or simple partial; 54% for complex partial with secondary generalization
2. number of seizures before control attained: those with ≥ 100 seizures before control had statistically significant higher relapse rate
3. the number of drugs that had to be tried before single drug therapy successfully controlled seizures: 29% if 1st drug worked, 40% if a change to a 2nd drug was needed, and 80% if a change to a 3rd drug was required
4. EEG class (*see Table 17-11*): class 4 had worst prognosis for relapse. Epileptiform discharges on EEG serves to discourage AED withdrawal[86]

In a larger randomized study[87], the most important factors identified to predict freedom from recurrent seizures were:

1. longer seizure-free period
2. use of only one AED (vs. multiple AEDs)

3. seizures other than tonic-clonic seizures

WITHDRAWAL TIMES

The recommended withdrawal times in *Table 17-12* should be used only as guide-lines.

Table 17-12 Recommended AED withdrawal times

AED	Recommended withdrawal period
phenytoin, valproic acid, carbamazepine	2-4 weeks
phenobarbital	6-8 weeks (25% per week)
clonazepam	3-6 months (see CAUTION on page 415)

17.4.3.2. Pregnancy and antiepileptic drugs

Women of childbearing potential with epilepsy should undergo counseling regarding pregnancy[88].

BIRTH CONTROL

AEDs that induce liver microsomal cytochrome P_{450} enzymes (*see Table 17-13*) increase the failure rate of oral contraceptives up to fourfold[90]. Patients desiring to use BCPs should employ barrier contraceptive measures until ovulation is consistently suppressed, and they should watch for breakthrough bleeding which may indicate a need for a change in the hormone dosage[84]. Non-oral hormonal contraceptives (e.g. levonorgestrel implant (Nor-plant®)) circumvents first pass liver degradation but should combined with a barrier method because of declining effectiveness with time.

Table 17-13 Effect of AEDs on liver cytochrome P_{450}*

Inducers	Noninducers
carbamazepine phenobarbital phenytoin felbamate primidone	valproic acid benzodiazepines gabapentin lamotrigine

* references[84, 89]

COMPLICATIONS DURING PREGNANCY

Women with epilepsy have more complications with pregnancy than mothers without epilepsy, but > 90% of pregnancies have a favorable outcome[84].

There is an increase in the number of gravid seizures in ≈ 17% (reported range: 17-30%) of epileptic women, which may be due to noncompliance or to changes of free drug levels of AEDs during pregnancy (*see Table 17-14*). Isolated seizures can occasionally be deleterious, but usually cause no problem. Status epilepticus poses serious risk to mother and fetus during pregnancy and should be treated aggressively.

There is also a slightly increased risk of toxemia (HTN of pregnancy) and fetal loss.

Table 17-14 Changes in free AED levels during pregnancy[91]

Drug	Change
carbamazepine	↓ 11%
phenobarbital	↓ 50%
phenytoin	↓ 31%
valproic acid	↑ 25%

BIRTH DEFECTS

The incidence of fetal malformations in offspring of patients with a known seizure disorder is ≈ 4-5%, or approximately double that of the general population[92]. The degree to which this is due to the use of AEDs vs. genetic and environmental factors is unknown. All AEDs have the potential to cause deleterious effects on the infant. Polytherapy is associated with an increased risk over monotherapy in a more than additive manner.

Generally, the risk of seizures (with possible concomitant maternal and fetal hypoxia and acidosis) is felt to outweigh the teratogenic risk of most AEDs, but this must be evaluated on a case-by-case basis. Occasionally patients may be weaned off AEDs.

Specific drugs

Carbamazepine **(CBZ)** produced an increased incidence of "minor" malformations (but not of "major" malformations) in one study[93] (this study may have had methodologic problems), and may increase the incidence of neural tube defects **(NTD)**[94]. In utero exposure to phenytoin may lead to the fetal hydantoin syndrome[68, 95] and a child with an IQ lower by ≈ 10 points[96]. Phenobarbital produced the highest incidence of major malformations (9.1%) in one prospective study[97] and was also associated with most of the increase in fetal

death or anomalies in another study[98]. Valproate **(VA)** causes the highest incidence of NTD (1-2%[72]), which can be detected with amniocentesis and allow an abortion if desired. TID dosing may reduce the risk of NTD (*see page 413*). Benzodiazepines given shortly before delivery can produce the "floppy infant syndrome"[99]. Similar effects may occur with other sedating AEDs such as phenobarbital.

Drug recommendations

A general consensus is that for most women of childbearing potential who require AEDs, that monotherapy with the lowest dose of CBZ that is effective is the method of choice if the seizure disorder is responsive to it[100]. If ineffective, then monotherapy with valproic acid (with TID dosing) is currently the recommended second choice. Folate supplementation (after confirming normal B_{12} levels, *see page 1187*) should be used in all.

17.5. Seizure surgery

20% of patients continue to have seizures even with AEDs. Many of these patients may be candidates for surgical procedures to control their seizures[6].

INDICATIONS

Seizure disorder must be severe, medically refractory with satisfactory trials of tolerable medication for at least ≈ 1 year, and disabling to the patient. Medically **refractory** is usually considered two attempts of high-dose monotherapy with two distinct AEDs, and one attempt at polytherapy.

The three general categories of patients suitable for seizure surgery have[101]:

1. partial seizures
   A. temporal origin: the largest group of surgical candidates (especially mesial temporal epilepsy which is often medically refractory)
   B. extratemporal origin
2. secondarily generalized seizures: e.g. Lennox-Gastaut
3. unilateral, multifocal epilepsy associated with infantile hemiplegia syndrome

EVALUATION

All patients should undergo imaging study to rule out neoplasm, AVM, etc. Noninvasive techniques allow localization in the majority of cases.

NONINVASIVE TECHNIQUES

MRI

The imaging modality of choice. Extremely good for detecting hippocampal asymmetry of mesial temporal sclerosis that may produce complex partial seizures **(CPS)**[102].

CAT SCAN

A seizure focus may enhance with IV contrast shortly following a seizure. Subtle enhancement may be present on the side of the focus on interictal CT scan[103].

VIDEO-EEG MONITORING

Most centers perform pre-operative long-term inpatient video-EEG monitoring to correlate the clinically disabling seizure with appropriate electrical abnormalities and possibly to identify the seizure focus.

PET SCAN (POSITRON EMISSION TOMOGRAPHY)

Interictal PET scan using fluorine-18 deoxyglucose (18FDG) shows hypometabolism lateralized to the side of temporal lobe focus in 70% of patients with medically refractory CPS (does not show actual site of origin). Useful when MRI and EEG cannot localize.

SPECT SCAN (SINGLE PHOTON EMISSION TOMOGRAPHY)

Used to demonstrate increased blood flow during a seizure to help localize site of onset. [99m] Technetium (Tc) hexamethyl-propylene-amine-oxime (HMPAO) is usually administered immediately after onset of seizure, and the scan may be obtained within several hours[104].

MILDLY INVASIVE TECHNIQUES

WADA TEST[105]

AKA intracarotid amytal test. Localizes dominant hemisphere (side of language function) and assesses ability of hemisphere without lesion to maintain memory when isolated. Usually reserved for candidates for large resections[106].

Start with angiogram to assess cross flow and to R/O persistent trigeminal artery (*see page 107*). Significant cross-flow is a relative contraindication to anesthetizing the side of dominant supply (patient goes to sleep).

Wada test may be grossly inaccurate with high flow AVM. Also, portions of hippocampus may be supplied by posterior circulation (not anesthetized by ICA injection).

EEG monitoring is usually performed during the test when it is being done for seizure surgery. Patient will show delta waves during deepest level of anesthesia.

Technique

- instruct patient as to what is expected
- catheterize ICA: usually start on side of lesion
- have patient hold contralateral arm in air, and instruct them to hold it there
- inject 100-125 mg sodium amobarbital (Amytal®) rapidly into internal carotid artery (effect starts almost instantaneously, begins to subside after ≈ 8 minutes (may subside in ≈ 2 minutes with AVM where flow rates are high))
- determine adequacy of injection by assessing motor function in elevated arm (should be ≈ flaccid)
- assess language skills by showing patient pictures of objects and ask them to name each one out loud and remember each one
- assess memory function by asking patient to name as many of the pictures as they can ≈ 15 minutes after test: if they have difficulty, ask them to pick out pictures from a group that contains additional ones not shown to patient
- repeat procedure on other side (use lower Amytal doses with each subsequent injection)

SURGICAL TECHNIQUES

EEG OBTAINED WITH INVASIVE ELECTRODES

Risk of infection with depth electrodes[106]: 2-10%.

Surface strip electrodes may be placed through a burr hole.

Depth electrodes may be placed stereotactically. Temporal depth electrodes

may be helpful for CPS, usually to determine the laterality of the mesiotemporal source of seizure. Frontal depth electrodes are also sometimes used. 2-3% risk of intracerebral hemorrhage[106].

Subdural grid electrodes are placed with a craniotomy. These sometimes may allow sufficient mapping to permit surgery under general anesthesia without need for intraoperative mapping under local anesthesia (helpful in children or in the mentally retarded).

SURGICAL CONSIDERATIONS

Three basic types of procedure: resections, disconnections and stimulation[A]:

1. resections
   A. resection of epileptic focus: higher chance of completely controlling seizures. Performed in noneloquent brain. Seizures must have focal onset (resection not encouraged if multifocal onset). Includes:
      1. anterior temporal lobectomy: *see below*
      2. amygdalo-hippocampectomy
      3. neocortical resections: especially with neuronal migration abnormalities
   B. resection of lesion in secondary epilepsy (e.g. tumor, AVM, cavernous malformation[107]…). In most cases the seizure focus is in or near the lesion, but some structural lesions are not responsible for the seizures. For seizure foci within the temporal lobe, seizure control is better when lesionectomy is accompanied by amygdalo-hippocampectomy[108]
2. disconnections: used when eloquent brain is involved, or to separate the electrical activity of the two cerebral hemispheres
   A. section of corpus callosum (callosotomy): when drop attacks are the most disabling seizure type or for multiple bilateral foci (*see below*)
   B. hemispherectomy: for unilateral seizures with widespread hemispheric lesions and profound contralateral neurologic deficit. If any cortex is left, must make sure it is functionally deafferented (disconnected)
      1. anatomic hemispherectomy
      2. functional hemispherectomy: preservation of the basal ganglia isolates the abnormal side with ≈ 80% seizure control rate (similar to anatomic hemispherectomy, but with lower complication rate).
   C. multiple subpial transection[109]: for partial seizure originating in eloquent cortical areas. The cortex is transected at 5 mm intervals, thus

interrupting the horizontal spread of the seizure while sparing the vertically oriented functional fibers

3. stimulation
   A. vagal nerve stimulation: *see page 424*
   B. deep brain stimulation (DBS)
      1. centromedian nucleus of the thalamus[110]: better for generalized tonic-clonic seizures
      2. bilateral anterior nucleus of the thalamus (report of 5 patients[111], and the recent “SANTE” trial[112]): for partial seizures
      3. hippocampus[110]: for partial seizures

A. all of the listed procedures are for <u>refractory</u> seizures. For the definition of refractory, *see page 420*

ANESTHETIC CONSIDERATIONS

If intraoperative electrocorticography is to be performed:

- under local anesthesia: the only anesthetic agents that may be used are narcotics (usually fentanyl) and droperidol
- under general anesthesia: <u>avoid</u> benzodiazepines and barbiturates

INTRAOPERATIVE ELECTROCORTICOGRAPHY ***(ECOG)***

May be performed with surface matrix that includes superior temporal gyrus and inferior frontal gyrus. Depth electrodes in the amygdala (3 cm from temporal tip) and hippocampus (5 cm from temporal tip) may also be used.

Methohexital (Brevitol®) may be given to try to provoke a seizure: observe for ↓ fast activity in suspected focus.

INTRAOPERATIVE CORTICAL MAPPING

For techniques of cortical mapping, *see page 150*.

CORPUS CALLOSOTOMY

Partial or total section may be most effective for generalized major motor seizures. Of little benefit for simple or complex seizures. Benefit has been supported for:

1. frequent episodes of <u>atonic seizures</u> (“drop attacks”) where loss of postural tone → falls and injuries[113] (70% reduction with callosotomy)

2. possibly for generalized seizure disorder with unilateral hemisphere damage (e.g. infantile hemiplegia syndrome); hemicortical resection may be better for this type, whereas callosotomy may promote partial seizures.

   Note: a "functional hemispherectomy" is recommended over "anatomically complete" hemispherectomy to reduce morbidity and mortality[101]

3. some patients with generalized seizures without identifiable, resectable focus

Division of the anterior two thirds of the corpus callosum **(CC)** (minimizes the risk of disconnection syndrome, *see below*) may be advantageous over complete callosotomy (controversial). Some advocate sectioning the CC with intraoperative EEG until the typical bisynchronous discharges that are usually seen become asynchronous[114]. No need to section anterior commissure. Can usually be performed via a bifrontal craniotomy utilizing a bicoronal skin incision.

May produce post-op ↓ verbalization or akinetic mutism that usually resolves in weeks. ✖ Contraindication: major behavioral and/or language deficits may occur even with partial division in patients with speech and dominant handedness located in opposite hemispheres ("crossed dominance"). Thus, Wada test is recommended in all left handed patients.

MRI sagittal cuts are superb for assessing extent of division of the CC[115].

DISCONNECTION SYNDROME

In a patient with a dominant left hemisphere, consists of left tactile anomia, left sided dyspraxia (may resemble hemiparesis), pseudohemianopsia, right sided anomia for smell, impaired spatial synthesis of right hand resulting in difficulty copying complex figures, decreased spontaneity of speech, incontinence.

More common with larger surgical sections of the CC. Risk is less if the anterior commissure is spared. Patients usually adapt after 2-3 months, with final function normal for most daily activities (deficits may show up on neuropsychological testing).

TEMPORAL LOBECTOMY

80% of patients with medically intractable seizures with demonstrable focus have foci in anterior temporal lobe. Most patients have neuronal loss and gliosis of mesial temporal structures. Thus, a standard resection of temporal tip (often with amygdalo-hippocampectomy) may be performed.

Limits of resection (without significant neurologic deficit)

Note that these values are generally considered safe, however, variations occur from patient to patient and only intraoperative mapping can reliably determine the location of language centers[116]. Some centers spare the superior temporal gyrus[117]. The following measurements are made along the middle temporal gyrus

- dominant temporal lobe: up to 4-5 cm may be removed. Over-resection may injure speech centers, which cannot be reliably localized visually
- non-dominant temporal lobe: 6-7 cm may be resected. Slight over-resection may → partial contralateral upper quadrant homonymous hemianopsia; resection of 8-9 cm → complete quadrantanopsia

Alternatively, intraoperative electrocorticography may be used to guide resection of electrically abnormal areas.

Resection should be performed in subpial plane to prevent injury to MCA branches.

AMYGDALO-HIPPOCAMPECTOMY

The amygdala lies in the roof of the anterior temporal horn of the lateral ventricle.

Two basic approaches:

1. transcortical: image guidance is very helpful
   A. Niemeyer approach[118]: 2-3 cm longitudinal cortical incision through the middle temporal gyrus centered at a point ≈ 4 cm posterior to the temporal tip
   B. approach through the anterior superior temporal gyrus
2. transsylvian: approach advocated by Yasargil. More restrictive and greater risk of injury to M1 portion of MCA within sylvian fissure

Complications: vascular injury is the most significant risk.

RISKS OF SEIZURE SURGERY

Major risks are related to[119]:

1. removal of essential areas of cortex
2. injury to medullary core underlying cortical resection (projection fibers, association fibers, and/or commissural fibers): the most common deficit

after temporal lobectomy is a contralateral (homonymous) superior quadrantanopsia (so-called "pie-in-the-sky" defect, due to an injury to Meyer's loop wherein the fibers for the superior visual field of the optic radiation take a slight rostral "detour" towards the temporal tip)

3. injury to vessels in area of resection → ischemic damage to areas supplied: especially sylvian branches during temporal lobectomy or ACA branches with corpus callosotomy
4. injury to nearby cranial nerves: especially third nerve during hippocampectomy where it lies medial to tentorium

PERIOPERATIVE MANAGEMENT FOR SEIZURE SURGERY

Management during evaluation:

During period when AEDs are being tapered, patient should be observed at all times (for patients not in ICU, a 24 hour-a-day sitter is required).

PRE-OP ORDERS (EPILEPTIC SURGERY)

1. taper anticonvulsants, completely D/C 1 day before surgery
2. 10 mg Decadron® PO hs before surgery, repeat PO or IV on AM of surgery
3. <u>if seizures develop</u>: phenobarbital 130 mg IV (@ < 100 mg/min)

POST-OP ORDERS (EPILEPTIC SURGERY)

1. for seizures in the immediate post-op period ("honeymoon seizures;"), not necessary to treat only one brief generalized seizure, otherwise load appropriately with phenytoin or phenobarbital;
2. continue 4 mg dexamethasone (Decadron®) PO q 6 hrs **x** <u>1 wk</u>, then taper over next week (essential to maintain for full week)
3. anticonvulsants are continued **x** 1-2 years even if no post-op seizures occur
4. before discharge:
   A. neuropsychiatric evaluation
   B. serum anticonvulsant level
   C. EEG

OUTCOME WITH RESECTION OF SEIZURE FOCUS

The greatest effect of seizure surgery is <u>reduction of seizure frequency</u>[117], however, any surgical procedure may fail to have a beneficial effect.

Seizure control is usually assessed at 1,3 & 6 most post op, and then annually. A post-op MRI is usually obtained at 3 most post-op to assess extent of surgical resection. Most patients take anti-epileptic drugs **(AEDs)** for 2 years post-op, and then may be discontinued in those free of seizures.

Recurrent seizures: although late seizures may occur, 90% of seizures that recur do so within 2 years.

2 years post-op in patients maintained on AEDs: 50% are seizure-free, and 80% have over 50% reduction of seizure frequency.

For temporal lobectomies in the dominant hemisphere without intraoperative monitoring, there is a 6% risk of mild dysphasia. Significant memory deficits occur in ≈ 2%.

VAGAL NERVE STIMULATION (VNS)

Electrodes wrapped around the vagus nerve in the neck are connected to an implanted programmable generator to stimulate the nerve to reduce seizure frequency.

As is also true with many AEDs, the mechanism of action is not well understood.

Indications: Although it has been used (off label) for treatment resistant depression and other psychiatric conditions, the FDA approved indication is for adjunctive therapy for patients > 12 years old with partial onset seizures refractory to medical treatment.

Outcome: In a 12 year retrospective review of VNS in 12 patients[120], mean seizure frequency decreased by 26% at 1 year, by 30% at 5 years, and by 52% after 12 years.

18. Spine & spinal cord

18.1. Low back pain and radiculopathy

Key concepts[1]:

- low back pain is common, and in ≈ 85% of cases, no specific diagnosis can be made
- initial assessment is geared to detecting "red flags" (indicating potentially serious pathology), and in the absence of these, imaging studies and further testing of patients is usually not helpful during the first 4 weeks of low back symptoms
- relief of discomfort is usually best achieved with nonprescription pain meds and/or spinal manipulation
- while activities may need to be modified, bed rest beyond 4 days may be more harmful than helpful, and patients are encouraged to return to work or their normal daily activities as soon as possible
- 89-90% of patients with low back problems will improve within 1 month even without treatment (including patients with sciatica from disc herniation)

Low back pain **(LBP)** is extremely prevalent, and is the second most common reason for people to seek medical attention[2]. LBP accounts for ≈ 15% of all sick leave from work, and is the most common cause of disability for persons < 45 yrs age[3]. Estimates of lifetime prevalence range from 60-90%, and the annual incidence is 5%[4]. Only 1% of patients will have nerve-root symptoms, and only 1-3% have lumbar disc herniation. The prognosis for most cases of LBP is good, and improvement usually occurs with little or no medical intervention.

DEFINITIONS/CLASSIFICATIONS

radiculopathy	dysfunction of a nerve root (signs and symptoms may include: pain in the distribution of that nerve root, dermatomal sensory disturbances, weakness of muscles innervated by

	that nerve root, and hypoactive muscle stretch reflexes of the same muscles)
mechanical low back pain	AKA "musculoskeletal" back pain (both non-specific terms). The most common form of low back pain. May result from strain of the paraspinal muscles and/or ligaments, irritation of facet joints… Excludes anatomically identifiable causes (e.g. tumor, disc herniation…)

INTERVERTEBRAL DISC

The function of the intervertebral disc is to permit stable motion of the spine while supporting and distributing loads under movement.

Anatomy

Anulus fibrosus (anulus may alternatively be spelled annulus, but fibrosus is the only correct spelling and is distinct from *fibrosis*)[5]: the multilaminated ligament that encompasses the periphery of the disc space. Attaches to the end-plate cartilage and ring apophyseal bone. Blends centrally with the nucleus pulposus.

Nucleus pulposus: the central portion of the disc. A remnant of the notocord.

Capsule[5]: combined fibers of the anulus fibrosus and the posterior longitudinal ligament (this term is useful because these 2 structures may not be distinguishable on imaging studies).

NOMENCLATURE FOR DISC PATHOLOGY

Historically, the terminology has been contentious and nonstandardized. Many diagnostic labels are used inconsistently (e.g. spondylosis, sprain, strain, musculoskeletal pain, myofascial pain…). A subset of nomenclature proposed by a task force[5] is shown in *Table 18-1*, which is useful primarily for consistent terminology related to radiographic reports, research….

Degenerated disc: some reports indicate that these can cause radicular pain possibly by an inflammatory mechanism[6], but this is not universally accepted.

Vacuum disc: gas in the disc space (empty space on imaging), usually indicates disc degeneration, <u>not</u> infection.

Non-Standard terms

Included for completeness, but are <u>not</u> recommended because they may be confusing or ambiguous[5].

Contained herniation[5]: displaced disc tissue that is entirely contained within an uninterrupted (but possibly distended) anulus or capsule (*see page 428*

for definition of *capsule*). It may be difficult to distinguish this on currently available imaging studies from an uncontained herniation which is underneath the posterior longitudinal ligament.

Ruptured disc: colloquial term usually intended to be equivalent to herniated disc.

Table 18-1 Nomenclature for lumbar disc pathology[5]

Term	Description
anular tears AKA anular fissures	separations between anular fibers, avulsions of fibers from their VB insertions, or breaks through fibers that extend radially, transversely, or concentrically
degeneration	desiccation, fibrosis, narrowing of the disc space, diffuse bulging of the anulus beyond the disc space, extensive fissuring (numerous anular tears), mucinous degeneration of the anulus, defects & sclerosis of end-plates, & osteophytes at the vertebral apophyses
degenerative disc disease	clinical syndrome of symptoms related to degenerative changes in the intervertebral disc (described above), also often considered to encompass degenerative changes *outside* the disc as well
bulging disc	generalized displacement of disc material (arbitrarily defined as > 50% or 180°) beyond the peripheral limits of the disc space*. Not considered a form of herniation. May be a normal finding, not usually symptomatic
herniation	localized displacement of disc material (< 50% or 180°) beyond the limits of the intervertebral disc space*
	focal: < 25% of the disc circumference
	broad-based: 25-50% of the disc circumference
	protrusion: the fragment does not have a "neck" that is narrower than the fragment in any dimension
	extrusion: the fragment has a "neck" that is narrower than the fragment in at least 1 dimension. 2 subtypes A. **sequestration**: the fragment has lost continuity with the disc of origin (AKA **free fragment**) B. **migration**: the fragment is displaced away from the site of extrusion, regardless of whether sequestered or not
	intravertebral herniation (AKA **Schmorl's node**): disc herniates in the cranio-caudal direction through the cartilaginous end-plate into the VB (*see page 455*)

* intervertebral disc space: bounded by VB endplates in the craniocaudal dimension, and by the outer edges of the vertebral ring apophyses (exclusive of osteophytes) in the peripheral direction

Recommended classification

It is recommended[1] that acute back problems be classified into one of the 3 categories shown in *Table 18-2* based on the history and physical exam (see

Initial assessment of the patient with back pain below). Further evaluation, treatment, and even some information regarding prognosis can be based on this simple classification. A major goal is to detect “red flags” that may indicate potentially serious spinal or nonspinal pathology (*see page 432*).

Table 18-2 AHCPR classification of back problems

Clinical category	Description
potentially serious spinal condition	includes spinal tumor, infection, fracture, or cauda equina syndrome (*see text*)
sciatica	pain along the course of the sciatic nerve, usually resulting from nerve root compromise
nonspecific back symptoms	symptoms occurring primarily in the back that suggest neither nerve root compromise nor a serious underlying condition

NOMENCLATURE FOR SPINE PATHOLOGY OUTSIDE THE DISC

Vertebral body marrow changes:

Associated with degenerative or inflammatory changes. **Modic’s classification**[7] of MRI characteristics is shown in *Table 18-3*.

Kyphosis: Focal kyphosis across a fracture is measured using the **Cobb angle**: the angle between two lines, one drawn parallel to the superior endplate of the VB one level above the injured VB, the other line parallel to the inferior endplate of the VB one level below (showed the best overall intraobserver and interobserver reliability[8]).

Table 18-3 Modic’s classification

Modic Type	Intensity changes		Description	
	T1WI	T2WI		
1*	↓	↑	bone marrow edema associated with acute or subacute inflammation	
2	↑	iso or ↑	chronic changes	replacement of bone marrow by fat
3	↓	↓		reactive osteosclerosis

* Type 1 may respond to fusion, *see page 440*

Scoliosis: Named for the side of the <u>convexity</u> of the curvature (i.e. dextroscoliosis = convex to right, levoscoliosis = convex to left). **Cobb angle**: may also be used (using the superior endplate of the uppermost vertebra

involved and the inferior endplate of the lowest vertebra involved). To make the lines meet within the borders of the film, it is some-times helpful to draw perpendiculars to these lines and measure the angles between those (*see Figure 18-1*).

DISABILITY, PAIN AND OUTCOME DETERMINATIONS

Disability scales for low back pain have been developed to assess outcomes for research purposes. Some widely used measures include:

1. visual analogue scale: used for any type of pain. The patient is asked to mark their pain level on a line divided into segments with sequential labels 0 (no pain) to 10 (the worst pain)
2. **Oswestry disability index (ODI)**[9]: a categorical ordinal scale that is used for low back pain. There are 4 English versions in wide use[10], version 2.011 is recommended[10]. It consists 10 questions related to activities of daily living. Each item is scored 0-5 (5 being the most disability) and the total is multiplied by 2% to obtain the final score (range: 0-100%). The interpretation of the final score is shown in *Table 18-4*. A score > 45% is essentially completely disabled. A score in the teens is very functional
3. Short Form 36 (SF36)[13]
4. Roland–Morris disability questionnaire[12]

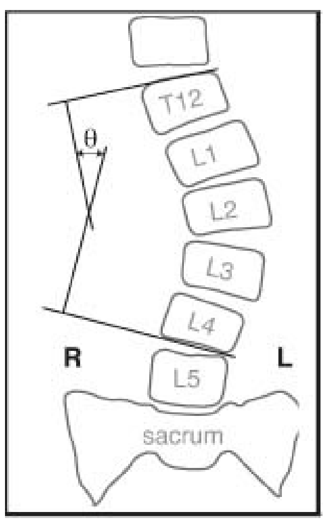

Figure 18-1 Cobb angle AP schematic showing levoscoliosis with Cobb angle?

Table 18-4 Oswestry disability index score

Score	Interpretation
0-20%	minimal disability: can cope with most daily activities

21-40%	moderate disability: pain and difficulty with sitting, lifting & standing. The patient may be disabled from work
41-60%	severe disability: pain is the main problem, but other areas are affected
61-80%	crippled: back pain impinges on all aspects of the patient's life
81-100%	these patients are either bed-bound or else are exaggerating their symptoms

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of low back pain (*see Low back pain*, page 1192) overlaps with that of myelopathy. In ≈ 85% of cases of LBP no specific diagnosis can be made[14].

INITIAL ASSESSMENT OF THE PATIENT WITH BACK PAIN

Initial assessment consists of a history and physical exam focused on identifying serious underlying conditions such as: fracture, tumor, infection or cauda equina syndrome. Serious conditions presenting as low back problems are relatively rare.

HISTORY

The following information has been found to be helpful in identifying patients with serious underlying conditions such as cancer and spinal infection[1]. *Table 18-5* shows the sensitivity and specificity.

1. age
2. history of cancer (especially malignancies that are prone to skeletal metastases: prostate, breast, kidney, thyroid, lung)
3. unexplained weight loss
4. immunosuppression: from steroids, organ transplant medication, or HIV
5. prolonged use of steroids
6. duration of symptoms
7. responsiveness to previous therapy
8. pain that is worse at rest
9. history of skin infection: especially furuncle
10. history of IV drug abuse
11. UTI or other infection

12. pain radiating below the knee
13. persistent numbness or weakness in the legs
14. history of significant trauma. In a young patient: MVA, a fall from a height, or a direct blow to the back. In an older patient: minor falls, heavy lifting or even severe coughing can cause a fracture especially in the presence of osteoporosis
15. findings consistent with cauda equina syndrome (*see page 446*):
    A. bladder dysfunction (usually urinary retention, or over-flow incontinence) or fecal incontinence
    B. saddle anesthesia: *see page 446*
    C. unilateral or bilateral leg weakness or pain
16. psychological and socioeconomic factors may influence the patient's report of symptoms (also *see page 436*), and one should inquire about:
    A. work status
    B. typical job tasks
    C. educational level
    D. pending litigation
    E. worker's compensation or disability issues
    F. failed previous treatments
    G. substance abuse
    H. depression

Table 18-5 Sensitivity and specificity of historical findings in patients with low back problems[1]

Condition	History	Sensitivity	Specificity
cancer	age ≥ 50 yrs	0.77	0.71
	previous Ca	0.31	0.98
	unexplained weight loss	0.15	0.94
	failure to improve after conservative therapy **x** 1 month	0.31	0.90
	any of the above	1.00	0.60
	pain > 1 month	0.50	0.81
spinal osteomyelitis	IV drug abuse, UTI, or skin infection	0.40	NA
compression fracture	age ≥ 50 yrs	0.84	0.61
	age ≥ 70yrs	0.22	0.96
	trauma	0.30	0.85
	steroid use	0.06	0.995
HLD	sciatica	0.95	0.88
spinal stenosis	pseudoclaudication	0.60	NA
	age ≥ 50 yrs	0.90*	0.70
ankylosing spondylitis	positive response to 4 out of 5 of the following	0.23	0.82
	age at onset ≤ 40 yrs	1.00	0.07
	pain not relieved when supine	0.80	0.49
	AM back stiffness	0.64	0.59
	pain ≥ 3 mos duration	0.71	0.54

* estimate

PHYSICAL EXAMINATION

Less helpful than the history in identifying patients who may be harboring conditions such as cancer, but may be more helpful in detecting spinal infections.

1. spinal infection (*see page 376*): findings that suggest this as a possibility (but are also common in patients without infection)
   A. fever: common in epidural abscess and vertebral osteomyelitis, less common in discitis
   B. vertebral tenderness
   C. very limited range of spinal motion
2. findings of possible neurologic compromise: the following physical findings will identify most cases of clinically significant nerve root compromise due to L4-5 or L5-S1 HLD which comprise > 90% of cases of radiculopathy due to HLD (limiting the exam to the following might not

detect the much less common upper lumbar disc herniations, which may be difficult to detect on PE, *see page 453*)

A. dorsiflexion strength of ankle and great toe: weakness suggests L5 and some L4 dysfunction
B. achilles reflex: diminished reflex suggests S1 root dysfunction
C. light touch sensation of the foot:
   1. diminished over medial malleolus and medial foot: suggests L4
   2. diminished over dorsum of foot: suggests L5
   3. diminished over lateral malleolus and lateral foot: suggests S1
D. straight leg raising **(SLR)** (also check for crossed SLR): *see page 443*

"Red flags" in the history and physical exam for low back problems

Based upon the above history and physical exam, the findings in *Table 18-6* would suggest the possibility of a serious underlying condition as the cause of the low back problem. Also, thoracic region pain is relatively uncommon and should raise the index of suspicion.

Further evaluation

For over 95% of patients with acute low back problems, no further testing within the first 4 weeks of symptoms is required[1].

In the absence of any of the "red flag" conditions shown in *Table 18-6*, no further testing is recommended (even for patients suspected of having a HLD) and the treatment is similar for most patients with an acute episode of low back problems.

Simple laboratory tests including CBC and ESR are sufficiently efficacious and inexpensive that they should be obtained when there is a suspicion of back related tumor or infection.

Table 18-6 "Red flags" for patients with low back problems

Condition	Red flags
cancer or infection	1. age > 50 or < 20 yrs 2. history of cancer 3. unexplained weight loss 4. immunosuppression (*see text*) 5. UTI, IV drug abuse, fever or chills 6. back pain not improved with rest
spinal fracture	1. history of significant trauma (*see text*) 2. prolonged use of steroids 3. age > 70 yrs
cauda equina syndrome or severe neurologic compromise	1. acute onset of urinary retention or overflow incontinence

	2. fecal incontinence or loss of anal sphincter tone 3. saddle anesthesia 4. global or progressive weakness in the LEs

FURTHER EVALUATION OF PATIENTS WITH LOW BACK PROBLEMS

Except for those exhibiting "red flags" (*see above*), special diagnostic tests are usually not needed during the first month of symptoms since it is not possible to predict which patients will improve (as most do) and which will not.

TESTS FOR EVIDENCE OF PHYSIOLOGIC DYSFUNCTION

Electrodiagnostics for low back problems: If the diagnosis of radiculopathy seems likely on clinical grounds, electrophysiologic testing is not recommended[1].

1. needle EMG: (*see page 269*) can assess acute and chronic nerve root dysfunction, myelopathy and myopathy, and may be useful for patients with suspicion of other conditions (e.g. neuropathy) or when a reliable strength exam is not possible. Reduced recruitment may be seen within the first several days of onset, however, spontaneous activity (*see page 270*) takes **10-21 days** to develop (∴ less helpful in the first ≈ 3 weeks). Also, not usually helpful with normal muscle strength exam. Accuracy is highly operator dependent and improves with knowledge about imaging studies and clinical information[15]. For findings in radiculopathy, *see page 270*
2. H-reflex (*see page 270*): measures sensory conduction through nerve roots. Correlates with achilles reflex. Use is limited to assessing S1 radiculopathy[16]
3. SSEPs: (*see page 266*) assesses afferent fibers which travel in peripheral nerve and the posterior column of the spinal cord. May be abnormal in conditions affecting the dorsal columns with impaired joint position and proprioception (e.g. cervical spondylotic spinal myelopathy)
4. nerve conduction studies (including NCVs): helps identify acute and chronic entrapment neuropathies that may mimic radiculopathy
5. ✖ not recommended for assessing acute low back problems[1]
   A. F-wave response (*see page 270*): measures motor conduction through nerve roots, used to assess proximal neuropathies
   B. surface EMG: assesses acute and chronic recruitment patterns during static or dynamic tasks using surface (instead of needle) electrodes

Bone scan for low back problems: Description: injection of a - radiolabeled compound (usually technetium-99m) that is taken up by metabolically active bone. A gamma camera localizes regions of uptake. Total radiation dose is ≈ to a set of lumbar spine x-rays[1]. Contraindicated during pregnancy, and breast feeding must be briefly suspended following a bone scan due to presence of radiotracer in the breast milk.

A moderately sensitive test which may be used in evaluating low back pain when spinal tumor[17], infection[18], or occult fracture is suspected from "red flags" (*see Table 18-6*) on history or examination, or results of lab tests or plain x-rays. Not very specific, but may locate occult lesions and help differentiate these conditions from degenerative changes. A positive bone scan suggesting one of these conditions usually must be confirmed by other diagnostic tests or procedures (no studies have compared bone scans to CT or MRI).

Low yield in patients with longstanding low back problems and normal plain x-rays and laboratory tests (especially ESR)[17].

SPECT scans may provide additional information to a bone scan.

Thermography for low back problems: Not recommended[1]. Did not accurately predict absence or presence of nerve root compression seen at surgery[19], and may be positive in a significant percentage of asymptomatic patients[20].

RADIOGRAPHIC EVALUATION

Diagnosing lumbar spinal stenosis or herniated intervertebral disc is usually helpful only in potential surgical candidates[21]. This includes patients with appropriate clinical syndromes who have not responded satisfactorily to adequate non-surgical treatment over a sufficient period of time, and who have no medical contraindications to surgery. Radiologic confirmation of these diagnoses usually requires CT, myelography, MRI, or some combination (*see below*). NB: myelography[22], CT[23], or MRI[24] may also show bulging or herniated lumbar discs **(HLD)** or spinal stenosis in asymptomatic patients (e.g. 24% of asymptomatic patients have herniated discs on MRI and 4% have spinal stenosis; these numbers become 36% and 21% respectively in patients 60-80 years old)[25]. Thus, these tests must be interpreted in light of clinical findings, and the anatomic level and side should correspond to the history, examination, and/or other physiologic data. Diagnostic radiology is of limited benefit as the initial evaluation in the majority of spinal disorders[26].

In the absence of red flags for serious conditions, imaging studies are not

recommended in the first month of symptoms[1]. For patients who have had previous back surgery, MRI with contrast is probably the best test. Myelography (with or without CT) is invasive and has increased risk of complications, and is therefore indicated only in situations where MRI cannot be done or is inadequate, and surgery is anticipated.

Σ

Patients for whom radiographic imaging is recommended are those with:
- suspected *benign* conditions with symptoms of great enough severity to consider surgery persisting beyond 4 weeks, including:
  - back related leg symptoms and clinically specific signs of nerve root compromise
  - a history of neurogenic claudication (*see page 477*) or other finding suggestive of lumbar spinal stenosis
- red flags: physical examination or other test results suggesting other serious conditions affecting the spine (e.g. cauda equina syndrome, fracture, infection, tumor, or other mass lesions or defects)

Recommendations for use of MRI and discography to select patients for fusion are shown in *PRACTICE GUIDELINE 18-1*.

PRACTICE GUIDELINE 18-1 MRI & DISCOGRAPHY FOR PATIENT SELECTION FOR LUMBAR FUSION*

Level II[27]:
- MRI is recommended as the initial diagnostic test
- normal appearing discs on MRI should not be considered for discography or treatment
- lumbar discography should not be used as a stand-alone test
- to consider a disc level for treatment, if discography is used, there should be a concordant pain response† and associated abnormalities on MRI‡

Level III[27]: discography should be reserved for equivocal MRI findings, especially at levels adjacent to unequivocally abnormal levels

* for recommendations on use of facet injections, see *PRACTICE GUIDELINE 18-2*, page 437

† concordant pain response: pain identical or very similar to the patient's usual pain complaints (NB: discography can produce severe LBP in patients with no prior complaints[28, 29])

‡ abnormal disc morphology on MRI: loss of T2WI signal intensity ("black disc"), disc space collapse, Modic changes (*see page 430*), and high-intensity zones (these findings also frequently occur in asymptomatic patients 30)

PLAIN LUMBOSACRAL X-RAYS

Unexpected findings occurred in only 1 in 2500 adults < 50 years age[31].

Diagnosis of surgical conditions of disc herniation and spinal stenosis cannot be made from plain films. Various congenital abnormalities of uncertain significance may be identified (e.g. spina bifida occulta), and evidence of degenerative changes (including osteophytes) are as frequent in symptomatic as in asymptomatic patients. Gonadal radiation is significant. Seldom indicated during pregnancy.

Recommendation

Not recommended for routine evaluation of patients with acute low back problems during the first month of symptoms unless a “red flag” is present (*see below*). Reserve LS x-rays for patients with a likelihood of having spinal malignancy, infection, inflammatory spondylitis, or clinically significant fracture. In these cases, plain x-rays are often just a starting point, and further study (CT, MRI…) may be indicated even if the plain x-rays are normal. “Red flags” for these conditions include the following:

1. age > 70 years, or < 20 yrs
2. systemically ill patients
3. temp > 100°F (or > 38° C)
4. history of malignancy
5. recent infection
6. patients with neurologic deficits suggesting possible cauda equina syndrome (saddle anesthesia, urinary incontinence or retention, LE weakness, *see page 446*)
7. heavy alcohol or IV drug abusers
8. diabetics
9. immunosuppressed patients (including prolonged treatment with corticosteroids)
10. recent urinary tract or spinal surgery
11. *recent* trauma: any age with significant trauma, or > 50 yrs old with mild trauma
12. unrelenting pain at rest
13. persistent pain for more than ≈ 4 weeks
14. unexplained weight loss

When spine x-rays are indicated, AP and lateral views are usually adequate[32]. Obliques and coned-down L5-S1 views more than double the radiation exposure, and add information in only 4-8% of cases[33], and can be

obtained in specific instances where warranted (e.g. to diagnose spondylolysis when spondylolisthesis is found on the lateral film).

MRI

Unless contraindicated, MRI has supplanted CT and myelography for diagnosing most cases of disc herniation and spinal stenosis. Specificity and sensitivity for HLD are on the same order as CT/myelography, which is better than myelography alone[1, 34, 35].

Advantages:

1. provides information in sagittal plane (can easily evaluate cauda equina)
2. provides information regarding tissue outside of the spinal canal (e.g. extreme lateral disc herniation (*see page 453*), tumors…)
3. non-invasive and does not involve ionizing radiation

Disadvantages:

1. patients in severe pain or with claustrophobia may have difficulty holding still
2. dose not visualize bone well
3. poor for studying blood early (e.g. spinal epidural hematoma)
4. expensive (note: may be more cost effective than myelography if post-myelogram overnight hospitalization is avoided, and especially if a rare complication from myelography occurs)
5. interpretation with scoliosis is more difficult, may be partially compensated by contouring plane through which axial cuts are taken. Myelogram/CT may be superior
6. a number of contraindications: see *Contraindications to MRI*, page 130

Findings:

In addition to demonstrating herniated lumbar disc **(HLD)** outside of the disc interspace compressing nerve root or thecal sac, MRI can demonstrate signal changes within the interspace suggestive of <u>disc degeneration</u>[36] (loss of signal intensity on T2WI, loss of disc space height) and is useful in diagnosing infections and tumors.

Lumbosacral CT

Not considered state of the art. If technically adequate images can be obtained (e.g. good quality scanner, images not obscured by artifact from patient movement or obesity), CT can demonstrate most spine pathology. For HLD,

sensitivity is 80-95%, and specificity is 68-88%[37, 38]. However, even some large disc herniations will be missed with plain CT. CT studies for HLD tend to be less satisfactory in the elderly. More utility with fractures.

Disc material has density (Hounsfield units) ≈ twice that of the thecal sac. Associated findings with herniated disc include:

1. loss of epidural fat (normally seen as low density in the anterolateral canal)
2. loss of normal “convexity” of thecal sac (indentation by herniated disc)

Advantages:

1. images soft tissue to a degree that may be adequate
2. excellent bony detail
3. non-invasive
4. outpatient evaluation
5. evaluates for extreme lateral disc herniation to some degree
6. evaluates paraspinal soft tissue (e.g. to rule out tumor, paraspinal abscess…)
7. advantages over MRI: faster scanning (significant in patients who have difficulty laying still for long time), less expensive, less claustrophobic, fewer contraindications (see *Contraindications to MRI*, page 130)

Disadvantages:

1. does not evaluate sagittal plane (may be partially ameliorated by eliminating skip regions and then utilizing computerized sagittal reconstructions)
2. evaluates only those levels that are scanned:
   A. higher cuts must be taken through the conus medullaris to avoid missing occasional pathology there
   B. performing cuts only through the disc spaces (a common practice) may miss pathology between the disc spaces
3. sensitivity is significantly lower than MRI or myelogram/CT

Myelography

With water soluble contrast, sensitivity (62-100%) and specificity (83-94%)[39-42] are similar to CT for detection of HLD. When combined with post-myelographic CT scan (myelogram/CT), the sensitivity and especially specificity increase[43]. A herniated disk in the large space between thecal sac and posterior border of vertebral bodies at L5-S1 (**insensitive space**) may not be seen on

myelography (CT or MRI are usually better at detecting this).

Advantages:

1. provides information in sagittal plane (unlike plain CT)
2. evaluates cauda equina (unlike routine CT)
3. provides "functional" information about degree of stenosis (a high-degree block will allow flow of dye only after certain position changes)

Disadvantages:

1. occasionally requires overnight hospitalization
2. may miss pathology outside of the dura (including far laterally herniated disc), sensitivity is improved with post-myelographic CT
3. invasive
   A. drugs e.g. warfarin must be stopped, and sometimes converted to heparin
   B. with occasional side effects (post LP H/A, N/V, rare seizures)
4. iodine allergic patients
   A. requires iodine allergy prep
   B. may still be risky (especially in severely iodine allergic patients)

Findings:

HLD produces extradural filling defect at the level of the intervertebral disc. Massive disc herniation or severe lumbar stenosis may produce a total or near total block. In some cases of HLD, the finding may be very subtle and may consist of a cut-off of the filling (with contrast) of the nerve root sleeve (compared to normal nerve(s) on contralateral side or at other levels). Another subtle finding may be a "dual shadow" on lateral view.

Bone scan

See *page 432*

Discography

Injection of water-soluble contrast agent directly into the nucleus pulposus of the intervertebral disc being studied. Results of the test depend on volume of dye accepted into the disc, the pressure needed to inject the dye, the configuration of the dye (including leakage from the confines of the disc space) on radiographic imaging (plain x-rays produce the so-called "discogram", CT scan may also be utilized), and reproduction of the patient's pain on injection. Some of the basis for performing a discogram is to identify levels that may produce "discogenic

pain" or "painful disc syndrome", a controversial point (see *PRACTICE GUIDELINE 18-1*, page 434).

Critique:

Invasive. Interpretation is equivocal, and complications may occur (disc space infection, disc herniation, and significant radiation exposure with CT-discography). May be abnormal in asymptomatic patients[28, 29] (as any of the above tests may be) although the false positive rate may not be quite this high[44]. See *PRACTICE GUIDELINE 18-1*, page 434 for recommendations.

PSYCHOSOCIAL FACTORS

Although some patients with chronic LPB (> 3 months duration) may have started off with a diagnosable condition, psychological and socioeconomic factors (such as depression, secondary gain…) may come to play a significant role in perpetuating or amplifying pain. Psychological factors, especially elevated hysteria or hypochondriasis scales on the Minnesota Multiphasic Personality Inventory **(MMPI)** were found to be a better predictor of outcome than findings on radiographic imaging in one study[15]. A screening scale of 5 factors has been proposed[45] (positive findings in any 3 suggests psychological distress):

1. pain on simulated axial loading: press on top of head
2. inconsistent performance: e.g. difficulty tolerating straight leg raising **(SLR)** while supine, but no difficulty when sitting
3. overreaction during the physical exam
4. inappropriate tenderness that is superficial or widespread } these two items may not be reliable, the others are potentially reliable[46]
5. motor or sensory abnormalities not corresponding to anatomic confines } these two items may not be reliable, the others are potentially reliable[46]

However, the usefulness of this information is limited, and no effective interventions have been identified to address these factors. Therefore the AHCPR panel was unable to recommend specific assessment tools or interventions[1].

TREATMENT

An initial period of nonsurgical management (see *"Conservative" treatment* below) is indicated except in the following circumstances where urgent surgery is indicated: symptoms of a cauda equina syndrome (urinary retention, saddle

anesthesia…, see *Cauda equina syndrome*, page 446), progressive neurologic deficit, or profound motor weakness. A relative indication for proceeding to surgery without conservative management is severe pain that cannot be controlled with adequate pain medication (rare).

If specific diagnoses such as herniated intervertebral lumbar disc or symptomatic lumbar stenosis are made, surgical treatment for these conditions may be considered if the patient fails to improve satisfactorily. In cases where no specific diagnosis can be made, management consists of conservative treatment and following the patient to rule out the possible development of symptoms suggestive of a more serious diagnosis that may not have initially been evident.

"Conservative" treatment

This term has regrettably come to be used for non-surgical management. With slight modification, similar approaches can be used for mechanical low back pain, as well as for acute radiculopathy from disc herniation.

PRACTICE GUIDELINE 18-2 INJECTION THERAPY FOR LOW-BACK PAIN

Therapeutic recommendations

Level III[47]: lumbar epidural injections or trigger point injections are not recommended for long-term relief of chronic LBP. These techniques or facet injections may be used to provide temporary relief in select patients

Diagnostic recommendations

Level III[47]: **lumbar facet injections**

- may predict the response to radiofrequency facet ablation
- ✖ not recommended as a diagnostic tool to predict the response to lumbar fusion

Recommendations (based on AHCPR findings[1] in the absence of "red flags"[A]):

A. some key literature citations are given here, primarily those from the better studies that support the Agency for Health Care Policy and Research **(AHCPR)** panel recommendations. However, refer to Bigos et al.[1] for full analysis and list of references

1. activity modifications: no studies were found that met the panels review criteria for adequate evidence. However, the following information was felt to be useful:
   A. bed rest: for 2-3 days maximum
      1. the theoretical objective is to reduce symptoms by reducing pressure on the nerve roots and/or intradiscal pressures which is lowest in the supine semi-Fowler position[48], and also to reduce movements which are experienced as painful by the patient
      2. deactivation from prolonged bed rest (> 4 days) appears to be worse for patients (producing weakness, stiffness, and increased pain) than a gradual return to normal activities[49]
      3. recommendations: the majority of patients with low back problems will not require bed rest. Bed rest for 2-4 days may be an option for those with severe initial *radicular* symptoms, however, this may be no better than watchful waiting[50] and may be harmful[51]
   B. activity modification
      1. the goal is to achieve a tolerable level of discomfort while continuing sufficient physical activity to minimize disruption of daily activities
      2. risk factors: although there is not agreement on their exact role, the following were identified as having an increased incidence of low back problems. Jobs requiring heavy or repetitive lifting, total body vibration (from vehicles or industrial machinery), asymmetric postures, or postures sustained for long periods (including prolonged sitting)
      3. recommendations: temporarily limit heavy lifting, prolonged sitting, and bending or twisting of the back. Establish activity goals to help focus attention on expected return to full functional status
   C. exercise (may be part of a physical therapy program):
      1. during the 1st month of symptoms, low-stress aerobic exercise can minimize debility due to inactivity. In the first 2 weeks, utilize exercises that minimally stress the back: walking, bicycling, or swimming
      2. conditioning exercises for trunk muscles (especially back extensors, and possibly abdominal muscles) are helpful if symptoms persist (during the first 2 weeks, these exercises may aggravate symptoms)
      3. there is no evidence to support stretching of back muscles, or to

recommend back-specific exercise machines over traditional exercise

4. recommended exercise quotas that are gradually escalated results in better outcome than having patients simply stop when pain occurs[52]

2. analgesics:
   A. for the initial short-term period, acetaminophen **(APAP)** or NSAIDs (*see* *page 44*) may be used. In one study 53 of acute LBP, NSAIDs did not add any benefit to APAP + standard education (*see below*)
   B. stronger analgesics (mostly opioids, *see* *page 46*) may be required for severe pain, usually severe radicular pain. For non-specific back pain, there was no earlier return to full activity than with NSAIDs or APAP1. Opioids should not be used > 2-3 weeks, at which time NSAIDs should be instituted
3. muscle relaxants (*see* *page 50*)
   A. muscle spasms have not been proven to cause pain, and the most commonly used muscle relaxants have no peripheral effect on muscle spasm
   B. probably more effective than placebo, but have not been shown to be more effective than NSAIDs
   C. potential for side effects: drowsiness (in up to 30%). Most manufacturers recommend use for < 2-3 weeks. Agents such as chlorzoxazone (Parafon Forte® and others) may be associated with risk of serious and potentially fatal hepatotoxicity[54]
4. education: (may be provided as part of a physical therapy program)
   A. explanation of the condition to the patient[55] in understandable terms, and positive reassurance that the condition will almost certainly subside[56] have been shown to be more effective than many other forms of treatment
   B. proper posture, sleeping positions, lifting techniques… should be conveyed to the patient. Formal "back school" seems to be marginally effective[57]
5. spinal manipulation therapy **(SMT)**: defined as manual therapy in which loads are applied to the spine using long or short lever methods with the selected joint being taken to its end range of voluntary motion, followed by application of an impulse loading (may be part of a physical therapy program)

A. may be helpful for patients with acute low back problems without radiculopathy when used in the first month of symptoms (efficacy after 1 month is unproven) for a period not to exceed 1 month. One study[53] found no added benefit to APA + standard education
B. insufficient evidence to recommend SMT in the presence of radiculopathy
C. SMT should not be used in the face of severe or progressive neurologic deficit until serious conditions have been ruled out
D. ✖ reports of arterial dissection (especially vertebral artery - *see page 985*) and CVA, myelopathy & subdural hematoma with <u>cervical</u> SMT and cauda equina syndrome with lumbar SMT[58-60] and the uncertainty of benefits have led to the questioning of the use of SMT[58] (especially cervical)

6. epidural injections:
A. epidural steroid injections **(ESI)**: there is no evidence that this is effective in treating acute radiculopathy[61]. Prospective studies yield varied results[62]. Some improvement at 3 & 6 weeks may occur (but no functional benefit, and no change in the need for surgery), with no benefit at 3 months[63]. The response in chronic back pain is poor in comparison to acute pain. ESI may be an option for <u>short-term</u> relief of *radicular* pain when control on oral medications is inadequate or for patients who are not surgical candidates
B. there is no evidence to support the use of epidural injections of steroids, local anesthetics and/or opioids for LBP without radiculopathy
C. efficacy with conditions such as lumbar spinal stenosis are conflicting 62

✖ <u>Not</u> recommended by the AHCPR panel[1] for treatment of acute low back problems in the absence of “red flags” (see *Table 18-6*, page 432):

1. medications
A. oral steroids: no difference was found at one week and 1 year after randomization to receive 1 week therapy with oral dexamethasone or placebo[64]
B. colchicine: conflicting evidence shows either some[65] or no[66] therapeutic benefit. Side effects of N/V and diarrhea[1]
C. antidepressant medications: most studies of these medications were

for *chronic* back pain. Some methodologically flawed studies failed to show benefits when compared to placebo for chronic (not acute) LBP[67]

2. physical treatments
   A. TENS (transcutaneous electrical nerve stimulation): not statistically significantly better than placebo, and added no benefit to exercise alone[68]
   B. traction (including pelvic traction): not demonstrated to be effective[69]
   C. physical agents and modalities: including heat (including diathermy), ice, ultrasound. Benefit is insufficiently proven, however, self-administered home programs for application of heat or cold may be considered. Ultrasound and diathermy should not be used in pregnancy
   D. lumbar corsets and support belts: not proven beneficial for acute back problems. Prophylactic use has been advocated, but this is controversial[70]
   E. biofeedback: has not been studied for acute back problems. Primarily advocated for chronic LBP, where effectiveness is controversial[71]
3. injection therapy
   A. trigger point and ligamentous injections: the theory that trigger points cause or perpetuate LBP is controversial and disputed by many experts. Injections of local anesthetic are of equivocal efficacy
   B. (zygapophyseal) facet joint injections: theoretical basis is that there exists a "**facet syndrome**" producing LBP which is aggravated by spine extension, with no nerve root tension signs (*see page 443*). No studies have adequately investigated injections for pain < 3 months duration. For chronic LBP, neither the agent nor the location (intrafacet or pericapsular) made a significant difference in outcomes[72, 73]
   C. epidural injections in the absence of radiculopathy: *see above*
   D. acupuncture: no studies were found that evaluated the use in acute back problems. All randomized clinical trials found were for patients with *chronic* LBP, and even the best studies were felt to be mediocre and contradictory. Meta-analysis found acupuncture was more effective in relieving *chronic* LBP than sham or no treatment[74], but there was no comparison to other therapies

Surgical treatment

Indications for surgery for herniated lumbar disc:

See *page 445*.

Indications for fusion for chronic LBP without stenosis or spondylolisthesis: Very controversial. Guidelines are shown in *PRACTICE GUIDELINE 18-3*.

PRACTICE GUIDELINE 18-3 LUMBAR FUSION FOR LBP WITHOUT STENOSIS OR SPONDYLOLISTHESIS

Level I[75]: lumbar fusion is recommended for carefully selected patients* with disabling LBP due to one- or two-level degenerative disease without stenosis or spondylolisthesis

Level III[75, 77]: an intensive course of PT and cognitive therapy is recommended as a option for patients with LBP in whom conventional medical management has failed

* in the primary quoted study 76 patients had chronic LBP for ≥ 2 years and had radiologic evidence of disc degeneration at L4-L5, L5-S1, or both, and had failed best medical management

PRACTICE GUIDELINE 18-4 CHOICE OF FUSION TECHNIQUE

Level II[78]: for ALIF or ALIF + instrumentation, the addition of a posterolateral fusion is not recommended*

Level III[78]:

- either a posterolateral fusion or an interbody fusion (PLIF, TLIF or ALIF) are options for patients with LBP due to DDD at 1 or 2 levels
- an interbody graft is an option to improve fusion rates and functional outcome†
- ✖ the use of multiple approaches (anterior + posterior) is not recommended as a routine option for LBP without deformity

* the demonstrated benefit does not outweigh the additional time and blood loss involved

† caution: the improvement in fusion rate and outcome is marginal, and interbody fusion is associated with an increased complication rate, especially with combined approaches (e.g. 360° fusion)

TYPE OF SURGICAL TREATMENT

The type of surgical procedure chosen is tailored to the specific condition identified. Examples are shown in *Table 18-7*. Discussion of some options is also provided below.

Lumbar spinal fusion

Although there is no consensus on the indications[79], lumbar spinal fusion **(LSF)** is accepted treatment for fracture/dislocation or instability resulting from tumor or infection.

For degenerative spine disease, practice parameters have been developed and are included herein. Pain associated with Modic type 1 changes (*see page 430*) may respond to stabilization procedures, the other types do not exhibit this association.

Table 18-7 Surgical options for low back problems

Condition	Surgical treatment options
"routine" HLD	• standard discectomy and microdiscectomy are of similar efficacy • intradiscal procedures: nucleotome, laser disc decompression. Not recommended (*see page 447*) • chymopapain: acceptable, but less efficacious than above. Significant risk of anaphylaxis (*see page 447*). Use has been largely abandoned
foraminal or far lateral HLD	• partial or total facetectomy (*see page 454*) • extracanal approach (*see page 454*) • endoscopic techniques
lumbar spinal stenosis	• simple decompressive laminectomy • laminectomy plus fusion: may be indicated for patients with degenerative spondylolisthesis, stenosis and radiculopathy

PRACTICE GUIDELINE 18-5 LUMBAR FUSION FOR DISC HERNIATION

Level III[80]:

- lumbar fusion is <u>not</u> routinely recommended following disc excision in patients with HLD or recurrent HLD causing radiculopathy
- lumbar fusion is a potential adjunct to disc excision in cases of a HLD or recurrent HLD:
  - with evidence of preoperative lumbar spinal deformity or instability
  - in patients with chronic axial LBP associated with radiculopathy

Instrumentation as an adjunct to fusion

PRACTICE GUIDELINE 18-6 PEDICLE SCREW FIXATION

Level III[81]: pedicle screw fixation is recommended as a treatment option for patients with LBP treated with posterolateral fusion who are at high risk for fusion failure*

- -

** routine use of pedicle screws is discouraged because of conflicting evidence of benefit, together with considerable evidence of increased cost and complications*

The use of instrumentation increases the fusion rate[82]. Hardware used in the absence of fusion will eventually fatigue, especially in the region of the lumbar lordosis. Therefore, instrumentation must be viewed as a temporary internal stabilizing measure while awaiting the fusion process to complete.

CHRONIC LOW BACK PAIN

Rarely can an anatomic diagnosis be made in patients with chronic LBP ≥ 3 months[83]. Also, see *Psychosocial factors*, page 436. Patients with chronic pain syndromes **(CPS)** refer to their problems with affective or emotional terms with a higher frequency than those with acute pain[84]. The amount of time that a patient has been out of work due to low back problems is related to the chances of the patient getting back to work as shown in *Table 18-8*.

Table 18-8 Chances of patients going back to work

Time out of work	Chances of getting back to work
< 6 mos	50%
1 yr	20%
2 yrs	< 5%

18.1.1. Post-op clinic visits - lumbar fusion

Patients are seen in the clinic at intervals depending on the preference of the surgeon. A typical follow-up schedule with studies routinely performed is shown in *Table 18-9*. For specific problems, additional investigations are usually needed.

Post-op x-rays: Items to check on post op x-rays include:

1. alignment
2. position of grafts if used (e.g. inter-body grafts)
3. integrity of hardware (look for screw or rod breakage, screw pullout, rod disconnection)
4. lucencies around screws which may indicate motion and implies non-union
5. any evidence of fusion (may be difficult, e.g. with synthetic interbody fusions)
6. flexion/extension films: look for motion across fused segments

(sometimes absence of motion is the only evidence of fusion on plain x-rays) and the development of abnormal motion at adjacent segments

Table 18-9 Sample post-op lumbar fusion clinic visit schedule

Time post-op	Agenda
7-10 d	wound check, D/C sutures/staples if used
6 wks	AP & lateral LS-spine x-ray in brace
10-12 wks	• AP & lateral LS-spine x-rays with flexion/extionsion views out of brace • if x-rays look good and patient is doing well, begin weaning brace
6 months	• AP & lateral LS-spine x-rays with flexion/extension views • some surgeons release patients at this time if they are doing well
1 year (optional)	• AP & lateral LS-spine x-rays with flexion/extension views • release patient if they are doing well

18.2. Sagittal balance

The normal curvature of the spine in the sagittal plane (cervical lordosis, thoracic kyphosis and lumbar lordosis) permits standing posture with the minimum of muscle activity and soft tissue deformity. Abnormalities in any component of this sagittal balance **(SB)** result in compensatory changes in other segments.

Hardacker et al[85] proposes the following (angles measured using Cobb's technique (*see page 430*)):

1. cervical lordosis: normally 40° ± 9.7°
2. the occipital cervical junction is actually in kyphosis
3. the majority of lordosis occurs between C1-C2
4. the lower cervical spine (C4-C7) is relatively flat with an average lordosis of 6°
5. thoracic kyphosis: normally 20-50°. Increases with age (especially significant in age > 40 yrs) and the rate of increase is higher in females[86] (*see Table 18-10* for normal values)
6. lumbar lordosis: normally 31-79°

To assess sagittal balance, on a standing lateral full-spine xray: a **plumb line** is drawn straight down from the center of the C7 VB (*see Figure 18-2*). There are various definitions for where the line should cross for normal sagittal balance, including:

1. the plumb line should pass within the L5-S1 disc space or within 2 cm of the sacral promontory and through or behind the axis of the hip joint
2. the mean sagittal vertical axis fell 3.2 ± 3.2 cm behind the front of the sacrum in asymptomatic patients > 40 years old[87]

A plumb line can also be drawn from the center of C2 down, and this line should pass through the C7 VB and then on to the same lumbosacral targets as above.

Patients with compensated sagittal balance can temporarily correct for an abnormal plumb line using back muscles and pelvic tilt which leads to pain and fatigue.

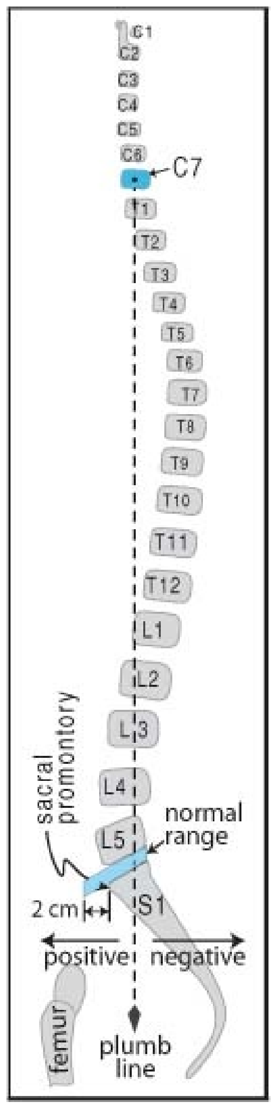

Figure 18-2 Sagittal balance plumb line Lateral spine schematic

Etiologies of loss of sagittal balance

1. congenital: Scheuermann's thoracic hyperkyphosis
2. aging: cervical lordosis and thoracic kyphosis increase, lumbar lordosis decreases
3. traumatic
4. iatrogenic: post-op flat-back syndrome
5. pathologic: osteoporosis
6. neuromuscular disorders

Clinical features:

1. pain
2. deformity
3. difficulty ambulating

Table 18-10 Normal values for thoracic kyphosis[86]*

Age (yrs)	Kyphosis (± SD)	
	Males	Females
< 10	20° (± 7.85)	24° (± 6.67)
10-19	25° (± 8.16)	26° (± 7.43)
40-49	30° (± 6.93)	33° (± 6.72)
50-59	33° (± 6.46)	41° (± 9.88)
70-79	41° (± 7.57)	42° (± 9.00)

* measured using a modified Cobb technique in asymptomatic patients

Flat back syndrome: AKA lumbar degenerative kyphosis. More common in Asia than Western countries. May also occur following lumbar fusion. Management: controversial. Restoring lost sagittal balance may cause improvement of symptoms[88].

Surgical management: for flexible deformity, the spine may be fused after sagittal balance is restored either manually or posturally. For fixed deformities, options to increase lumbar lordosis:

1. Smith-Peterson (facet) osteotomy: shortens posterior elements and lengthens anterior elements. Anterior elements may be lengthened using interbody grafts placed from an anterior approach
2. pedicle subtraction osteotomy: decreases pedicle and posterior VB. Does not produce an anterior defect

18.3. Intervertebral disc herniation

18.3.1. Lumbar disc herniation

Key concepts:

- typical disc herniation → radiculopathy in the nerve exiting at the level below
- massive disc herniations can → cauda equina syndrome (a medical emergency). Typical symptoms: saddle anesthesia, urinary retention, LE weakness (*page 446*)
- most patients do as well with conservative treatment as with surgery, ∴ initial conservative treatment should be considered for the vast majority
- surgery indications: cauda equina syndrome, progressive symptoms or neurologic deficits despite conservative treatment, or severe *radicular* pain $> \approx 6$ weeks

PATHOPHYSIOLOGY

Intervertebral discs may undergo degenerative changes (see *Table 18-1*, page 429 for description) which increases the risk of herniation (see same table for definition).

Variants:

1. intravertebral disc herniation (Schmorl's node): *see page 455*
2. intradural disc herniation: *see page 455*
3. **limbus fracture**: traumatic separation of a segment of bone from the edge of the vertebral ring apophysis at the site of anular attachment. May accompany HLD

CLINICAL ASPECTS

The posterior longitudinal ligament is strongest in the midline, and the posterolateral annulus may bear a disproportionate portion of the load. This may explain why most herniated lumbar discs **(HLD)** occur posteriorly, slightly off to one side, characteristically compressing the nerve root en passage → severe radicular pain.

Characteristic findings on the history often include:

1. symptoms may start off with back pain, which after days or weeks gradually or sometimes suddenly yields to radicular pain often with reduction of the back pain
2. precipitating factors: various factors are often blamed, but are rarely identified[89] with certainty
3. pain relief upon flexing the knee and thigh
4. patients generally avoid excessive movements, however, remaining in any one position (sitting, standing, or lying) too long may also exacerbate the pain, sometimes necessitating position changes at intervals that range from every few minutes to 10-20 minutes. This is distinct from constant writhing in pain e.g. with ureteral obstruction
5. "**cough effect**": ↑ pain with coughing, sneezing, or straining at the stool. Occurred in 87% of patients with HLD in one series[90]
6. **bladder symptoms**: the incidence of voiding dysfunction is 1-18%[91 (p 966)]. Most common: difficulty voiding, straining, or urinary retention. Reduced bladder sensation may be the earliest finding. Later it is not unusual to see "irritative" symptoms including urinary urgency, frequency (including nocturia), increased post-void residual. Less common: enuresis, and dribbling incontinence[92] (NB: frank urinary retention may indicate cauda equina syndrome, *see page 446*). Occasionally a HLD may present only with bladder symptoms which may improve after surgery[93]. Discectomy may improve bladder function, but this cannot be assured

PHYSICAL FINDINGS IN RADICULOPATHY

Back pain per se is usually a minor component (only 1% of patients with acute low back pain have sciatica[4]), and when it is the only presenting symptom, other causes should be sought (see *Low back pain*, page 1192). Sciatica has such a high sensitivity for disc herniation, that the likelihood of a clinically significant disc herniation[94] in the absence of sciatica is ≈ 1 in 1000. Exceptions include a central disc herniation which may cause symptoms of lumbar stenosis (i.e. neurogenic claudication) or a cauda equina syndrome.

Nerve root impingement gives rise to a set of signs and symptoms present to variable degrees. Characteristic syndromes are described for the most common nerve roots involved (see *Nerve root syndromes* below).

In a series of patients referred to neurosurgical outpatient clinics for radiating leg pain, 28% had motor loss (yet only 12% listed motor weakness as a presenting complaint), 45% had sensory disturbance, and 51% had reflex

changes[95].

Findings suggestive of nerve root impingement include the following. *Table 18-11* shows the sensitivity and specificity of some findings on the exam among patients with sciatica.

1. signs/symptoms of radiculopathy (see *Table 18-13*, page 445)
   A. pain radiating down LE
   B. motor weakness
   C. dermatomal sensory changes
   D. reflex changes: mental factors may influence symmetry[96]
2. positive nerve root tension sign(s): including Lasègue's sign (*see below*)
3. tenderness over the sciatic notch

Table 18-11 Sensitivity and specificity of physical findings for HLD in patients with sciatica[1]

Test	Comment	Sensitivity	Specificity
ipsilateral SLR	positive result: pain at < 60° elevation	0.80	0.40
crossed SLR	reproduction of contralateral pain	0.25	0.90
↓ ankle jerk	HLD usually at L5-S1 (total absence increases specificity)	0.50	0.60
sensory loss	area of loss is poor in localizing level of HLD	0.50	0.50
↓ patellar reflex	suggests upper HLD	0.50	NA
WEAKNESS			
knee extension (quadriceps)	HLD usually at L3-4	< 0.01	0.99
ankle dorsiflexion (anterior tibialis)	HLD usually at L4-5	0.35	0.70
ankle plantarflexion (gastrocs)	HLD usually at L5-S1	0.06	0.95
great toe extension (EHL)	HLD at L5-S1 in 60%, at L4-5 in 30%	0.50	0.70

Nerve root tension signs

Includes[97]:

1. **Lasègue's sign**: AKA straight leg raising **(SLR)** test. Helps differentiate sciatica from pain due to hip pathology. Test: with patient supine, raise afflicted limb by the ankle until pain is elicited[98] (should occur at **< 60°**,

tension in nerve increases little above this angle). A positive test consists of leg pain or paresthesias in the distribution of pain (back pain alone does not qualify). The patient may also extend the hip (by lifting it off table) to reduce the angle. Although not part of Lasègue's sign, ankle dorsiflexion with SLR usually augments pain due to nerve root compression. SLR primarily tenses L5 and S1, L4 less so, and more proximal roots very little. Nerve-root compression produces a positive Lasègue's sign in ≈ 83% of cases[90] (more likely to be positive in patients < 30 yrs age with HLD[99]). May be positive in lumbosacral plexopathy (*see page 795*). Note: flexing both thighs with the knees extended ("long-sitting" or sitting knee extension) may be tolerated further than flexing the single symptomatic side alone

2. **Cram test**: with patient supine, raise the symptomatic leg with the knee slightly flexed. Then, extend the knee. Results similar to SLR
3. **crossed straight leg-raising** test AKA **Fajersztajn's sign**: SLR on the painless leg causes contralateral limb pain (a greater degree of elevation is usually required than the painful side). More specific but less sensitive than SLR (97% of patients undergoing surgery with this sign have confirmed HLD[100]). May correlate with a more central disc herniation
4. **femoral stretch test**[101], AKA **reverse straight leg raising**: patient prone, examiner's palm at popliteal fossa, knee is maximally dorsiflexed. Often positive with L2, L3, or L4 nerve root compression (e.g. in upper lumbar disc herniation), or with extreme lateral lumbar disc herniation (may also be positive in diabetic femoral neuropathy or psoas hematoma); in these situations SLR (Lasègue's sign) is frequently negative (since L5 & S1 not involved)
5. "**bowstring sign**": once pain occurs with SLR, lower the foot to the bed by flexing knee, keeping the hip flexed. Sciatic pain ceases with this maneuver, but hip pain persists
6. **sitting knee extension** test: with patient seated and both hips and knees flexed 90°, slowly extend one knee. Stretches nerve roots as much as a moderate degree of SLR

Other signs useful in evaluation for lumbar radiculopathy

1. **FABER**: an acronym for Flexion ABduction External-Rotation, AKA FABERE test (the trailing "e" is for extension), AKA Patrick's-test. A test

of hip motion. Method: the hip and knee are flexed and the lateral malleolus is placed on the contralateral knee. The ipsilateral knee is gently displaced downward towards the exam table. This stresses the hip joint and does not usually exacerbate true nerve-root compression. Often markedly positive in the presence of hip joint disease (e.g. trochanteric bursitis, *see page 478*), sacroiliitis or mechanical low-back pain

2. **Trendelenburg sign**: examiner observes pelvis from behind while patient raises one leg while standing. Normally the pelvis remains horizontal. A positive sign occurs when the pelvis tilts down toward the side of the lifted leg indicating weakness of the contralateral thigh adductors (primarily L5 innervated)
3. **crossed adductors**: in eliciting patellar reflex (knee jerk **(KJ)**), the contralateral thigh adductors contract. In the presence of a hyperactive ipsilateral KJ it may indicate an upper motor neuron lesion, in the presence of a hypoactive ipsilateral KJ it may be a form of pathological spread, indicating nerve root irritability
4. **Hoover sign** 102: to distinguish unilateral functional weakness of iliopsoas from organic weakness using synergistic contraction of the contralateral gluteus medius. The supine patient is asked to lift one leg off the bed against resistance from the examiner's hand. The examiner simultaneously places the palm of his/her other hand under the heel of the unlifted leg and gently lifts. Test 1: when the patient lifts the normal leg, if the paretic leg pushes down with more force than was exhibited on manual testing of the limb beforehand, the weakness is judged functional, if the force is equally weak the weakness is judged organic. Test 1 cannot be used if the hip extensor was normal beforehand. Test 2: (the better known test) the patient is asked to lift the weak leg. If the heel on the normal side lifts passively by the examiner, it suggests the weakness is functional (i.e. the patient is not trying). Not totally reliable[103, 104]
5. **abductor sign**: an alternative to the Hoover test, to differentiate functional from organic weakness in the thigh abductors using synergistic contraction of the contralateral thigh abductors[104]. With the patient supine, the examiner places a hand on the lateral aspect of both legs. The patient is asked to abduct legs. The patient is asked to abduct one leg, and then the other while the examiner applies resistance with his/her hand. The examiner mentally notes the response of the *non-abducting* LE. The results are as noted in *Table 18-12*

Table 18-12 Abductor sign

Abducting LE	Contralateral (nonabducting) LE	
	Organic weakness	Functional weakness
weak LE	maintains position	hyperadducts
normal LE	hyperadducts	maintains position

Nerve root syndromes

Due to the facts listed below, a herniated lumbar disc **(HLD)** usually spares the nerve root exiting at that interspace, and impinges on the nerve exiting from the neural foramen one level below (e.g. a L5-S1 HLD usually causes S1 radiculopathy). This gives rise to the characteristic lumbar nerve root syndromes shown in *Table 18-13*.

Important facts in lumbar disc disease:

1. in the lumbar region, the nerve root exits below and in close proximity to the pedicle of its like-numbered vertebra
2. the intervertebral disc space is located well below the pedicle
3. not all patients have 5 lumbar vertebrae (see *Localizing levels in spine surgery*, page 173)

Table 18-13 Lumbar disc syndromes

	— Level of herniated lumbar disc —		
	L3-4	**L4-5**	**L5-S1**
root usually compressed	L4	L5	S1
% of lumbar discs	3-10% (5% average)	40-45%	45-50%
reflex diminished	knee jerk* (Westphal's sign)	medial hamstring†	Achilles* (ankle jerk)
motor weakness	quadriceps femoris (knee extension)	tibialis anterior (foot drop) & EHL‡	gastrocnemius (plantarflexion), ± EHL‡
decreased sensation§	medial malleolus & medial foot	large toe web & dorsum of foot	lateral malleolus & lateral foot
pain distribution	anterior thigh	posterior LE	posterior LE, often to ankle

* **Jendrassik maneuver** may reinforce (*see page 786*)

† medial hamstring reflex is unreliable (not always pure L5), may also stimulate adductors when eliciting

‡ see WEAKNESS in *Table 18-11*, page 443 for breakdown

§ sensory impairment is most common in the distal extremes of the dermatome[105]

Radiographic evaluation

See *Radiographic evaluation* on page 433 under *Low back pain*.

NONSURGICAL TREATMENT

For nonsurgical treatment, see *"Conservative" treatment*, page 437.

SURGICAL TREATMENT

INDICATIONS

No predictive factors have been identified that can determine which patients are likely to improve on their own and which would be better served with surgery.

Surgical indications in patients with a radiographically identified herniated disc that correlates with findings on the history and physical exam:

1. failure of non-surgical management to control pain after 5-8 weeks: over 85% of patients with acute disc herniation will improve without surgical intervention in an average of 6 weeks[106] (70% within 4 weeks[107]). Most clinicians advocate waiting somewhere between 5-8 weeks from the onset of radiculopathy before considering surgery (assuming none of the items listed below applies)
2. **"EMERGENT SURGERY":** (i.e. before the 5-8 weeks have lapsed). Indications:
   A. cauda equina syndrome **(CES)**: (*see below*)
   B. progressive motor deficit (e.g. foot drop). NB: paresis of unknown duration is a doubtful indication for surgery[89, 108, 109] (no study has documented that there is less motor deficit in surgically treated patients with this finding[110]). However, the acute development or progression of motor weakness is considered an indication for rapid surgical decompression
   C. "urgent" surgery may be indicated for patients whose pain remains intolerable in spite of adequate narcotic pain medication
3. ± patients who do not want to invest the time in a trial of non-surgical treatment if it is possible that they will still require surgery at the end of the trial

Cauda equina syndrome

The clinical condition arising from dysfunction of multiple lumbar and sacral nerve roots within the lumbar spinal canal. Usually due to compression of the

cauda equina. See *Table 21-86*, page 744 for features to help differentiate CES from a conus lesion.

Possible **findings** in CES:

1. sphincter disturbance:
   A. urinary retention: the most consistent finding. Sensitivity ≈ 90% (at some point in time during course)[111, 112]. To evaluate acutely: have patient empty bladder and check post-void residual (by catheterization or with bladder ultrasound). In a patient without retention, only 1 in 1000 will have a CES. Cystometrogram (when done) shows a hypotonic bladder with decreased sensation and increased capacity
   B. urinary and/or fecal incontinence[113]: some patients with urinary retention will present with overflow incontinence
   C. anal sphincter tone: diminished in 60-80%
2. "**saddle anesthesia**": the most common sensory deficit. Distribution: region of the anus, lower genitals, perineum, over the buttocks, posterior-superior thighs. Sensitivity ≈ 75%. Once total perineal anesthesia develops, patients tend to have permanent bladder paralysis[114]
3. significant motor weakness: usually involves more than a single nerve root (if untreated, may progress to paraplegia)
4. low back pain and/or sciatica (sciatica is usually bilateral, but may be unilateral or entirely absent, prognosis may be worse when absent or bilateral[112])
5. bilateral absence of Achilles reflex has been noted[115]
6. sexual dysfunction (usually not detected until a later time)

Etiologies of CES includes:

1. compression of cauda equina
   A. massive herniated lumbar disc: *see below*
   B. tumor
      1. from compression: e.g. with metastatic disease to the spine with epidural extension
      2. **intravascular lymphomatosis (B-cell lymphoma)**: a circulating lymphoma without solid mass (*see page 674*). Often presents with CNS findings: dementia, enhancing meninges on MRI, lymphoma cells in CSF, and CES
   C. free fat graft following discectomy[116]
   D. trauma: fracture fragments compressing cauda equina

    E. spinal epidural hematoma
2. infection: may cause neurologic deficit from
    A. compression: typically from spinal epidural abscess complicating discitis or vertebral osteomyelitis
    B. a significant number of cases of CES from infection may be due to vascular compromise resulting from local septic thrombophlebitis. This may carry a worse prognosis as surgical decompression cannot correct this mechanism
3. neuropathy:
    A. ischemic
    B. inflammatory
4. ankylosing spondylitis: etiology is often obscure (*see page 502*)

CES from HLD: May be due to massive herniated disc, usually midline, most common at L4-5, often superimposed on a preexisting condition (spinal stenosis, tethered cord…)[113].

Prevalence of CES:
1. 0.0004 in all patients with LBP[94]
2. only ≈ 1-2% of HLD that come to surgery[94]

Time course: CES tends to develop either acutely, or (less typically) slowly (prognosis is worse in the acute onset group, especially for return of bladder function, which occurred in only ≈ 50%)[111]. 3 patterns[117]:
- Group I - sudden onset of CES symptoms with no previous low back symptoms
- Group II - previous history of recurrent backache and sciatica, the latest episode combined with CES
- Group III - presentation with backache & bilateral sciatica that later develop CES

Surgical issues: some advise a bilateral laminectomy[113] (but this is not mandatory). Occasionally, when it is difficult to remove a very tense midline disc, transdural removal may be helpful[115].

Timing of discectomy in CES: controversial, and the point of contention in numerous law suits. In spite of early reports emphasizing rapid decompression[115], other re-ports found no correlation between the time to surgery after presentation and the return of function[111, 112]. Some evidence supports the goal of performing surgery **within 48 hours** (although performing

surgery within 24 hours is desirable if possible, there is no statistically significant proof that delaying up to 48 hrs is detrimental)[118, 119].

Booking the case - lumbar discectomy

Also see defaults & disclaimers (*page v*).

1. position: prone
2. equipment: microscope (if used), minimally invasive retractors (if used)
3. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: through the back to go between the bones and remove the piece of disc that is pressing on the nerve(s)
   B. alternatives: nonsurgical management
   C. complications: (usual spine surgery complications - *see page v*) *plus* the disc can herniate again in the same place in ≈ 6% of cases, it is possible that a fragment of disc can be missed at the time of surgery, there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain),

Surgical options for lumbar radiculopathy

Once it is decided to treat surgically, options include:

1. trans-canal approaches
   A. standard open lumbar laminectomy and discectomy: 65-85% reported no sciatica one year post-op compared to 36% for conservative treatment[120]. Long-term results (> 1 year) were similar. 10% of patients underwent further back surgery during the first year[120]
   B. "microdiscectomy"[121, 122]: similar to standard procedure, however smaller incision is utilized. Advantages may be cosmetic, shortened hospital stay, lower blood loss. May be more difficult to retrieve some fragments[123 (p 1319), 124]. Overall efficacy is similar to standard discectomy[125]
   C. sequestrectomy: removal of only the herniated portion of disc
2. intradiscal procedures (*see below*)
   A. chemonucleolysis: using chymopapain (*see below*)
   B. automated percutaneous lumbar discectomy: utilizes a nucleotome
   C. percutaneous endoscopic discectomy: *see below*
   D. intradiscal endothermal therapy (**IDET** or **IDTA**): *see below*

E. laser disc decompression

Chemonucleolysis

Acceptable treatment, but less efficacious than discectomy[1] ("open" or micro). **Chymopapain** (Chymodiactin®) is injected intradiscally. Proven more effective than placebo injection[126, 127]. Typical success rates: at 1 year 85% of patients undergoing discectomy had good or excellent results compared to 44%[128] to 63%[129] for chemonucleolysis **(CNL)**. Although sciatica improves in both groups, only the discectomy group had significant improvement in back pain[128]. In one study, at 6 months 56% of patients initially having CNL had undergone surgery for unrelieved symptoms[130].

Risks[131, 132]:

Risk of the significant complication of anaphylaxis (sometimes fatal) may be reduced by skin-tests for allergic sensitivity to the agent. Other complications reported include: discitis[133], neurologic injury, vascular injury, thrombophlebitis, PE, transverse myelitis[134] (very uncommon).

Intradiscal surgical procedures (ISP)

ISPs (*see below* for specific procedures) are among the most controversial procedures for lumbar spine surgery. The theoretical advantage is that epidural scarring is avoided, and that a smaller incision or even just a puncture site is used. This is also purported to reduce postoperative pain and hospital stay (often performed as an outpatient procedure). The conceptual problem with ISPs is that they are directed at removing disc material from the center of the disc space (which is not producing symptoms) and rely on the reduced intradiscal pressure to decompress the herniated portion of the disc from the nerve root. Only ≈ 10-15% of patients considered for surgical treatment of disc disease are candidates for an ISP. ISPs are usually done under local anesthetic in order to permit the patient to report nerve root pain to identify impingement on a nerve root by the surgical instrument or needle. Overall, ISPs are not recommended until controlled trials prove the efficacy[1].

Indications utilized by proponents of intradiscal procedures:

1. type of disc herniation: appropriate only for "contained" disc herniation (i.e. outer margin of anulus fibrosus intact)
2. appropriate level: best for L4-5 HLD. May also be used at L3-4. Difficult

but often workable (utilizing angled instruments or other techniques) at L5-S1 because of the angle required and interference by iliac crest

3. not recommended in presence of severe neurologic deficit[135]

Results:

"Success" rate (≈ pain free and return to work when appropriate) reported ranges from 37-75%[136-138].

Automated percutaneous lumbar discectomy: AKA nucleoplasty. Utilizes a nucleotome[139] to remove disc material from the center of the intervertebral disc space. Significantly less efficacious than chymopapain[138], with 1 year success rate of 37% (compared to 66% for CNL). Complications include cauda equina syndrome from improper nucleotome placement[140]. In another study, nucleoplasty (with or without IDET (*see below*)) for HLD showed only modest reduction in pain at 9 months[141].

Laser disc decompression: Insertion of a needle into the disc, and introduction of a laser fiberoptic cable through the needle to allow a laser to burn a hole in the center of the disc[142, 143] (with or without endoscopic visualization).

Percutaneous endoscopic lumbar discectomy (PELD): This term refers to an essentially intradiscal procedure indicated primarily for contained disc herniations, although some small "noncontained" fragments may be treatable[144]. No large randomized study has been done to compare the technique to the accepted standard, open discectomy (with or without microscope). In one report[145] of 326 patients with L4-5 HLD, only 8 (2.4%) met study criteria (no previous operation, failure of conservative treatment, imaging study proving disc protrusion followed by discography to R/O "disc perforation") for PELD. Of these 8, only 3 were reported as having a good result. This study is not adequate for evaluating the technique.

Intradiscal endothermal therapy (IDET): AKA intradiscal (electro)thermal anuloplasty **(IDTA)**. Efficacy: 23-60% at 1 year for treating "internal disc disruption"[146] (radial fissures in the nucleus pulposus extending into the anulus fibrosus) which is purported to account for 40% of patients with chronic low back pain of unknown etiology[147].

Adjunctive treatment in lumbar laminectomy

Epidural steroids following discectomy

In a single-blinded non-randomized study of the use of epidural steroids (methylprednisolone acetate (Depo-Medrol®), dose not specified) irrigation of the thecal sac and nerve root following discectomy prior to wound closure found no statistically significant evidence of benefit in terms of amount of post-op analgesic medication needed, duration of hospital stay, or time to return to work[148]. However, the combination of *systemic* steroids at the start of the case (Depo-Medrol® 160 mg IM and methylprednisolone sodium succinate (Solu-Medrol®) 250 mg IV) combined with infiltration of 30 ml of 0.25% bipuvicaine (Marcaine®) into the paraspinal muscles at incision and closure, may reduce hospital stay and post-op narcotic requirements[149].

Methods to reduce scar formation

Epidural free fat graft: The use of an autogenous free fat graft in the epidural space has been employed in an attempt to reduce post-op epidural scar formation. Opinion varies widely as to the effectiveness, some feel it is helpful, others feel it actually exacerbates scarring[150]. In some patients, no evidence of the graft will be found on reoperation years later. The fat graft can very rarely be a cause of nerve root compression[151] or cauda equina syndrome[116] within the first few days post-op, and there is a case report of compression 6 years following surgery[152].

Other measures: Other measures include the placement of barrier films or gels. There are numerous products available, none has been shown to have reproducible benefit.

Risks of lumbar laminectomy

Overall risk of mortality in large series[153, 154]: 6 per 10,000 (i.e. 0.06%), most often due to septicemia, MI, or PE. Complication rates are very difficult to determine accurately[120], but the following is included as a guideline.

Common complications

(consider discussing these as part of informed consent)

1. infection:
   A. superficial wound infection: 0.9-5%[155] (risk is increased with age, long term steroids, obesity, ? DM): most are caused by *S. aureus* (see

Laminectomy wound infection, page 348 for management)
   B. deep infection: < 1%(*see below* under *Uncommon complications*)
2. increased motor deficit: 1-8% (some transient)
3. unintended "incidental" durotomy[A]: (*see below*) incidence is 0.3-13% (risk increases to ≈ 18% in re-do operations)[156]. Possible sequelae include those listed in *Table 18-14*
   A. CSF fistula (external CSF leak): the risk of a CSF fistula requiring operative repair is ≈ 10 per 10,000153
   B. pseudomeningocele: 0.7-2%[156] (may appear similar radiographically to spinal epidural abscess **(SEA)**, but post-op SEA often enhances, is more irregular, and is associated with muscle edema)
4. recurrent herniated lumbar disc (same level either side): 4% (with 10 year followup)[157] (*see page 460*)

A. the term "unintended durotomy" has been recommended in preference to "dural tear" (*see below*)

Uncommon complications

1. direct injury to neural structures. For large disc herniations, consider a bilateral exposure to reduce risk
2. injury to structures anterior to the vertebral bodies **(VB)**: injured by breaching the anterior longitudinal ligament **(ALL)** through the disc space, e.g. with pituitary rongeur. The depth of disc space penetration with instruments should be kept **≤ 3 cm**, since 5% of lumbar discs had diameters as small as 3.3 cm[158]. Asymptomatic perforations of the ALL occur in up to 12% of discectomies. Breach of the ALL risks potential injuries to:
   A. great vessels[159]: risks include potentially fatal hemorrhage, and arteriovenous fistula which may present years later. Most such injuries occur with L4-5 discectomies. Only ≈ 50% bleed into the disc space intraoperatively, the rest bleed into the retroperitoneum. Emergent laparotomy is indicated, preferably by a surgeon with vascular surgical experience, if available. Mortality rate is 37-67%
      1. aorta: the aortic bifurcation is on the left side of the lower part of the L4 VB, and so the aorta may be injured above this level
      2. below L4, the common iliac arteries may be injured

        3. veins (more common than arterial injuries)
            a. vena cava at and above L4
            b. common iliac veins below L4
    B. ureters
    C. bowel: at L5-S1 the ileum is the most likely viscus to be injured
    D. sympathetic trunk
3. wrong site surgery: incidence in self-reporting survey was 4.5 occurrences per 10,000 lumbar spine operations[160]. Factors identified as potential contributors to the error: unusual patient anatomy, not performing localizing radiograph. 32% of responding neurosurgeons indicated that they removed disc material from the wrong level at some time in their career
4. rare infections:
    A. meningitis
    B. deep infection: < 1%. Including:
        1. discitis: 0.5% (*see* *page 383*),
        2. spinal epidural abscess **(SEA)**: 0.67% (*see* *page 376*)
5. cauda equina syndrome: may be caused by post-op spinal epidural hematoma (*see below*). Incidence was 0.21% in one series of 2842 lumbar discectomies[161] and 0.14% in a series of 12,000 spine operations[162]. Red flags: urinary retention, anesthesia that may be saddle or <u>bilateral LE</u>
6. postoperative visual loss **(POVL)**[163]:
    A. ischemic optic neuropathy[164]: the most common cause of POVL. Commonly bilateral. Usually associated with significant blood loss (**median: 2 L**), and/or prolonged operative time (**≥ 6 hrs**). All cases had anesthetic time > 5 hrs or blood loss > 1 L. Blood loss can cause hypotension (may cause release of endogenous vasoconstrictors in addition to reduced blood flow due to low hemodynamic pressure) and increased platelet aggregation. Is <u>not</u> due to direct pressure on the globe in most cases, and can occur at any age and even in otherwise healthy patients. Blindness can be extensive and is often permanent, although early aggressive treatment may result in some improvement
        1. posterior ischemic optic neuropathy **(PION)**[164]: may follow surgery (surgical PION). Risk factors as above, plus:
            a. surgery in the <u>prone</u> position (can cause peri-orbital edema, and rarely, direct pressure on the orbit)
            b. lack of tight glycemic control

c. use of Trendelenburg position
d. hemodilution or overuse of crystalloid vs. colloid (blood) fluid replacement
e. prolonged hypotension
f. cellular hypoxia
g. decreased renal perfusion
2. anterior ischemic optic neuropathy (AION): divided into arteritic (as with GCA) and nonarteritic (common with DM)
B. central retinal artery occlusion
C. cortical blindness
7. complications of positioning:
A. compression neuropathies: ulnar, peroneal nerves. Use padding over elbows and avoid pressure on posterior popliteal fossa
B. anterior tibial compartment syndrome: due to pressure on anterior compartment of leg (reported with Andrew's frame). An orthopedic emergency that may require emergent fasciotomy
C. pressure on the eye: corneal abrasions, damage to the anterior chamber
D. cervical spine injuries during positioning due to relaxed muscles under anesthesia
8. post op arachnoiditis: risk factors include epidural hematoma, patients who tend to develop hypertrophic scar, post op discitis, and intrathecal injection of Pantopaque®, anesthetic agents or steroids. Surgical treatment is disappointing. Intrathecal depo-medrol may provide short-term relief (in spite of the fact that steroids are a risk factor for the development of arachnoiditis). Also *see page 458*
9. thrombophlebitis and deep-vein thrombosis with risk of pulmonary embolism **(PE)**[153]: 0.1% (see *Thromboembolism in neurosurgery*, page 42)
10. complex regional pain syndrome AKA reflex sympathetic dystrophy **(RSD)**: reported in up to 1.2% of cases, usually after posterior decompression with fusion, often following reoperations[165] with onset 4 days to 20 weeks post-op. *See page 576* for a critique of RSD. Treatment includes some or all of: PT, sympathetic blocks, oral methylprednisolone, removal of hardware if any
11. very rare: Ogilvie's syndrome (pseudo-obstruction ("ileus") of the colon). Usually seen in hospitalized/debilitated patients. May be related to narcotics, electrolyte deficiencies, possibly from chronic constipation. Also

reported following spinal surgery/trauma, spinal/epidural anesthesia, spinal metastases, & myelography[166]

Unintended durotomy

Unintentional opening of the dura during spinal surgery has an incidence of 0-14%[167].

Terminology: The terms "unintended durotomy", "incidental durotomy"[167], or even just "dural opening", have been recommended in preference to "dural tear" which may imply carelessness[156] when none was present. Dural openings have been associated with one or more alleged complications or sequelae in medical malpractice suits involving surgery on the lumbar spine.

The injury: By itself, opening the dura intentionally or otherwise is not expected to have a deleterious effect on the patient[156, 168]. In fact, dural opening is often a standard part of the operation for intradural disc herniation[169], tumors, etc. Although not frequent, (for incidence, *see above*) unintended durotomy is not an unusual occurrence, and alone, is not considered an act of malpractice. However, it may result from an event or events that produce more serious injuries. These events and injuries should be dealt with on their own merits.

Possible sequelae include those listed in *Table 18-14*. A CSF leak may produce "spinal headache" with its associated symptoms (*see page 58*), and if it breaches the skin it may be a risk factor for meningitis. Pain or sensory/motor deficits may be associated with injuries to nerve roots or delayed herniation of nerve roots through the dural opening.

Etiologies: For incidence, *see above*. Potential causes are many, and include[156]: unanticipated anatomic variations, adhesion of the dura to removed bone, slippage of an instrument, an obscured fold of dura caught in a rongeur or curette, thinning of the dura in cases of long-standing stenosis, and the possibility of a delayed CSF leak caused by perforation of the dura when it expands onto a surgically created spicule of bone[170]. The risk may be increased with anterior decompression for OPLL, with revision surgery, and with the use of high-speed drills[167].

Table 18-14 Possible sequelae of dural opening

Well documented
1. CSF leak
A. contained: pseudomeningocele

B. external: CSF fistula
2. herniation of nerve roots thorough opening
3. associated nerve root contusion, laceration or injury to the cauda equina
4. CSF leak collapses the thecal sac and may increase blood loss from epidural bleeding
Less well documented
1. arachnoiditis
2. chronic pain
3. bladder, bowel and/or sexual dysfunction

Treatment: If the opening is recognized at the time of surgery, watertight primary closure (with or without patch graft) should be attempted with nonabsorbable suture if at all possible to prevent pseudomeningocele and/or CSF fistula. A cottonoid placed over the opening prevents aspiration of nerve roots[171]. Care must be taken to avoid incorporating a nerve root into the closure. Most repairs will be accomplished with no complication or sequelae to the patient. When the opening is in the far (anterior) side of the dura, consideration may be given to intradural repair accessed through a posterior durotomy which is subsequently closed (this may risk additional injury to the nerve roots). Biocompatible fixatives (e.g. fibrin glue[167]) may be used to supplement primary closure.

Primary repair may be impossible in some situations (e.g. when the opening cannot be found or accessed, as is sometimes the case when it occurs on the nerve root sleeve) and alternatives here include placement of a fat or muscle graft over the suspected leak site, use of a the patient's own blood for a "blood patch" (one technique is to have the anesthesiologist draw ≈ 5-10 ml of the patient's blood from an arm vein, keeping it in the syringe for several minutes until it starts to coagulate, and then to have the anesthesiologist inject the blood onto the dura), use of gelfoam, fibrin glue… Some recommend that the wound not be drained post-op, with a water-tight closure of fascia, fat, and skin to add to the barrier. Others use a subcutaneous drain or epidural catheter. CSF diversionary procedures (e.g. through a drain inserted 1 or more levels away) may also be used.

Although bed rest **x** 4-7 days is often advocated to reduce symptoms and facilitate healing, when watertight closure has been achieved, normal post-op mobilization is not associated with a high failure rate (bed rest is recommended if symptoms develop)[167].

In one report of 8 patients with leaks that appeared post-op, re-operation was avoided when treated by resuturing the skin under local anesthesia, followed by bed rest in slight Trendelenburg position (to reduce pressure on the leakage site), broad spectrum antibiotics and antibiotic ointment over the skin incision, and daily puncture and drainage of the subcutaneous collection[172].

For other treatment measures for H/A associated with CSF leak, *see page 59*.

POST-OP CARE

Post-op orders

The following are guidelines for post-operative orders for a lumbar laminectomy without intraoperative complications; variations between surgeons and institutions must be taken into consideration:

1. admit post-anesthesia recovery (PAR) unit
2. vital signs on the nursing unit: q 2° **x** 4 hrs, q 4° **x** 24°, then q 8°
3. activity: up with assist, advance as tolerated
4. nursing care
   A. I's & O's
   B. intermittent catheterization q 4-6° PRN no void
   C. *optional*: TED hose (may reduce risk of DVT) or PCB
   D. *optional (if drain used):* empty drain q 8° and PRN
5. diet: clear liquids, advance as tolerated
6. IV: D5 1/2 NS + 20 mEq KCl/l @ 75 ml/hr, D/C when tolerating PO well (after antibiotics D/C'd if prophylactic antibiotics are used)
7. meds
   A. laxative of choice **(LOC)** PRN
   B. sodium docussate (e.g. Colace®) 100 mg PO BID when tolerating PO (stool softener, does not substitute for LOC)
   C. *optional:* prophylactic antibiotics if used at your institution
   D. acetaminophen (Tylenol®) 650 mg PO or PR q 3° PRN
   E. *narcotic analgesic*
   F. *optional*: steroids are used by some surgeons to reduce nerve-root irritation from surgical manipulation
8. labs
   A. *optional (if significant blood loss during surgery):* CBC

Post-op check

In addition to routine, the following should be checked:

❑ 1. strength of lower extremities, especially muscles relevant to nerve root, e.g. gastrocnemius for L5-S1 surgery, EHL for L4-5 surgery…

❑ 2. appearance of dressing: look for signs of excessive bleeding, CSF leak…

❑ 3. signs of **cauda equina syndrome** (*see page 446*), e.g. by post-op spinal epidural hematoma:

A. loss of perineal sensation ("saddle anesthesia")

B. inability to void: may not be not unusual after lumbar laminectomy, more concerning if accompanied by loss of perineal sensation

C. pain out of the ordinary for the post-op period

D. weakness of multiple muscle groups

Any new neurologic deficit should prompt rapid evaluation for spinal epidural hematoma[162] **(EDH)**. Delayed deficits may be due to EDH or epidural abscess. Post-op films in the recovery room can rule out graft or hardware malposition for fusions or instrumentation procedures, or changes in alignment. The diagnostic test of choice is MRI. If contraindicated or not available, CT/myelography may be indicated. An extradural defect immediately post-op suggests EDH.

Outcome of surgical treatment

In a series of 100 patients undergoing discectomy, at 1 year post-op 73% had complete relief of leg pain and 63% had complete relief of back pain; at 5-10 years the numbers were 62% for each category[90]. At 5-10 years post-op, only 14% felt that the pain was the same or worse than pre-op (i.e. 86% felt improved), and 5% qualified as having a **failed back surgery syndrome** (a heterogeneous not-precisely defined term, here meaning not returned to work, requiring analgesics, receiving worker's compensation, see *Failed back surgery syndrome*, page 457).

Attempts to measure relative merits of conservative treatment vs. surgery have failed. The recent SPORT study[173, 174] suffered from significant selection bias since patients were allowed to crossover to the other arm of the study and thus more nearly approximated the current methodology of surgical selection than an actual RCT[175]. Earlier attempts at randomized trials also suffered from methodological flaws[89]. Conclusions that can be drawn from these studies[175]: most patients with manageable or improving pain and less disability typically choose conservative treatment and most have improvement in symptoms, whereas patients with severe, persistent or worsening pain and/or neurologic deficit are more likely to choose surgery with a resultant excellent outcome.

In patients with a diminished knee-jerk or ankle-jerk pre-op, 35% and 43% (respectively) still had reduced reflexes 1 year post-op[95]; reflexes were lost post-

op in 3% and 10% respectively. The same study found that motor loss was improved in 80%, aggravated in 3%, and was newly present in 5% post-op; and that sensory loss was improved in 69% and was worsened in 15% post-op.

Foot drop: severe or complete paralysis of ankle dorsiflexion occurs in 5-10% of HLD, and about 50% of cases recover with or without treatment. Discectomy does not improve the outcome, especially in cases of painless foot drop[110].

Recurrent disc herniation: (*see page 460*)

HERNIATED UPPER LUMBAR DISCS (LEVELS L1-2, L2-3, & L3-4)

L4-5 & L5-S1 herniated lumbar discs **(HLD)** account for most cases of HLD (realistically ≈ 90%, possibly as high as 98%[94]). 24% of patients with HLD at L3-4 have a past history of a HLD at L4-5 or L5-S1, suggesting a generalized tendency towards disc herniation. In a series of 1,395 HLDs, there were 4 at L1-2 (0.28% incidence), 18 at L2-3 (1.3%), and 51 at L3-4 (3.6%)[176].

PRESENTATION

Typically presents with LBP, onset following trauma or strain in 51%. With progression, paresthesias and pain in the anterior thigh occur, with complaints of leg weakness (especially on ascending stairs).

SIGNS

Quadriceps femoris was the most common muscle involved, demonstrating weakness and sometimes atrophy.

Straight leg raising was positive in only 40%. Psoas stretch test was positive in 27%. Femoral stretch test may be positive (*see page 444*).

50% had reduced or absent knee jerk; 18% had ankle jerk abnormalities; reflex changes were more common with L3-4 HLD (81%) than L1-2 (none) or L2-3 (44%).

EXTREME LATERAL LUMBAR DISC HERNIATIONS

Definition: herniation of a disc at (**foraminal disc herniation**) or distal to (**extraforaminal disc herniation**) the facet (some authors do not consider foraminal disc herniation to be "extreme lateral"). See *Figure 18-3*.

Incidence (*see Table 18-15*): 3-10% of herniated lumbar discs **(HLD)** (series with higher numbers[177] include some HLD that are not truly *extreme* lateral).

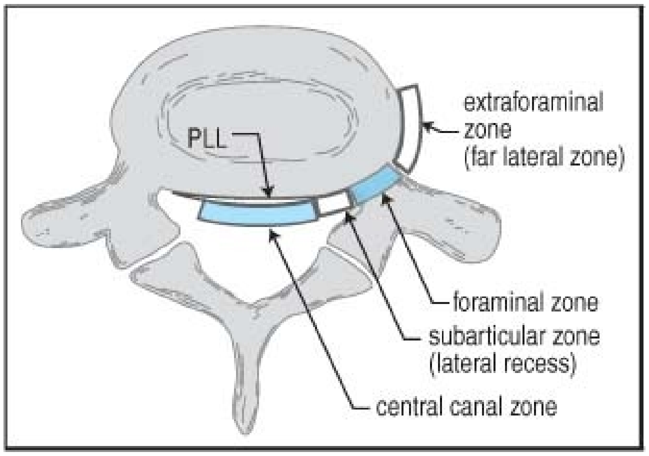

Figure 18-3 Zones of lumbar disc herniation

Differs from the more common central and subarticular HLD in that:

- the nerve root involved is usually the one exiting at that level (c.f. the root exiting at the level below)
- straight leg raising **(SLR)** is negative in 85-90% of cases ≥ 1 week after onset (excluding double herniations; ≈ 65% will be negative if double herniations are included); may have positive femoral stretch test (*see page 444*)
- pain is reproduced by lateral bending to the side of herniation in 75%
- myelography alone is rarely diagnostic (usually requires CT[178, 179] or MRI) subarticular
- higher incidence of extruded fragments (60%)
- higher incidence of double herniations on the same side at the same level (15%)
- pain tends to be more severe (may be due to fact that the dorsal root ganglion may be compressed directly) and often has more of a burning dysesthetic quality

Table 18-15 Incidence of extreme lateral HLD by level*

Disc level	No.	%
L1-2	1	1%
L2-3	11	8%
L3-4	35	24%
L4-5	82	60%
L5-S1	9	7%

* series of 138 cases[177]

Occurs most commonly at L4-5 and next at L3-4 (*see Table 18-15*), thus L4 is the most common nerve involved and L3 is next. With a clinical picture of an upper lumbar nerve root compression (i.e. radiculopathy with negative SLR), chances are ≈ 3 to 1 that it is an extremely lateral HLD rather than an upper lumbar disc herniation.

PRESENTATION

Quadriceps weakness, reduction of patellar reflex, and diminished sensation in the L3 or L4 dermatome are the most common findings.

Differential diagnosis includes:

1. lateral recess stenosis or superior articular facet hypertrophy
2. retroperitoneal hematoma or tumor
3. diabetic neuropathy (amyotrophy): *see page 796*
4. spinal tumor
   A. benign (schwannoma or neurofibroma)
   B. malignant tumors
   C. lymphoma
5. infection
   A. localized (spinal epidural abscess)
   B. psoas muscle abscess
   C. granulomatous disease
6. spondylolisthesis (with pars defect)
7. compression of conjoined nerve root
8. on MRI, enlarged foraminal veins may mimic extreme lateral disc herniation

RADIOGRAPHIC DIAGNOSIS

Radiographic diagnosis may be elusive, and up to one third are initially missed[180]. However, if actively sought, many asymptomatic far-lateral disc herniations may be demonstrated on CT or MRI.

Myelography: fails to disclose the pathology even with water soluble contrast in 87% of cases due to the fact that the nerve root compression occurs distal to the nerve root sleeve (and therefore beyond the reach of the dye)[181].

CT scan[179]: reveals a mass displacing epidural fat and encroaching on the intervertebral foramen or lateral recess, compromising the emerging root. Or,

may be lateral to foramen. Sensitivity is ≈ 50% and is similar with *post-myelographic* CT[181]. Post-discography CT[182] may be the most sensitive test (94%)[181].

MRI: similar sensitivity to post-myelographic CT. Sagittal views through the neural foramen may help demonstrate the disc herniation[180]. MRI may have ≈ 8% false positive rate due to presence of enlarged foraminal veins that mimic extreme lateral HLD[183].

SURGICAL TREATMENT

NB: compression of the dorsal root ganglion may result in a slower recovery from discectomy and overall less satisfying outcome than with the more commonplace para-median disc herniation.

Foraminal discs

Usually requires mesial facetectomy to gain access to the region lateral to the dural sac without undue retraction on nerve root or cauda equina. Caution: total facetectomy combined with discectomy may result in a high incidence of instability (total facetectomy alone causes ≈ 10% rate of slippage), although other series found this risk to be lower (≈ 1 in 33[184, 185]). An alternative technique is to remove just the lateral portion of the superior articular facet below[186]. Endoscopic techniques may be well suited for herniated discs in this location[187].

Discs herniated beyond (lateral to) the foramen

Numerous approaches are used, including:

1. traditional **midline hemilaminectomy**: the ipsilateral facet must be partially or completely removed. The safest way to find the exiting nerve root is take the laminectomy of the inferior portion of the upper vertebral level (e.g. L4 for a L4-5 HLD) high enough to expose the nerve root axilla, and then follow the nerve laterally through the neural foramen by removing facet until the HLD is identified
2. **lateral approach** (i.e. extra-canal) through a paramedian incision[188]. Advantages: the facet joint is preserved (facet removal combined with discectomy may lead to instability), muscle retraction is easier. Disadvantages: unfamiliar approach for most surgeons and the nerve cannot be followed medial to lateral. A localizing x-ray is taken with a

spinal needle. A 4-5 cm vertical skin incision is made 3-4 cm lateral to the midline on the side of the disc herniation. The incision is taken down to the thoracolumbar fascia and the subcutaneous tissue is dissected off the fascia. Above L4, one may palpate the groove between multifidus (medial) and long-issimus (lateral), where the fascia is incised. The facet joint is palpated, and blunt dissection is used to gain access to the lateral facet joint and transverse processes above and below the level of the disc herniation. The correct level is confirmed on x-ray using a probe as a marker. The intertransversarius muscle and fascia are divided. Care must be taken to avoid mechanical and electrocautery injury to the nerve and dorsal root ganglion (which lies immediately beneath the intertransverse ligament). The radicular artery, vein, and nerve root are located just beneath the transverse processes, usually slightly medial to this position. The nerve root hugs the pedicle of the level above as it exits the neural foramen (palpating this e.g. with a dental dissector helps locate it), and it may be splayed over the herniated disc fragment. If more medial exposure is necessary, the lateral facet joint may be resected. The HLD is removed. Additional removal of disc material from the disc space may be performed with down-biting pituitary rongeurs. Extracanal approach to L5-S1 requires removal of part of the sacral ala in order to access the space caudal to the L5 transverse process

DISC HERNIATIONS IN PEDIATRICS

Less than one percent of surgery for herniated lumbar disc is performed on patients between the ages of 10 and 20 yrs (one series at Mayo found 0.4% of operated HLD in patients < 17 yrs age[189]). These patients often have few neurologic findings except for a consistently positive straight leg raising test[190]. Herniated disc material in youths tends to be firm, fibrous and strongly attached to the cartilaginous end-plate unlike the degenerated material usually extruded in adult disc herniation. Plain radiographs disclosed an unusually high frequency of congenital spine anomalies (transitional vertebra, hyperlordosis, spondylolisthesis, spina bifida…). 78% did well after their first operation[189].

INTRADURAL DISC HERNIATION

Herniation of a fragment of disc into the thecal sac, or into the nerve root sleeve (the latter sometimes referred to as “intraradicular” disc herniation) has

been recognized with a reported incidence of 0.04-1.1% of disc herniations[169, 191]. Although it may be suspected on the basis of pre-op myelography or MRI, the diagnosis is rarely made preoperatively[191]. Intraoperatively, it may be suggested by the impression of a tense firm mass within the nerve root sleeve or by the negative exploration of a level with obvious clinical signs and clear cut radiographic abnormalities (after verifying that the correct level is exposed).

Surgical treatment:

Although a surgical dural opening may be utilized[169], others have found this to be necessary in a minority of cases[192].

INTRAVERTEBRAL DISC HERNIATION

AKA Schmorl's node or nodule. AKA Schmor's (no "l") nodule AKA Geipel hernia[193]. Disc herniation through the cartilaginous end plate into the cancellous bone of the vertebral body **(VB)** (AKA intraspongious disc herniation). Often an incidental finding on xray or MRI. Clinical significance is controversial. May produce low back pain initially that lasts ≈ 3-4 months after onset. Diffuse displacement (as may be seen in osteoporosis) is sometimes referred to as a **balloon disc**[5].

Clinical findings

During the acute (symptomatic) phase, patients may exhibit LBP that is aggravated by weight bearing and movement. There may be tenderness to percussion or manual compression over the involved segment.

Table 18-16 MRI signal intensity in Schmorl's nodes*

Lesion	T1WI	T2WI
symptomatic (acute)	low	high
asymptomatic (chronic)	high†	low†

* signal intensity in surrounding marrow

† the same as normal marrow

Radiographic findings

Plain x-ray: ≤ 33% may be seen on plain x-rays[194]. They may not be detectable acutely until sclerotic osseous bone casting develops.

MRI: the extrusion of disc material into the VB is easily appreciated on sagittal images. It has been suggested[195] that acute (symptomatic) lesions may appear differentiated from chronic (asymptomatic) lesions by the presence of MRI findings of inflammation in the bone marrow immediately surrounding the node as outlined in *Table 18-16*.

Treatment

Conservative treatment is indicated, usually consisting of non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally stronger pain medication and/or lumbar bracing may be required. Surgery is rarely indicated.

Outcome

With conservative treatment, symptoms generally resolve within 3-4 months of onset (as with most vertebral body fractures).

JUXTAFACET CYSTS OF THE LUMBAR SPINE

The term juxtafacet cyst **(JFC)** was originated by Kao et al.[196] and includes both **synovial cysts** (those having a synovial lining membrane) and **ganglion cysts** (those lacking synovial lining) adjacent to a spinal facet joint or arising from the ligamentum flavum. Distinction between these two types of cysts may be difficult without histology (*see below*) and is clinically unimportant[197].

JFC occur primarily in the lumbar spine (although cysts in the cervical[198-200] and thoracic[201] spine have been described). They were first reported in 1880 by von Gruker during an autopsy[202], and were first diagnosed clinically in 1968[203]. The etiology is unknown (possibilities include: synovial fluid extrusion from the joint capsule, latent growth of a developmental rest, myxoid degeneration and cyst formation in collagenous connective tissue…), increased motion seems to have a role in many cysts, and the role of trauma in the pathogenesis is debated[199, 204] but probably plays a role in a small number (≈ 14%)[205]. JFC are relatively rare, only 3 cases were identified in a series of 1,500 spinal CT exams[206], but the frequency of diagnosis may be on the rise due to the widespread use of MRI and an increasing awareness of the condition.

Clinical

The average age was 63 years in one series[205] and 58 years in a review of 54

cases in the literature[207] (range: 33-87) with a slight female preponderance in both series. Most occur in patients with severe spondylosis and facet joint degeneration[208], 25% had degenerative spondylolisthesis[205]. L4-5 is the most common level[205, 209]. They may be bilateral. Pain is the most common symptom, and is usually radicular. Some JFC may contribute to canal stenosis and can produce neurogenic claudication[210] (*see page 477*) or on occasion a cauda equina syndrome. Symptoms may be more intermittent in nature than with firm compressive lesions, such as HLD. A sudden exacerbation in pain may be due to hemorrhage within the cyst. Some JFC may be asymptomatic[211].

Differential diagnosis (also see *Differential diagnosis, Sciatica* on page 1188). Differentiating JFC from other masses relies largely on the appearance and location. Other distinguishing features include:

1. neurofibroma: unlikely to be calcified
2. free fragment of HLD: not cystic in appearance
3. epidural or nerve root metastases: not cystic
4. dural subarachnoid root sleeve dilatation: see *Spinal meningeal cysts*, page 509
5. arachnoid cyst (from arachnoid herniation through a dural defect): not associated with facet joint, margins thinner than JFC[212]
6. perineurial cysts (Tarlov's cyst): arise in space between perineurium and endoneurium, usually on sacral roots[213], occasionally show delayed filling on myelography. Usually associated with remodelling of adjacent bone

Pathology

Cyst walls are composed of fibrous connective tissue of varying thickness and cellularity. There is usually no signs of infection or inflammation. There may be a synovial lining[207] (synovial cyst) or it may be absent[208] (ganglion cyst). The distinction between the two may be difficult[197], possibly owing in part to the fact that fibroblasts in ganglion cysts may form an incomplete synovial-like lining[214]. Proliferation of small venules is seen in the connective tissue. Hemosiderin staining may be present, and may or may not be associated with a history of trauma[205].

Evaluation

Identifying a JFC pre-op helps the surgeon, as the approach differs slightly from that for HLD, and the cyst might otherwise be missed or unknowingly

deflated and unnecessary time wasted afterwards trying to find a compressive lesion. Or, the unwitting surgeon may misinterpret the cyst as a "transdural disc extrusion" and needlessly open the dura. Pre-op diagnoses were incorrect in 30% of operated cases of JFC[205].

Myelography: posterolateral filling defect (whereas most discs are situated anteriorly, an occasional fragment may migrate posterolaterally, whereas a JFC will always be posterolateral), often with a round extradural appearance.

CT scan: shows a low density epidural cystic lesion typically with a posterolateral juxtaarticular location. Some have calcified rim[211], and some may have gas within[215]. Erosion of bony lamina is occasionally seen[209, 216].

MRI: variable findings (may be due to differing composition of cyst fluid: serous vs. proteinaceous[217]). Unenhanced signal characteristics of non-hemorrhagic JFC are very similar to CSF. Hemorrhagic JFC are hyperintense. May be missed on sagittal imaging without contrast. Axial images may better demonstrate JFC. Gadolinium enhancement increases the sensitivity[208]. MRI usually misses bony erosion.

Treatment

Optimal treatment is not known. There is one case report of a cyst that resolved spontaneously[206]. If symptoms persist with conservative treatment, some promote cyst aspiration or facet injection with steroids[218], while most advocate surgical excision of the cyst.

Surgical treatment considerations: The cyst may be adherent to the dura. The cyst may also collapse during the surgical approach and may be missed. A JFC may serve as a marker for possible instability and should prompt an evaluation for the same. Some argue for performing a fusion since JFC may arise from instability, however, it appears that fusion is not required for a good result in many cases[218]. Therefore it is suggested that consideration for fusion be made on the basis of any instability and not merely on the basis of the presence of a JFC.

Minimally invasive spine surgery (MISS) has also been used for removal[219], long-term follow-up is lacking. A 15 mm entry incision is made 1.5 cm lateral to midline.

Following surgical treatment, symptomatic JFCs may recur or may develop on the contralateral side[205].

FAILED BACK SURGERY SYNDROME

Definition: failure to improve satisfactorily following back surgery (for herniated intervertebral disc, laminectomy for stenosis…). These patients often require analgesics and are unable to return to work. The failure rate for lumbar discectomy to provide satisfactory long-term pain relief is ≈ 8-25%[220]. Pending legal or worker's compensation claims were the most frequent deterrents to a good outcome[157].

Factors that may cause or contribute to the failed back syndrome:

1. incorrect initial diagnosis
   A. inadequate pre-op imaging
   B. clinical findings not correlated with abnormality demonstrated on imaging
   C. other causes of symptoms (sometimes in the presence of what was considered to be an appropriate lesion on imaging studies which may have been asymptomatic): e.g. trochanteric bursitis, diabetic amyotrophy…
2. continued nerve root or cauda equina compression caused by:
   A. residual compression (retained disc material, osteophytes…)
   B. recurrent pathology at same level: disc reherniation at the same level (usually have pain-free interval > 6 mos post-op (*see page 460*)) or restenosis (over many years[221] - was more common with midline fusions))
   C. adjacent level pathology: disc herniation or stenosis[221]
   D. compression of nerve root by peridural **scar** (granulation) tissue (*see below*)
   E. pseudomeningocele
   F. epidural hematoma
   G. conjoined nerve roots with compression at another level or in atypical location
   H. segmental instability: 3 patterns[222, 1]) lateral rotational instability, 2) postop spondylolisthesis, 3) post-op scoliosis
3. permanent nerve root injury from the original disc herniation or from surgery, includes deafferentation pain which is usually constant and burning or ice cold
4. adhesive **arachnoiditis**: responsible for 6-16% of persistent symptoms in post-op patients[223] (*see below*)
5. discitis: usually produces exquisite back pain 2-4 weeks post-op (*see page*

383)

6. spondylosis
7. other causes of back pain unrelated to the original condition: paraspinal muscle spasm, myofascial syndrome… Look for trigger points, evidence of spasm
8. post-op reflex sympathetic dystrophy **(RSD)**: *see page 450*
9. "non-anatomic factors": poor patient motivation, secondary gains, drug addiction, psychological problems… (see *Psychosocial factors*, page 436)

ARACHNOIDITIS (AKA ADHESIVE ARACHNOIDITIS)

Inflammatory condition of the lumbar nerve roots. Actually a misnomer, since adhesive arachnoiditis is really an inflammatory process or fibrosis that involves all three meningeal layers (pia, arachnoid, and dura). Many putative "risk factors" have been described for the development of arachnoiditis, including[224]:

1. spinal anesthesia: either due to the anesthetic agents *or* to detergent contaminants on the syringes used for same
2. spinal meningitis: pyogenic, syphilitic, tuberculous
3. neoplasms
4. myelographic contrast agents: less common with currently available water soluble contrast agents
5. trauma
   A. post-surgical: especially after multiple operations
   B. external trauma
6. hemorrhage
7. idiopathic

Radiographic findings in arachnoiditis

NB: Radiographic evidence of arachnoiditis may also be found in asymptomatic patients[224]. Arachnoiditis must be differentiated from tumor: the central adhesive type (*see below*) may resemble CSF seeding of tumor, and myelographic block may mimic intrathecal tumor.

Myelogram: May demonstrate complete block, or clumping of nerve roots. One of many myelographic classification systems[225] for arachnoiditis is shown in *Table 18-17*.

MRI:[3] patterns on MRI[226, 227]:

1. central adhesion of the nerve roots into 1 or 2 central "cords"
2. "empty thecal sac" pattern: roots adhere to meninges around periphery, only CSF signal is visible intrathecally
3. thecal sac filled with inflammatory tissue, no CSF signal. Corresponds with myelographic block and candle-dripping appearance

Enhancement: acute arachnoiditis may enhance. Chronic arachnoiditis usually does not enhance with gadolinium as much as tumor.

Table 18-17 Myelographic classification of arachnoiditis

Type	Description
1	unilateral focal filling defect centered on the nerve root sleeve adjacent to disc space
2	circumferential constriction around thecal sac
3	complete obstruction with "stalactites" or "candle guttering", "candle-dripping", or "paint-brush" filling defects
4	infundibular cul-de-sac with loss of radicular striations

Peridural scar

Although peridural scar is frequently blamed for causing recurrent symptoms[228, 229], there has been no proof of correlation[230]. Peridural fibrosis is an inevitable sequelae to lumbar disc surgery. Even patients who are relieved of their pain following discectomy develop some scar tissue post-op[231]. Although it has been shown that if a patient has recurrent radicular pain following a lumbar discectomy there is a 70% chance that extensive peridural scar will be found on MRI[230], this study also showed that on post-op MRIs at 6 months, 43% of patients will have extensive scar, but 84% of the time this will be asymptomatic[232]. Thus, one must use clinical grounds to determine if a patient with extensive scar on MRI is in the 16% minority of patients with radicular symptoms attributable to scar[232].

For a discussion of measures to reduce peridural scarring, *see page 448*.

Radiologic evaluation

Patients with only persistent low back or hip pain without a strong radicular component, with a neurologic exam that is normal or unchanged from pre-op, should be treated symptomatically. Patients with signs or symptoms of recurrent radiculopathy (positive SLR is a sensitive test for nerve root compression),

especially if these follow a period of apparent recovery, should undergo further evaluation.

It is critical to differentiate residual/recurrent disc herniation from scar tissue and adhesive arachnoiditis as surgical treatment has generally poor results with the latter two (see *Treatment of failed back surgery syndrome* below).

MRI without and with IV gadolinium

Diagnostic test of choice. The best exam for detecting residual or recurrent disc herniation, and to reliably differentiate disc from scar tissue. Pre-contrast studies with T1WI and T2WI yields an accuracy of ≈ 83%, comparable to IV enhanced CT[233, 234]. With the addition of gadolinium, using the protocol below yields 100% sensitivity, 71% specificity, and 89% accuracy[235]. May also detect adhesive arachnoiditis (*see above*). As scar becomes more fibrotic and calcified with time, the differential enhancement with respect to disc material attenuates and may become undetectable at some point, ≈ 1-2 years postop[234] (some scar continues to enhance for > 20 yrs).

Recommended protocol[235]

Get pre-contrast T1WI and T2WI. Give 0.1 mmol/kg gadolinium IV. Obtain T1WI images within 10 minutes (early post-contrast). No benefit from post-contrast T2WI.

Findings on unenhanced MRI

Signal from a HLD becomes more intense as the sequence is varied from T1WI → T2WI, whereas scar tissue becomes less intense with this transition. Indirect signs (also applicable to CT):

1. mass effect: a nerve root is displaced away from disc material, whereas it may be retracted toward scar tissue by adherence to it
2. location: disc material tends to be in contiguity with the disc interspace (best seen on sagittal MRI)

Findings on enhanced MRI

On *early* (≤ 10 mins post-contrast) T1WI images: scar enhances inhomogeneously, whereas disc does not enhance at all. A nonenhancing central area surrounded by irregular enhancing material probably represents disc wrapped in scar. Venous plexus also enhances, and may be more pronounced

when it is distorted by disc material, but the morphology is easily differentiated from scar tissue in these cases.

On *late* (> 30 mins post-contrast) T1WI: scar enhances homogeneously, disc had variable or no enhancement. Normal nerve roots do not enhance even on late images.

CT scan without and with IV (iodinated) contrast

Unenhanced CT scan density measurements are unreliable in the postoperative back[236]. Enhanced CT is only fairly good in differentiating scar (enhancing) from disc (un-enhancing with possible rim enhancement). Accuracy is about equal to unenhanced MRI.

Myelography, with post-myelographic CT

Postoperative myelographic criteria alone are unreliable for distinguishing disc material from scar[224, 237]. With the addition of CT scan, neural compression is clearly demonstrated, but scar still cannot be reliably distinguished from disc.

Myelography (especially with post-myelographic CT) is very capable of demonstrating arachnoiditis[237] (*see above*).

Plain LS X-rays

Generally helpful only in cases of instability, malalignment, or spondylosis[237]. Flexion/extension views are most helpful when trying to demonstrate instability.

Treatment of failed back surgery syndrome

For treatment of intervertebral disc-space infection, see *Discitis*, page 383.

Symptomatic treatment

Recommended for patients who do not have radicular signs and symptoms, or for most patients demonstrated to have scar tissue or adhesive arachnoiditis on imaging. As in other cases of non-specific LBP treatment includes: short-term bed rest, analgesics (non-narcotic in most cases), anti-inflammatory medication (non-steroidal, and occasionally a short course of steroids), and physical therapy.

Surgery

Reserved for those with recurrent or residual disc herniation, segmental

instability, or patients with a pseudomeningocele. Patients with post-op spinal instability should be considered for spinal fusion[222] (*see page 440*).

In most series with sufficient follow-up, success rates after reoperation are lower in patients with only epidural scar (as low as 1%) compared to those patients with disc and scar (still only ≈ 37%)[220]. An overall success rate (> 50% pain relief for > 2 yrs) of ≈ 34% was seen in one series[229], with better results in patients that were young, female, with good results following previous surgery, a small number of previous operations, employment prior to surgery, predominantly radicular (cf axial) pain, and absence of scar requiring lysis.

In addition to the absence of disc material, factors associated with poor outcome were: sensory loss involving more than one dermatome, and patients with past or pending compensation claims[220, 238].

Arachnoiditis: Surgery for carefully selected patients with arachnoiditis (those with mild radiographic involvement (Types 1 & 2 in *Table 18-17*), and < 3 previous back operations)[225] has met with moderate success (although in this series, no patient returned to work). Approximate success rate in other series[239, 240]: 50% failure, 20% able to work but with symptoms, 10-19% with no symptoms. Surgery consists of removal of extradural scar enveloping the thecal sac, removing any herniated disc fragments, and performing foraminotomies when indicated. Intradural lysis of adhesions is <u>not</u> indicated since no means for preventing reformation of scar has been identified[240].

RECURRENT HERNIATED LUMBAR DISC

Rates quoted in the literature range from 3-19% with the higher rates usually in series with longer follow-up[241]. In an individual series with 10 year mean F/U, the rate of recurrent disc herniation was 4% (same level, either side), one third of which occurred during the 1st year post-op (mean: 4.3 yrs)[157]. A <u>second</u> recurrence at the same site occurred in 1% in another series[241] with mean F/U of 4.5 yrs. In this series[241], patients presenting for a second time with disc herniation had a recurrence at the same level in 74%, but 26% had a HLD at another level. Recurrent HLD occurred at L4-5 more than twice as often as L5-S1241.

It is often possible for a smaller amount of recurrent herniated disc to cause symptoms than in a "virgin back", due to the fact that the nerve root is often fixated by scar tissue and has little ability to deviate away from the fragment[150].

TREATMENT

Initial recommended treatment is as with a first time HLD. Nonsurgical treatment should be utilized in the absence of progressive neurologic deficit, cauda equina syndrome **(CES)** or intractable pain.

Surgical treatment

Disagreement occurs regarding optimal treatment. See *PRACTICE GUIDELINE 18-5*, page 440.

Surgical outcome:

As with first time HLD, the outcome from surgical treatment is worse in worker's compensation cases and in patients undertaking litigation, only ≈ 40% of these patients benefit[241, 242]. A worse prognosis is also associated with: patients with < 6 mos relief after their first operation, cases where fibrosis without recurrent HLD is found at operation.

Spinal cord stimulation

One study actually showed a better response rate to spinal cord stimulation than to reoperation[243]. Since surgery for recurrent HLD carries a higher risk of dural and nerve root injury, and a lower success rate than first time operations, this may be a viable option for some patients.

18.3.2. Cervical disc herniation

CLINICAL ASPECTS

The following facts explain the findings in herniated cervical disc **(HCD)**:

1. in the cervical region, the nerve root exits <u>above</u> the pedicle of its like-numbered vertebra (opposite to the situation in the lumbar spine, due to the fact that there are 8 cervical nerve roots and only 7 cervical vertebrae)
2. each root exits passes through its neural foramen in close relation to the undersurface of the pedicle
3. the intervertebral disc space is located close to the inferior portion of the pedicle (unlike the lumbar region)

CERVICAL NERVE ROOT SYNDROMES (CERVICAL RADICULOPATHY)

Due to the facts listed above, a HCD usually impinges on the nerve exiting from the neural foramen at the level of the herniation (e.g. a C6-7 HCD usually

causes C7 radiculopathy). This gives rise to the characteristic cervical nerve root syndromes shown in *Table 18-18*.

Some clinical specifics:

C4 radiculopathy is not common, and may produce nonradiating axial neck pain. Left C6 radiculopathy (e.g. from C5-6 HCD) occasionally presents with pain simulating an MI (pseudo-angina). C8 and T1 nerve root involvement may produce a partial Horner's syndrome.

The most common scenario for patients with herniated cervical disc is that the symptoms were present upon awakening in the morning, without identifiable trauma or stress[244].

Table 18-18 Cervical disc syndromes

	— Level of herniated cervical disc —			
	C4-5	**C5-6**	**C6-7**	**C7-T1**
% of cervical discs	2%	19%	69%	10%
compressed root	C5	C6	C7	C8
reflex diminished	deltoid & pectoralis	biceps & brachioradialis	triceps	finger-jerk*
motor weakness	deltoid	forearm flexion	forearm ext (wrist drop)	hand intrinsics
paresthesia & hypesthesia	shoulder	upper arm, thumb, radial forearm	fingers 2 & 3, all fingertips	fingers 4 & 5

* not everyone has a finger flexor reflex. Description: gently lift the fingertips of the patient's pronated hand and tap the underside of the fingers with a reflex hammer. When present, fingers flex in response

Differential diagnosis: *see page 1197*.

Cervical myelopathy and SCI due to cervical disc herniation

Acute cord compression presenting with myelopathy or SCI (including complete SCI and incomplete syndromes, especially central cord syndrome (*see page 948*) and some-times Brown-Sequard syndrome[245] (*see page 950*)) is well described in association with traumatic cervical disc herniation[246]. Less commonly, these findings may occur in non-traumatic cervical disc herniation.

Signs useful in evaluating cervical radiculopathy

Almost all herniated cervical discs cause painful limitation of neck motion. Neck extension usually aggravates pain when cervical disc disease is present (a minority of patients instead exhibit pain with flexion). Some patients find relief

in elevating the arm and cupping the back or the top of the head with the hand (**abduction relief sign**, *see below* for shoulder abduction test). Lhermitte's sign (electrical shock-like sensation radiating down the spine) may be present (*see page 1198* for DDx).

Miscellaneous

The following tests were found to be specific, but not particularly sensitive in detecting cervical root compression[247]:

1. **Spurling's sign** 248: radicular pain reproduced when the examiner exerts down-ward pressure on vertex while tilting head towards symptomatic side (sometimes adding neck <u>extension</u>). Causes narrowing of the intervertebral foramen and possibly increases disc bulge. Used as a "mechanical sign" analogous to SLR for lumbar disc herniation
2. **axial manual traction**: 10-15 kg of axial traction is applied to a supine patient with radicular symptoms (pull up on patient's mandible and occiput). The reduction or disappearance of radicular symptoms is a positive finding
3. **shoulder abduction test** 249: a sitting patient with radicular symptoms lifts their hand above their head. The reduction or disappearance of radicular symptoms is a positive finding. Moderately sensitive, fairly specific[250]

EVALUATION

MRI

The study of choice for initial evaluation for herniated cervical disc **(HCD)**. Accuracy is less than water soluble contrast myelogram/CT (≈ 85-90% accuracy for MRI because of only fair to good imaging of neural foramen), but is non-invasive. For <u>myelopathy</u>, MRI is > 95% effective in diagnosing.

CT AND MYELOGRAM/CT

Indications: when MRI cannot be done, when resolution or image quality on MRI is inadequate, or when more bony detail is required. Also, to evaluate for ossification of the posterior longitudinal ligament **(OPLL)** in suspicious cases.

Plain CT: is usually good at C5-6, is variable at C6-7 (due to artifact from patient's shoulders, depending on body habitus), and is usually poor at C7-T1.

Myelogram/CT (water soluble intrathecal contrast): invasive, on rare

occasions requires overnight hospitalization. Accuracy is ≈ 98% for cervical disc disease.

TREATMENT

Over 90% of patients with acute cervical radiculopathy due to cervical disc herniation can improve without surgery[251]. The recovery period may be made more tolerable by adequate pain medication, anti-inflammatory medication (NSAIDs or short-course tapering steroids) and intermittent cervical traction (e.g. 10-15 lbs for 10-15 minutes, 2-3 **x** daily).

Surgery is indicated for those that fail to improve or those with progressive neurologic deficit while undergoing non-surgical management.

Management of myelopathy/central cord syndrome associated with acute cervical disc herniation is controversial, since the natural history is favorable in most cases. However, some patients have poor recovery and experience permanent deficits even with emergency surgery[252].

Surgical options:

1. anterior cervical discectomy: *see below*
    A. without any prosthesis or fusion
    B. combined with fusion: the most common approach
        1. without anterior cervical plating
        2. with anterior cervical plating
    C. with artificial disc (arthroplasty)
2. posterior approaches
    A. cervical laminectomy
    B. keyhole laminotomy

For practice guidelines regarding intra-op electrophysiologic monitoring for surgery for cervical radiculopathy, see *PRACTICE GUIDELINE 18-18*, page 491.

ANTERIOR CERVICAL DISCECTOMY WITH FUSION (ACDF)

Without special modifications, a routine anterior approach is limited ≈ to levels C3-7.

Advantages over posterior (nonfused) approach:

1. safe removal of osteophytes
2. fusion of disc space affords immobility (up to 10% incidence of

subluxation with extensive posterior approach)

3. only viable means of directly dealing with centrally herniated disc

Disadvantages over posterior approach: immobility at fused level may increase stress on adjacent disc spaces. If a fusion is performed, some surgeons prescribe a rigid collar (e.g. Philadelphia collar) for 6-12 weeks. Multiple level ACDF can devascularize the vertebral body (or bodies) between discectomies.

Booking the case - ACDF

Also see defaults & disclaimers (*page v*).

1. position: supine, some use halter traction with this
2. equipment:
   A. microscope (not used by all surgeons)
   B. C-arm
3. implants: graft (e.g. PEEK, cadaver bone, titanium cage…) and anterior cervical plate (optional, especially on single level ACDF)
4. neuromonitoring: (optional) some surgeons used SSEP/MEP
5. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place a graft where the disc was, and possibly place a metal plate on the front of the spine. Some surgeons take bone from the hip to replace the removed disc
   B. alternatives: nonsurgical management, surgery from the back of the neck, artificial disc (in some cases)
   C. complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (< 4% chance of it being permanent), injury to: food-pipe (esophagus), windpipe (trachea), arteries to the brain (carotid), spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs

Technique

A summary of the steps involved is included here. For C5-6, the skin incision is made at level of cricoid cartilage, for other levels, appropriate adjustments up or down may be made, sometimes with the assistance of fluoroscopy. The incision is approximately 5-6 cm horizontally, centered on the SCM. Many right handed surgeons prefer operating from the right side of the neck, although the

risk to the recurrent laryngeal nerve **(RLN)** is lower with a left sided approach (the RLN lies in a groove between the esophagus and trachea). The skin may be undermined off the platysma to permit a vertical incision in the platysma in the same orientation as its muscle fibers. Alternatively, some incise the platysma horizontally with scissors horizontally.

Dissect in tissue plane medial to SCM. For the C5-6 interspace, angle slightly cranially during dissection. For the C6-7 disc, proceed almost straight down to spine. Sweep omohyoid medially (to stay out of it and to protect the RLN). The trachea + esophagus are retracted medially. The carotid sheath + SCM are retracted laterally.

After verification of level with lateral C-spine x-ray with spinal needle in the interspace, bipolar the prevertebral fascia and medial edges of the longus coli muscles longitudinally in the midline. Self-retaining retractor blades are inserted underneath the fascia to retract the longus coli muscles laterally. The anesthesiologist is asked to deflate the cuff on the endotracheal tube and then to re-inflate it using minimal leak technique to reduce the risk of compression injury from the retractor. The disc space is incised with a 15 scalpel blade. The discectomy is performed with curettes and pituitary rongeurs; a vertebral body spreader aids the exposure. The posterior longitudinal ligament is incised, one technique is to elevate it with a sharp nerve hook and then incise it with a #11 scalpel. The subligamentous space is probed with a blunt nerve hook. The posterior lip of the VB above and below are removed with a Kerrison rongeur with a small foot-plate. Decompression of the roots is verified with the blunt nerve hook. Fusion is performed at this time if desired by placing the graft in the interspace.

For redo operations (same or different levels): approach is usually from the same side as previous operation(s) since many patients have swallowing issues post-op, and some may be due to partial recurrent laryngeal nerve injury (which can be subclinical) and which could result in a permanent need for a feeding tube if a contralateral injury occurs. If for some reason it is desired to go to the opposite side, an evaluation by an ENT physician is recommended, and should include scoping the patient to rule-out subclinical problems that could turn into major difficulties if bilateral.

To fuse or not to fuse?

Table 18-19 compares ACD (no fusion) to ACDF for radiculopathy in a number of aspects[253].

Choice of graft material:

Autologous bone (usually from iliac crest), non-autologous bone (cadaveric), bone substitutes (e.g. hydroxyapatite[254]) or synthetics (e.g. PEEK or titanium cage) filled with osteogenic material. Substitutes for autologous bone eliminate problems with the donor site (*see page 465*), but may have a higher rate of absorption. There were also cases of HIV transmission from cadaveric bone grafts in 1985, however, no further cases have been reported.

Anterior cervical plating: Recommendations for plating following ACDF are shown in *PRACTICE GUIDELINE 18-7*.

Table 18-19 Comparison of ACD to ACDF for radiculopathy[253]

Component	Assessment
Clinical outcome measures*	ACD & ACDF are equivalent (**Level C**, Class I)
Relief of arm pain	
Relief of neck pain associated with 1-level disc degeneration	Conflicting evidence which is better (Class II)
More <u>rapid</u> relief of neck and arm pain	ACDF is better than ACD (**Level D**, Class III) (functional outcomes are similar)
Maintaining foraminal or disc space height	ACDF cannot be recommended over ACD (**Level C**, Class II)
Risk of post-op kyphosis	ACDF is better than ACD (**Level C**, Class II)
Fusion rate	

* VAS, Odom's criteria, McGill pain questionnaire, SF-36

PRACTICE GUIDELINE 18-7 ANTERIOR CERVICAL PLATING

1 level ADCF: The addition of an anterior plate to an ACDF is recommended to reduce the pseudarthrosis rate and graft problems (**Level D** Class III) and to maintain lordosis (**Level C** Class II) but it does not improve clinical outcome alone (**Level B** Class II)[253]
2 level ADCF: Plating is recommended to improve arm pain. Plating does not improve other outcome parameters (**Level C** Class II)[253]

Use of bone morphogenic proteins (BMP):

PRACTICE GUIDELINE 18-8 USE OF BMP IN CERVICAL INTERBODY

GRAFTING
Current evidence does not support the *routine* use of rhBMP-2 for cervical arthrodesis (Level C Class II)[255]*

* italics added. Use with precautions (see text) may be indicated in cases with high risk of nonunion

Use of BMP in anterior cervical discectomies is not FDA approved, but has been used off-label. Complication rates as high as 23-27% have been reported (including postop swallowing or respiratory difficulties as a result of edema which is usually temporary) compared to 3% without BMP[255]. If used, it is recommended that a smaller dose be employed than in the lumbar spine (25% has been advocated) and to avoid contact of BMP with soft tissues in the neck.

POST-OP CHECK

In addition to routine, the following should be checked

❑ 1. evidence of significant post-op wound hematoma: should be first consideration in patient with airway obstruction post-op. Wound may need to be emergently opened on floor if airway is compromised, see *Carotid endarterectomy, disruption of arteriotomy closure, management* on page 1154. Also consider swelling from IJV thrombosis (rare) in differential diagnosis (*see below*)

A. respiratory distress

B. extreme difficulty swallowing: alternatively may indicate anterior extrusion of bone graft impinging upon esophagus (check lateral C-spine x-ray)

C. tracheal deviation: may be visible or may be seen on AP C-spine x-ray

❑ 2. weakness of nerve root of level operated: e.g. biceps for C5-6, triceps for C6-7

❑ 3. long tract signs (Babinski sign…) which may indicate cord compression by spinal epidural hematoma

❑ 5. hoarseness: may indicate vocal cord paresis from recurrent laryngeal nerve injury: hold oral feeding until this can be further assessed

ACDF COMPLICATIONS

Common ones listed below, see references[256, 257] for more details. The most common complication following ACDFs: swallowing difficulties (may be multifactorial).

- exposure injuries
    A. perforation of pharynx, esophagus and/or trachea: minimize by blunt retraction until longus colli is separated from its attachment to vertebrae.
        - Esophageal injuries are very difficult to manage, and require ENT involvement. The incidence may be higher with use of anterior cervical plate, and injury may not manifest until years after the fusion (may be due to repetitive motion of esophagus over the plate). Treatment of esophageal perforation is usually facilitated by plate removal
    B. vocal cord paresis: due to injury of the recurrent laryngeal nerve **(RLN)** or vagus. Incidence: **11%** temporary, **4%** permanent paresis. Symptoms include: hoarseness, breathiness, cough, aspiration, mass sensation, dysphagia, and vocal cord fatigue[258]. Avoid sharp dissection in paratracheal muscles. Some cases may be due to prolonged retraction against trachea and not to nerve division; to reduce this risk, after the self-retaining retractor is placed, have the anesthesiologist deflate the cuff on the ET tube and then inflate it to minimal leak pressure. More common with right sided approaches, primarily in the lower cervical spine (C5-6 and below) where the RLN is more vulnerable[258]
    C. vertebral artery injury: thrombosis or laceration. 0.3% incidence[257]. Treatment alternatives include: packing, direct repair by temporary clipping with aneurysms clips and repair with 8-0 prolene[259] and endovascular trapping. Risks of treating hemorrhagic complications with packing include: recurrent bleeding, AV fistula, pseudoaneurysm, arterial thrombosis[257], distal embolic CVA (primarily in cerebellum)
    D. carotid injury: thrombosis, occlusion, or laceration (usually by retraction)
    E. CSF fistula: usually difficult to repair directly. Place fascial graft beneath bone plug. Keep HOB elevated post op. Consider: dural sealant (fibrin glue, DuraSeal®…), lumbar drain
    F. Horner’s syndrome: sympathetic plexus lies within longus coli, thus do not extend dissection far laterally into these muscles

G. thoracic duct injury: in exposing lower cervical spine, primarily on left

H. thrombosis of **internal jugular vein**[260]: rare. Carries 2-3% risk of PE[261]. Treatment options: anticoagulation (oral or IV) may lower the mortality[262], SVC filter if anticoagulation is contraindicated[263], percutaneous thrombectomy[264]

- spinal cord or nerve root injuries
  A. spinal cord injury: especially risky in myelopathy due to narrowed canal. Minimize risk by penetrating the osteophyte at the lateral margin of interspace (however, this increases risk to nerve root)
  B. avoid hyperextension during intubation: anesthesiologist may need to determine patient's tolerance pre-op. Consider fiberoptic guided or awake nasotracheal intubation in extreme stenosis
  C. bone graft must be shorter than interspace depth. Exercise caution in tapping graft into position
  D. sleep induced apnea: rare but serious complications of C3-4 level operations[265]. May be associated with bradycardia & cardiorespiratory instability. Possibly due to disruption of the afferent component of the central respiratory control mechanism
- bone fusion problems
  A. failure of fusion (pseudarthrosis): *see below*
  B. anterior (kyphotic) angulation deformity: may be as high as 60% with Cloward technique (may be reduced by collar immobilization). May develop in Hirsch technique with excessive bone removal
  C. graft extrusion: 2% incidence (rarely requires re-operation unless compression of cord posteriorly, or esophagus or trachea anteriorly occurs)
  D. donor site complications: hematoma/seroma, infection, fracture of ilium, injury to lateral femoral cutaneous nerve, persistent pain due to scar, bowel perforation
- miscellaneous
  A. wound infection: incidence < 1%
  B. post-op hematoma: *see above*. Placing cervical collar in O.R. may delay recognition
  C. dysphagia and hoarseness: common. Usually transient (*see below*)
  D. adjacent level degeneration: controversial whether this represents a sequelae to altered biomechanics from surgery, or a predisposition to

cervical spondylosis[266]. Many (≈ 70%) are asymptomatic[267]

E. postoperative discomfort:
   1. globus: the sensation of a lump in throat (*see below*)
   2. nagging discomfort in neck, shoulder, and very commonly in interscapular regions (may last several months). May correlate with amount of distraction of the disc space

F. complex regional pain syndrome AKA reflex sympathetic dystrophy **(RSD)**: rarely described in the literature[268], possibly due to stellate ganglion injury (*see page 576*)

G. angioedema: massive edema of the tongue and neck[269]. A dramatic hypersensitivity reaction (not really a direct complication of ACDF, but superficially can mimic some findings of post-op hematoma). If limited to the tongue, the airway is not compromised. For treatment, *see page 125*

H. pneumothorax or hemothorax[270]: accessing C7-T1 or lower may expose the pleural apex

Dysphagia following ACDF

Symptoms: Include: difficulty swallowing (solids, liquids including saliva), pain with swallowing (odynophagia), globus (sensation of a lump in throat) and compromise of ability to protect against aspiration. Food may stick in the throat (or feel as if it is) and there may be coughing or choking.

Incidence: Early dysphagia is common. Incidence: 60%[271] in retrospective survey after noninstrumented fusion[A], 50% in prospective study[272]. At 6 months, only ≈ 5% reported moderate or severe dysphagia[272]. Surgery at multiple levels increased the risk at 1 & 2 months[272]. Decreases significantly in most cases by 6 months[272].

Etiologies: Etiologies of post-op dysphagia include:

1. post-op hematoma. If severe, may cause tracheal obstruction (*see above*)
2. post-op edema, due in part to retraction of esophagus
3. effects of general anesthesia: e.g. irritation from ET tube. Accounts for up to 23% of early symptoms[A]. Usually subsides within ≈ 24-72 hours
4. recurrent laryngeal nerve dysfunction:
   A. temporary: usually due to traction on the nerve
   B. permanent: 1.3% at 12 months[272]

5. esophageal injury
   A. at time of surgery
   B. delayed: possibly from repetitive abrasion on surgical site/hardware
6. cervical collar
   A. prevents patient from lowering jaw during swallow phase, which compromises effective glottic closure of airway
   B. may be too tight thereby directly squeezing the throat
7. protrusion of graft/hardware anterior to the vertebral bodies
   A. some protrusion is present with most anterior hardware. This may be minimized with “zero profile” instrumentation
   B. hardware failure (screw-pullout/backout/breakage, plate pullout)
   C. interbody graft migration: without anterior plate, or in conjunction with anterior plate displacement
8. excessive adhesions[273]
9. denervation of the pharyngeal plexus[273]
10. rare conditions: swelling from IJV thrombosis, angioedema

---

A. dysphagia occurred in 23% in a control group undergoing unrelated lumbar spine surgery[271]

Management:

1. initial management: rule-out emergent/serious conditions (severe edema, hematoma with airway compromise, risk of aspiration)
   A. if there is significant stridor or dysphonia, especially if tracheal deviation is obvious, someone must stay with the patient as efforts are made to emergently take the patient to the O.R. for wound exploration evacuation. Consider opening the wound at the bedside if delays occur or if symptoms are severe (see *Carotid endarterectomy, disruption of arteriotomy closure, management* on page 1154). Emergent anesthesia consultation for airway protection - alert them to the likelihood of deviated trachea which challenges even the most expert at intubating
2. once emergent conditions are ruled out, early management is geared towards amelioration of symptoms
   A. advise patient to eat softer foods (temporarily avoiding steak or bread), to chew food well, to wash down dry foods with a drink. Reassure patient that most cases largely resolve with 6 months[272]

B. if significant symptoms persist > 2 weeks
   1. refer patient to ENT for laryngoscopy to rule out vocal cord paralysis (from RLN injury) or other etiologies
   2. modified barium swallow
3. persistent symptoms may be amenable to surgical intervention, including hardware removal and lysing of adhesions[273], management of esophageal perforation usually requires consultation with ENT

Pseudarthrosis (or pseudoarthrosis) following ACDF

PRACTICE GUIDELINE 18-9 ASSESSMENT OF SUBAXIAL FUSION

> 2 mm movement between spinous processes on dynamic (flexion-extension) cervical spine x-rays is recommended as a criteria for pseudarthrosis (**Level B** Class II), this measurement is unreliable when performed by the treating surgeon (**Level C** Class II)[274].
Visualization of bone trabeculation across the fusion on static films is a less reliable marker for fusion (**Level D** Class III) (2D reformatted CT increases the accuracy (**Level D** Class III))[274]

Pseudarthrosis may occur with or without supplemental anterior cervical plating.

Incidence: Difficult to assess because of lack of validated criteria. Estimate: 2-20%. Higher with dowel technique (Cloward) than with keystone technique of Bailey & Badgley or with interbody method of Smith-Robinson (10%) or with non-fusion advocated by Hirsch. One criteria: motion > 2 mm between the tips of the spinous processes on lateral flexion/extension x-rays[275, 276]. Other criteria: lucencies around the screws of an anterior plate, toggling of the screws on flexion/extension x-rays.

Presentation: Not uniformly associated with symptoms or problems[275, 277]. Some patients may have chronic or recurrent neck pain, some may present with radicular symptoms. (NB: when DePalma's data is analyzed with patients reclassified as failures if neck and/or arm symptoms persist, the success rate of surgery is lower with pseudarthrosis[278]).

Management: (Guidelines are shown in *PRACTICE GUIDELINE 18-10*). No treatment is required for <u>asymptomatic</u> pseudarthrosis. Options for symptomatic

patients include re-resection of the bone graft with repeat fusion[279] (some recommend using autologous bone if allograft was used, a plate may be considered if one was not used previously), cervical corpectomy with fusion[279], or posterior cervical fusion.

PRACTICE GUIDELINE 18-10 MANAGEMENT OF ANTERIOR CERVICAL PSEUDARTHROSIS

Revision of *symptomatic** pseudarthrosis should be considered (**Level D** Class III)[280]. Posterior approaches may be associated with higher fusion rates on revision than anterior approaches (**Level D** Class III)[280]

* italics added

CERVICAL DISC ARTHROPLASTY

PRACTICE GUIDELINE 18-11 CERVICAL DISC ARTHROPLASTY

Cervical arthroplasty is a recommended alternative to ACDF in selected patients for control of arm and neck pain (**Level B** Class II)[253]

An alternative to fusion. Uses an artificial disc to preserve motion at the level of the discectomy. Some of the available cervical disc replacement **(CDR)** models are shown in *Table 18-20*[281].

Table 18-20 Artificial cervical discs

Trade name	Manufac-turer	Material	IAR*	Comment
Prestige®	Medtronic	MOM* (chrome cobalt stainless steel)	variable ball in trough	1st FDA approved CDR; lots of MRI artifact
Bryan®	Medtronic	lubricated elastic nucleus sealed in a flexible membrane	variable in center of disc space	
Advent®	Blackstone (Orthofix)	flexible elastomer core		withdrawn from market
ProDisc-C	Synthes	metal-on-polyethylene	posterior part of inferior VB	midline keel inserts into VB; lots of MRI artifact
Cervicore®	Stryker	MOM	inferior VB	
PCM*®	Cervitech	metal-on-polyethylene	gliding motion	contoured to endplates

* Abbreviations: IAR = instantaneous axis of rotation, MOM = metal-on-metal, PCM = Porous-coated Motion

Booking the case - cervical disc arthroplasty

Also see defaults & disclaimers (*page v*).

1. position: supine, some use halter traction with this
2. equipment:
   A. microscope (not used by all surgeons)
   B. C-arm
3. implants: schedule vendor to provide desired artificial disc
4. neuromonitoring: (optional) some surgeons used SSEP/MEP
5. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place an artificial disc
   B. alternatives: nonsurgical management, surgical fusion (from the front or the back of the neck)
   C. complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (< 4% chance of it being permanent), injury to: food-pipe (esophagus), windpipe (trachea), arteries to the brain (carotid) with stroke, spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs (if used). The disc may eventually wear out and further surgery may be needed

Post-op orders:

1. no cervical collar (the goal is to preserve motion at the operated level)
2. NSAIDs around the clock for ≈ 2 weeks (this inhibits bone growth which theoretically helps avoid undesirable fusion at the operated level)

POSTERIOR CERVICAL DECOMPRESSION (CERVICAL LAMINECTOMY)

Not necessary for unilateral radiculopathy (use either ACD or keyhole laminotomy). Consists of removal of cervical lamina (laminectomy) and spinous processes in order to convert the spinal canal from a "tube" to a "trough".

Usually reserved for the following conditions:

1. multiple cervical discs or osteophytes (anterior cervical discectomy **(ACD)** is usually used to treat only 2, or possibly 3, levels without) with myelopathy
2. where the anterior pathology is superimposed on cervical stenosis, and the latter is more diffuse and/or more significant (see *Cervical spinal stenosis*, page 485)
3. in professional speakers or singers where the 4% risk of permanent voice change due to recurrent laryngeal nerve injury with ACD may be unacceptable

Booking the case - cervical laminectomy

Also see defaults & disclaimers (*page v*).

1. position: prone, some use pin headholder
2. equipment:
   A. C-arm
   B. high-speed drill
3. implants: cervical lateral mass screws and rods if fusion is being done
4. neuromonitoring: some surgeons used SSEP/MEP
5. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the back of the neck to remove the bone over the compressed spinal cord and nerves and possibly to place screws and rods to fuse the boned together
   B. alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery without fusion, laminoplasty

C. complications: nerve root injury (C5 nerve root is the most common), may not relieve symptoms necessitating further surgery, possible seizures with MEPs. If fusion is not done, risk of progressive bone slippage which would require further surgery

POSTERIOR KEYHOLE LAMINOTOMY

PRACTICE GUIDELINE 18-12 CERVICAL LAMINOFORAMINOTOMY

Cervical laminoforaminotomy is recommended as a surgical treatment option for symptomatic cervical radiculopathy caused by disc herniation or lateral recess narrowing (**Level D** Class III)[282]

AKA “keyhole foraminotomy”. Decompresses only individual nerve roots (but not the spinal cord) by creating a small “keyhole” in the lamina to access the nerve root.

Indications for keyhole approach (as opposed to anterior discectomy):

1. monoradiculopathy with posterolateral <u>soft</u> disc sequestration (small <u>lateral</u> osteophytic spurs may also be addressed)
2. radiculopathy in patients who are professional speakers or singers (*see above*)
3. for lower (e.g. C7, C8 or T1) or upper (e.g. C3 or C4) cervical nerve root compression, especially in a patient with a short thick neck, making an anterior approach more difficult

Booking the case - cervical keyhole laminectomy

BOOKING

Also see defaults & disclaimers (*page v*).

1. position: prone, some use pin headholder
2. equipment:
   A. microscope (not used by all surgeons)
   B. C-arm
3. instrumentation: some surgeons use a tube retractor system
4. neuromonitoring: some surgeons used SSEP/MEP
5. consent (in lay terms for the patient - not all-inclusive):

A. procedure: surgery through the back of the neck to remove the bone over the compressed nerve root and possibly remove fragment of herniated disc

B. alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery with fusion

C. complications: nerve root injury, may not relieve symptoms necessitating further surgery, possible seizures with MEPs

Technique[283-285]

1. position

   A. prone, on chest rolls. Adhesive tape is used to retract shoulders down for any level below about C4-5. The head is stabilized on a horse-shoe headrest or in a Mayfield head holder.

   B. sitting position: generally abandoned. May be used with proper precautions (*see page 153*)

"Open" keyhole foraminotomy

The desired level is localized with intra-op x-ray or fluoroscopy before making the skin incision, a 2-3 cm midline incision is adequate. A unilateral exposure suffices. Periosteal elevators are used to dissect muscles off the lamina and facet joint in the sub-periosteal plane. A Kocher clamp may be placed on the spinous process to permit confirmation of the correct level on intraoperative x-ray. A Scoville retractor or equivalent is employed.

A high-speed drill (e.g. with diamond burr) is used to make an opening in the medial one-third to one-half of the inferior facet of the vertebra above the desired disc space, extending slightly medially into the junction with the lamina. Once the inferior facet is penetrated, the superior facet of the inferior vertebral level will be visualized. This is also thinned with the drill (it is critical to remove the bone of the superior facet of the level below caudally to where it meets the pedicle). A small Kerrison rongeur may be used to slightly enlarge the laminectomy. An opening is made in the ligamentum flavum overlying the lateral aspect of the spinal cord dura. The nerve root can be identified as it exits from the thecal sac, and can be followed as it travels between the pedicles of the vertebrae above and below. Soft tissues (including ligamentum flavum) form fibrous bands across the dorsum of the nerve, and are removed to further expose the dura of the nerve root. The venous plexus around the nerve root is coagulated with bipolar cautery and then divided to mobilize the nerve. The nerve may then

be gently moved a few millimeters rostrally using a micro nerve hook. The dura overlying the spinal cord should not be manipulated, and the disc space need not be entered. Inspection for free disc fragments should begin in the nerve root axilla using a probe (e.g. blunt nerve hook). Next, the space anterior to the root (the region of the disc) may be palpated. Any disc fragments that are dislodged are removed with a small pituitary rongeur. If the disc fragment is contained anterior to the posterior longitudinal ligament **(PLL)**, the PLL may be incised in the region of the nerve root axilla with a #11 scalpel blade in a motion that is directed downward and laterally, away from the nerve root and spinal cord. The foraminotomy may be extended slightly laterally if the foramen still feels tight when probed. Small osteophytes can potentially be reduced using a small reversed-angled curette, although some surgeons believe that the need for this is obviated by the decompression provided by the keyhole opening. In some cases, simple posterior decompression of the nerve root (without removing a disc fragment) may be adequate to relieve compression. Spinal stability is usually preserved if less than half the facet joint is removed.

MIS keyhole foraminotomy

Positioning as described above.

1. skin incision (use fluoro to locate the correct level for the incision)
    A. incision 1 cm off midline on the side of the pathology at the level of the disc space
    B. remove adhesive plastic barrier (e.g. Ioban®) from around the opening to prevent pieces from being dragged into the incision
2. avoid using a guidewire to reduce the risk of penetrating the interlaminar space. STAY LATERAL and insert the thinnest dilator. Dock the dilator on the lateral mass and insert progressively sized dilators
3. use Bovie to expose lateral lamina and medial facet joint. Start laterally where bone is more easily felt and there is little danger of penetrating the interlaminar space and injuring the spinal cord
4. use a straight curette to expose the inferior edge of the superior lateral lamina and the medial facet joint
5. drill off the medial inferior facet, to expose the superior facet of the level below
6. drill the medial superior facet until you are flush with the superior aspect of the pedicle below
7. this completes the bony work, the soft tissue work proceeds as above

under open keyhole foraminotomy

Outcome

A number of large series have reported good or excellent outcome in the range of 90-96%[284].

18.3.3. Thoracic disc herniation

Key concepts:

> • comprise only 0.25% of herniated discs, and < 4% of operations for herniated disc
> • usually occur at or below T8 (the more mobile portion of the thoracic spine)
> • frequently calcified ∴ get CT through disc (may affect choice of surgical approach)
> • primary indications for surgery: refractory pain, progressive myelopathy
> • surgical treatment: laminectomy is usually not appropriate

Account for 0.25-0.75% of all protruded discs[286]. 80% occur between the 3rd and 5th decades. 75% are below T8 (the more mobile portion of the thoracic spine), with a peak of 26% at T11-12. 94% were centrolateral and 6% were lateral[287]. A history of trauma may be elicited in 25% of cases.

Most common symptoms: pain (60%), sensory changes (23%), motor changes (18%). With thoracic radiculopathy, pain and sensory disturbance is in a band-like distribution radiating anteriorly and inferiorly along the involved root's dermatome. Motor involvement is difficult to document.

SURGICAL TREATMENT

INDICATIONS

Herniated thoracic discs requiring surgery are rare[287]. Indications: refractory pain (usually radicular, bandlike) or progressive myelopathy. Uncommon: symptomatic syringomyelia originating at level of disc herniation.

APPROACHES

Surgery for thoracic disc disease is problematic because of: the difficulty of anterior approaches, the proportionately tighter space between cord and canal

compared to the cervical and lumbar regions, and the watershed blood supply which creates a significant risk of cord injury with attempts to manipulate the cord when trying to work anteriorly to it from a posterior approach. Herniated thoracic discs are calcified in 65% of patients considered for surgery[287] (more difficult to remove from a posterior or lateral approach than non-calcified discs).

Open surgical approaches[287, 288]:

1. posterior (midline laminectomy): primary indication is for decompression of posteriorly situated intracanalicular pathology (e.g. metastatic tumor) especially over multiple levels. There is a high failure and complication rate when used for single-level anterior pathology (e.g. midline disc herniation)
2. posterolateral
   A. lateral gutter: laminectomy plus removal of pedicle.
   B. transpedicular approach[289]
   C. costotransversectomy (*see below*)
   D. transfacet pedicle sparing
3. anterolateral (transthoracic)
4. lateral extracavitary

An option to open surgery is thoracoscopic surgery.

Choice of approach

For anterior approaches to the thoracic spine, see sections beginning on *page 178*.

Intraoperative SSEPs and MEPs may be helpful for cases of myelopathy.

For a laterally herniated thoracic disc without myelopathy: posterolateral approach with medial facetectomy is technically simple, and has generally good results. For a central disc herniation, or when myelopathy is present: transthoracic approach has the lowest incidence of cord injury with the best operative results (*see Table 18-21*). For anterior access, unless pathology is predominantly left-sided, a right-sided thoracotomy is preferred because the heart does not impede access.

Table 18-21 Results with various approaches for thoracic spine pathology[290]

Approach	Indication	Total no.	OUTCOME			
			Normal	Improved	Same	Worse
laminectomy	posteriorly located tumor	129	15%	42%	11%	32%
posterolateral (transpedicular)	radicular pain with lateral disc herniation; biopsy of tumor	27	37%	45%	11%	7%
lateral (costotransversectomy)	fair for midline disc; good ipsilateral access, poor access to opposite side	43	35%	53%	12%	0
transthoracic	best for midline lesions, especially for reaching both sides of cord	12	67%	33%	0	0

COSTOTRANSVERSECTOMY

Indications: in the past this was often used to drain tuberculous spine abscess. It may be used for lateral disc herniation, biopsy of VB or pedicle, limited unilateral decompression of spinal cord from tumor or bone fragments, sympathectomy. Can be used at ≈ any T-spine level. Limitations: difficult to visualize anterior canal to access midline anterior pathology. Better for soft disc than for calcified central disc.

Involves resection of the transverse process and at least ≈ 4-5 cm of the posterior rib. A serious risk of this approach is interruption of a significant radicular artery which may compromise spinal cord blood supply (see *Spinal cord vasculature*, page 95). There is also a risk of pneumothorax which is less grave.

Booking the case - costotransversectomy

BOOKING

Also see defaults & disclaimers (*page v*).

1. position: prone, usually on chest rolls
2. equipment:
   A. microscope (not used for all cases)
   B. C-arm
3. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g. for fracture or tumor, not typically for disc herniation)
4. neuromonitoring: SSEP/MEP
5. blood availability: type and cross 2 U PRBC
6. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the back of the chest to remove a small

piece of rib to permit removal of the herniated/calcified disc

B. alternatives: nonsurgical management, surgery from the side through the chest

C. complications: spinal cord injury with paralysis, lung complications including pneumothorax or hemothorax (blood or air outside lungs), possible seizures with MEPs

Surgical technique

☞ The approach can be somewhat difficult due to the infrequent encounter with the anatomy by most neurosurgeons. Be prepared for a "deep, red hole, where everything initially looks the same and the bony anatomy is not easy to define". With patience and persistence and the help of an anatomic model in the O.R., the surgeon can get his/her bearings. One of the most helpful landmarks is following the NVB (or just the nerve root) medially to the neural foramen.

In the O.R. before the skin incision, localizing x-rays are obtained; a spinal needle inserted between 2 spinous processes may be used as a marker.

Patient position: the approach is from the side of the pathology/symptoms; for central disc herniations a right-sided approach reduces risk of injury to artery of Adamkiewicz (located on the left in 80%, *see page 96*). Options:

1. lateral oblique, ≈ 30° elevated from straight prone, a "bean-bag" is good for stabilization. For a thin patient, the surgeon may stand in <u>front</u> of the patient (gives more horizontal angle of view - does not work as well with heavier patients due to mass of skin/muscle in the way laterally)
2. prone on chest rolls: the chest roll on the side of the pathology should be more medial to allow the shoulder and scapula to fall forward out of the way

Skin incision: options

1. curved paramedian skin incision: apex oriented away from the midline along the slight depression demarcating the junction of the lateral border of the paraspinal muscles with the ribs (≈ 6-7 cm lateral to midline) centered over the interspace of interest extending ≈ 3 vertebral bodies **(VB)** above and below. The incision is carried through the skin, subcutaneous fat, trapezius, and (for lower 6 thoracic levels, where most thoracic disc herniations occur) the latissimus dorsi, down to the ribs, and this musculocutaneous flap can be reflected medially as a unit
2. midline incision: need to extend 3-4 levels above and below the level of pathology to get an angle low enough to visualize posterior to the facet in

order to access the posterior vertebral body. The inferior aspect can be curved laterally towards the side of pathology. Advantage: a laminectomy can more easily be performed if needed (if the angle does not provide adequate visualization, as a "bail-out" contingency, a facetectomy may be performed, and pedicle may even be removed to access inferior to the disc space. This usually permits easy decompression of the entire thecal sac. In the thoracic spine, stabilization is optional, and if chosen, unilateral pedicle screws and fusion are usually adequate)

Rib removal and thoracic exposure: for a simple biopsy or drainage of a small abscess, removal of only 1 rib may suffice. The rib to be removed is from the level inferior to the disc space to be accessed[291] (e.g. remove the T4 rib to access T3-4). For most other pathologies, 2 or 3 ribs are often removed[292]. To access a VB, the like-numbered rib and the rib below are removed.

There are a number of ligaments attached to the rib: the intercostal neurovascular bundle **(NVB)** courses medial to the superior costotransverse ligament which extends from the superior aspect of the rib to the transverse process of the level above. This ligament and the lateral costotransverse ligament are divided and the transverse process is rongeured off (the base of which lies on the lamina directly posterior to the pedicle). This exposes the rib anterior to the transverse process. The periosteum is incised on the rib from the angle of the rib to the costovertebral articulation, and by subperiosteal dissection around its circumference the pleura is dissected off the anterior surface of the rib. The NVB is dissected from the deep-inferior surface along with the periosteum. The rib is then transected laterally at the angle (≈ 5 cm lateral to the rib head) with rib shears, it is gripped with a clamp, and is rotated while the ligaments (including the radiate ligaments which attach the rib to the both the VB above and the VB below the disc space at the superior and inferior costal facet, respectively, except T1, 11 & 12 which only articulate with their like-numbered VB) are sharply dissected off the rib which is then removed. The removed rib material may be used for fusion substrate except in cases of tumor or infection. The pleura is then dissected from the deep surface of the adjacent ribs and VB (taking care not to injure the segmental vessels and to dissect the sympathetic trunk off the VB with the pleura). The pleura is then retracted laterally with a malleable ribbon or Deaver retractor.

The intervertebral foramen of interest may be located by following the NVB of the rib above proximally, the intercostal nerve (the ventral ramus of the nerve root at that level) enters between the two pedicles. The dura may then be exposed by enlarging the neural foramen by removing part of the pedicles with a

high-speed drill and Kerrison rongeurs.

Instrumentation/fusion are rarely required for simple discectomy. Instability due to fracture, tumor, or extensive resection (e.g. with total facet takedown) necessitates surgical stabilization, typically with pedicle screws/rods extending 2 levels above and 2 levels below. Prior to closure, check for air leak by filling the opening with saline and having the anesthesiologist apply a valsalva maneuver. If an air leak is identified, a Cook catheter may be placed into the pleural space through the surgical exposure, or alternatively a chest tube is placed through a separate intercostal incision after the laminectomy wound is closed. A post-op CXR is obtained regardless of whether an air leak is identified.

TRANSPEDICULAR APPROACH

Drilling down the pedicle and removing a small amount of bone from the vertebral body, then pushing material from the epidural space into the defect created and removing it. Requires removal of just the rib head. Advantages: minimal risk of pneumothorax, more familiar anatomy. Disadvantages: requires instrumentation especially if done bilaterally, the angle is not very obliques so visualization of epidural space is minimal, may need to be done bilaterally if there are extensive bilateral components to the pathology.

Booking the case - transpedicular approach

Same as for costotransversectomy (*see page 472*).

TRANSTHORACIC APPROACH

Indications: thoracic disc disease, burst fractures of the thoracic spine, etc.

Advantages[293]:

- excellent anterior exposure (especially advantageous for multiple levels)
- little compromise of stability (due to supporting effect of rib cage)
- low risk of mechanical cord injury

Disadvantages:

- requires thoracic surgeon (or familiarity with thoracic surgery)
- some risk of vascular cord injury (due to sacrifice of intercostal arteries)
- definitive diagnosis may not be possible if it is uncertain prior to procedure

Possible complications:

• pulmonary complications: pleural effusion, atelectasis, pneumonia, empyema, hypoventilation
• CSF-pleural fistula

Booking the case - transthoracic spine surgery

Also see defaults & disclaimers (*page v*).

1. position: typically on the side, often on a beanbag
2. equipment:
   A. microscope (not used for all cases)
   B. C-arm
3. anesthesia: double lumen tube
4. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g. for fracture or tumor, not typically for disc herniation)
5. neuromonitoring: SSEP/MEP
6. blood availability: type and cross 2 U PRBC
7. some surgeons use chest surgeon for the approach, closure and for follow-up
8. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery through the chest with removal of a small piece of rib to permit removal of the herniated/calcified disc
   B. alternatives: nonsurgical management, surgery from the side or through the back
   C. complications: spinal cord injury with paralysis, pneumothorax, possible seizures with MEPs

Key technical points

1. the services of an experienced thoracic surgeon are usually engaged
2. position: true lateral (facilitates intra-op localizing x-rays); approached from the more involved side. For the upper thoracic midline region, some prefer right-side-up to eliminate thoracic aorta from obstructing exposure and to reduce the possibility of encountering the artery of Adamkiewicz[294], others prefer left-side-up to use the aorta as a landmark[293] (for levels below the cardiophrenic angle, a left-sided

approach is preferred because the inferior vena cava is difficult to mobilize)

3. usually one rib is resected; most often the rib of the vertebra immediately above the disc space desired (facilitates exposure). Multiple ribs may be resected to increase exposure
4. when removing the vertebral body **(VB)** (corpectomy, e.g. for osteomyelitis, especially Pott's disease or for kyphoscoliosis)
   A. the posterior cortex of the VB must be pulled anteriorly (e.g. with angled curettes) to avoid mechanical cord trauma
   B. anterior fusion may be performed using the removed rib. If inadequate, fibula or iliac crest may be used
5. sizeable radicular arteries are spared. The intercostal nerve is used as a guide to the intervertebral foramen (nerve enters foramen superiorly and posteriorly)
6. the disc space is situated off the caudal aspect of the intervertebral foramen for most thoracic levels
7. one or two intervertebral arteries and veins usually have to be sacrificed; to minimize the risk of ischemic cord injury, cut them as close to the midline of the spine as possible (collaterals tend to lie on the lateral aspect of the spine)
8. the sympathetic chain is dissected off the VBs and is pushed posteriorly

Lateral approach

The same instrumentation used for lateral lumbar interbody fusion (*see page 194*) may be used to access the lateral thoracic bodies for thoracic disc herniation.

Check the pre-op MRI for the location of the aorta and to rule-out aortic aneurysm. Above T11, enter on the right side. The access retractor is "reversed" so that the center blade is positioned anteriorly and the shim is place so that as the retractor is expanded in the AP direction, the lateral blades move posteriorly, giving more access to the posterior disc space. In general, do not penetrate the contralateral anulus because of proximity of aorta. At or just below L12-L1, the diaphragm attached to the VB. A dual lumen endotracheal tube is not required. A chest tube is mandatory if there is an air leak, otherwise it is optional (a pigtail catheter may suffice).

18.4. Degenerative disc/spine disease

Since structures outside of the disc are usually also involved, the term degenerative spine disease **(DSD)** may be preferable to degenerative *disc* disease. Spondylosis is a non-specific term which may include degenerative spine disease. “Cervical spondylosis” is occasionally used synonymously with cervical stenosis (see *Cervical spinal stenosis*, page 485).

DSD is a progressive deterioration of the structures of the spine including:

1. disc abnormalities:
   A. the proteoglycan content of the disc nucleus decreases with age
   B. disc desiccation (loss of hydration) occurs
   C. tears develop in the disc annulus and progress to internal disruption of the lamellar architecture. Herniation of the nucleus may occur from increased nuclear pressure under mechanical loads
   D. mucoid degeneration and ingrowth of fibrous tissue ensues (disc fibrosis)
   E. subsequently disc resorption occurs
   F. there is a loss of disc space height and increased susceptibility to injury
2. facet joint abnormalities: hypertrophy and capsular laxity
3. osteophytes often form on the edges of the VB bordering the degenerated disc
4. spondylolisthesis: subluxation of one VB on another (see *Spondylolisthesis* below)
5. spondylolysis: alternative term for isthmic spondylolisthesis (*see below*), a failure of the neural arch due to a defect in the pars interarticularis which may present as spondylolisthesis. There may be a fibrous mass from the nonunion
6. hypertrophy of the ligamentum flavum

Clinical presentation:

1. the above abnormalities may produce **spinal stenosis** which can lead to neural compromise producing the following symptoms
   A. radicular symptoms (more common in cervical spine than lumbar)
   B. neurogenic claudication (lumbar) or spinal myelopathy (cervical)
2. discogenic pain (controversial) may be less prevalent in the late stages of DSD. May contribute to “musculoskeletal low back pain” but the actual pain generators here are not definitively identified

Etiology

The etiology of DSD is multifactorial and includes:

1. cumulative effects of microtrauma and macrotrauma to the spine
2. osteoporosis
3. cigarette smoking: several epidemiologic studies have shown that the incidence of back pain, sciatica and spinal degenerative disease is higher among cigarette smokers than among nonsmokers[295, 296]
4. in the lumbar spine:
   A. stresses on the spine including effects of excess body weight
   B. loss of muscle tone (primarily abdominals and paraspinals) resulting in increased dependence on the bony spine for structural support

SPONDYLOLISTHESIS

Anterior subluxation of one vertebral body on another. Usually L5 on S1, the next most common is L4 on L5. The Meyerding[297, 298] grading of subluxation in the sagittal plane is shown in *Table 18-22*.

Disc herniation and nerve root compression: It is rare for a herniated lumbar disc to occur at the level of the listhesis, however the disc may "roll" out as it is exposed and produce findings on MRI that have been termed a "pseudodisc". It is more common to see a herniated disc at the level above the listhesis. If the listhesis does cause nerve root compression, it tends to involve the nerve exiting below the pedicle of the anteriorly subluxed vertebra. The compression is usually due to upward displacement of the superior articular facet of the level below together with disc material, and symptoms typically resemble neurogenic claudication, although true radiculopathy may sometimes occur.

Table 18-22 Spondylolisthesis grading

Grade	% subluxation*
I	< 25%
II	25-50%
III	50-75%
IV	75%-complete
spondyloptosis	> 100%

* % of the AP diameter of the VB

Classification of Spondylolisthesis

Type 1: dysplastic: congenital. Upper sacrum or arch of L5 permits the spondylolisthesis. No pars defect. 94% are associated with spinal bifida occulta. Some of these may progress (no way to identify these)

Type 2: isthmic spondylolisthesis AKA **spondylolysis**: a failure of the neural arch manifesting as a defect in the **pars interarticularis** (the neck of the "Scotty dog" on oblique LS-spine x-ray). May be seen in 5-20% of spine x-rays[4]. Three subtypes:

C. lytic: fatigue fracture or insufficiency fracture of pars. In the pediatric age group may occur in athletes (especially gymnasts or football players); in some this may be an exacerbation of a pre-existing defect, in others it may be a result of repetitive trauma

D. elongated but intact pars: possibly due to repetitive fractures and healing

E. acute fracture of pars Type 3: degenerative: due to long-standing intersegmental instability. Usually at

L4-5. No break in the pars. Found in 5.8% of men and 9.1% of women (many of whom are asymptomatic)[4]

Type 4: traumatic: due to fractures usually in areas other than the pars

Type 5: pathologic: generalized or local bone disease, e.g. osteogenesis imperfecta

ISTHMIC SPONDYLOLISTHESIS (SPONDYLOLYSIS) - PARS INTERARTICULARIS DEFECT

Presentation

Isthmic spondylolisthesis rarely produces central canal stenosis since only the anterior part of the spinal canal is shifted forward. May present with radiculopathy, with the nerve exiting under the pedicle at that level being the most vulnerable. May also present with low back. Many cases are asymptomatic.

Management[4]

1. lesions with sclerotic borders are usually well established with little chance of healing. Surgery is reserved for patients with neurologic deficit or incapacitating symptoms
2. lesions without sclerosis that show increased uptake on bone scan (indicating active lesion with potential for healing) or MRI high signal changes on T2WI[299] or

STIR may heal in a rigid orthosis such as the **Boston brace** for ≥ 3 months
3. management of symptoms:
   A. LBP only: treat with NSAIDs, PT
   B. LBP with myelopathy, radiculopathy, or neurogenic claudication: surgical treatment[300] (*see Table 18-23* for surgical options)
4. in pediatrics: may be managed with TLSO and long course of PT (e.g. 6-9 months) for symptoms. Resumption of sports may be considered when symptoms subside, but recurrence should prompt elimination of athletics or consideration of surgery

SURGICAL CONSIDERATIONS

When surgery is indicated, *Table 18-23* serves as a guide to the type of procedure.

Table 18-23 Surgical recommendations for spondylolisthesis

Nature of spondylolisthesis	Nature of problem	Type of procedure needed
degenerative	nerve root compression within confines of spinal canal	decompression (preserving facets)
	spinal stenosis at the level of spondylolisthesis	decompression; some advocate with intertransverse-process fusion[301]
	nerve root compression far lateral, outside confines of spinal canal	radical decompression (Gill procedure, *see below*) plus fusion
traumatic	(does not matter)	decompression plus fusion

Reduction of high-grade (grade III or IV) spondylolisthesis carries a risk of radiculopathy (e.g. L5 radiculopathy in cases of L5-S1 spondylolisthesis) in 50% of cases (some permanent) and may produce a cauda equina syndrome, probably from stretching nerve roots by distraction. The risk of nerve root injury with reduction of grade I or II spondylolisthesis is low.

Gill procedure: This procedure, and its modifications[302], consist of radical decompression of nerve roots including removal of the loose posterior elements and total facetectomy. This is often followed by fusion (posterolateral or interbody). Fusion rate may be enhanced with the use of internal fixation (e.g. transpedicular screw-rod fixation)[303].

18.4.1. Spinal stenosis

Classified as:

1. central canal stenosis: narrowing of the AP dimension of the spinal canal. The reduction in canal size may cause local neural compression and/or compromise of the blood supply to the spinal cord (cervical) or the cauda equina (lumbar)
2. foraminal stenosis: narrowing of the neural foramen. May be the result of any combination of: foraminal disc protrusion, spondylolisthesis, facet hypertrophy, disc space collapse, hypertrophy of uncovertebral joints (cervical), synovial cyst
3. lateral recess stenosis (lumbar spine only): *see page 484*

Central canal stenosis

May be congenital (as in the achondroplastic dwarf), acquired, or most commonly acquired superimposed on congenital.

In the lumbar region, the syndrome of neurogenic claudication (*see below*) is well recognized. In the cervical region, cervical myelopathy and ataxia (from spinocerebellar tract compression) may be present. In 5%, lumbar and cervical stenoses are symptomatic simultaneously[304]. Symptomatic spinal stenosis in the thoracic region is rare[305].

18.4.1.1. Lumbar spinal stenosis

Unless indicated otherwise, this discussion refers primarily to central canal stenosis

Key concepts:

- caused by hypertrophy of facets and ligamentum flavum, may be exacerbated by disc bulging or spondylolisthesis, may be superimposed on congenital narrowing
- most common at L4-5 and then at L3-4
- symptomatic stenosis produces gradually progressive back and leg pain with standing and walking that is relieved by sitting or lying (neurogenic claudication)
- symptoms differentiated from vascular claudication which is usually relieved at rest regardless of position
- usually responds to decompressive surgery (sometimes with fusion) or interspinous spacer

Symptomatic lumbar stenosis is most common at L4-5, then L3-4, L2-3 and lastly L5-S1306. It is rare at L1-2. Generally occurs in patients with congenitally shallow lumbar canal (see *Normal LS spine measurements*, page 480) with superimposed acquired degeneration in the form of some combination of facet hypertrophy, hypertrophy of the ligamentum flavum, protruding (and often calcified) intervertebral discs, and spondylolisthesis. First recognized as a distinct clinical entity producing characteristic symptoms in the 1950's and 60's[307, 308].

May be classified as[309]:

1. **stable** form of lumbar spinal stenosis: hypertrophy of facets and ligamentum flavum accompanied by disc degeneration and collapse
2. **unstable**: have the above with superimposed
   A. degenerative spondylolisthesis: (*see page 475*) the unisegmental form
   B. degenerative scoliosis: the multisegmental form

CLINICAL EVALUATION

PRESENTATION

Often presents as **neurogenic claudication (NC)**, (claudicate: from Latin, *claudico*, to limp) AKA **pseudoclaudication**. To be differentiated from **vascular claudication** (AKA intermittent claudication) which results from ischemia of exercising muscles (*see Table 18-24*). NC characteristics: unilateral or bilateral buttock, hip, thigh or leg discomfort that is precipitated by standing or walking and characteristically relieved by a change in posture.

NC is thought to arise from ischemia of lumbosacral nerve roots, as a result of increased metabolic demand from exercise together with vascular compromise of the nerve root due to pressure from surrounding structures. NC is only moderately sensitive (≈ 60%) but is highly specific for spinal stenosis[311]. Pain may not be the major complaint, instead, some patients may develop paresthesias or LE weakness with walking. Some may complain of muscle cramping, especially in the calves.

Relief from symptoms: occurs with positions that decrease the lumbar lordosis which increases the diameter of the central canal (by reducing inward buckling of the ligamentum flavum) and distracts the facet joints (which enlarges the neural foramina. Favored positions include sitting, squatting and recumbency. Patients may develop "**anthropoid posture**" (exaggerated waist flexion). "Shopping cart sign" patients often can walk farther if they can lean

forward e.g. as on a grocery cart. Riding a bicycle is also often well tolerated.

Table 18-24 Clinical features distinguishing neurogenic from vascular claudication[310]

Feature	Neurogenic claudication	Vascular claudication
distribution of pain	in distribution of nerve (dermatomal)	in distribution of muscle group with common vascular supply (sclerotomal)
sensory loss	dermatomal distribution	stocking distribution
inciting factors	variable amounts of exercise, also with pro-longed maintenance of a given posture (65% have pain on standing at rest); coughing produces pain in 38%	reliably reproduced with fixed amount of exercise (e.g. distance ambulated) that decreases as disease progresses; rare at rest (27% have pain on standing at rest)
relief with rest	slow (often > 30 min), variable, usually positional (stooped posture or sitting often required, ★ <u>standing and resting is usually not sufficient</u>)	almost immediate; not dependent on posture (relief of walking induced symptoms with standing is a key differentiating feature)
claudicating distance	variable day-to-day in 62%	constant day-to-day in 88%
discomfort on lifting or bending	common (67%)	infrequent (15%)
foot pallor on elevation	none	marked
peripheral pulses	normal; or if ↓ usually reduced only unilaterally	↓ or absent; femoral bruits are common
skin temp of feet	normal	decreased

Neurologic exam

The neurologic exam is normal in ≈ 18% of cases (including normal muscle stretch reflexes and negative straight leg raising). Absent or reduced ankle jerks and diminished knee jerks is common[311]. Pain may be reproduced by lumbar <u>extension</u>.

Differential diagnosis

1. vascular insufficiency: (AKA vascular or intermittent claudication) *see above*
2. hip disease: trochanteric bursitis (*see below*), degenerative joint disease
3. disc herniation (lumbar or thoracic)
4. facet joint pain (controversial): may respond to medial branch block (therapeutic & diagnostic)

5. **Baastrup's syndrome**[312]: AKA arthrosis interspinosa. Radiographically: contact of adjacent spinous processes ("kissing spines") with enlargement, flattening and reactive sclerosis of apposing interspinous surfaces. Produces localized midline lumbar pain & tenderness on back extension relieved by flexion, local anesthetic injection or partial excision of the involved spinous processes
6. juxtafacet cyst: *see page 456*
7. arachnoiditis
8. intraspinal tumor
9. Type I spinal AVM (spinal dural AVM): *see page 507*
10. diabetic neuritis: with this, the sole of the foot is usually very tender to pressure from the examiner's thumb
11. delayed onset muscle soreness (DOMS): onset usually 12-48 hours after beginning a new activity or changing activities (NC occurs *during* the activity). Symptoms typically peak within 2 days and subside over several days
12. inguinal hernia: typically produces groin pain
13. functional etiologies

Trochanteric bursitis (TBS) and degenerative arthritis of the hip are also included in the differential diagnosis of NC[313, 314]. Although TBS may be primary, it can also be secondary to other conditions including lumbar stenosis, degenerative arthritis of the lumbar spine or knee, and leg length discrepancy. TBS produces intermittent aching pain over the lateral aspect of the hip. Although usually chronic, it occasionally may have acute or subacute onset. Pain radiates to lateral aspect of thigh in 20-40% (so called "**pseudoradiculopathy**"), but rarely extends to the posterior thigh or as far distally as the knee. There may be numbness and paresthesia-like symptoms in the upper thigh which are usually not dermatomal in distribution. Like NC, the pain may be triggered by prolonged standing, walking and climbing, but unlike NC it is also painful to lie on the affected side. Localized tenderness over the greater trochanter can be elicited in virtually all patients, with maximal tenderness at the junction of the upper thigh and greater tro-chanter. Pain increases with weight bearing (and is often present from the very first step, unlike NC) and with certain hip movements, especially external rotation (over half the patients have a positive Patrick-FABERE test, *see page 444*), and rarely with hip flexion/extension. Treatment includes NSAIDs, local injection of glucocorticoid (usually with local anesthetic), physical therapy (with stretching and muscle strengthening exercises) and local application of ice.

No controlled studies have compared these.

ASSOCIATED CONDITIONS

1. congenital:
   A. achondroplasia
   B. congenitally narrowed canal
2. acquired:
   A. spondylolisthesis
   B. acromegaly
   C. post-traumatic
   D. Paget's disease (see *Paget's disease*, page 498)
   E. ankylosing spondylitis: *see page 502*
   F. ossification of the ligamentum flavum: more common in East Asians, rare in Caucasians[315]. Often, but not always, associated with OPLL[316]

DIAGNOSTIC EVALUATION

RADIOGRAPHIC EVALUATION

Comparison of modalities:

Lumbosacral spine x-rays: may disclose spondylolisthesis. AP diameter of canal is usually narrowed (congenitally or acquired) (see *Normal LS spine measurements* below) whereas the interpediculate distance **(IPD)** may be normal[310]. Oblique films may demonstrate pars defects.

CT scan (either routine, or following water-soluble myelography): classically shows "**trefoil**" canal (cloverleaf shaped, with 3 leaflets). CT also demonstrates AP canal diameter, hypertrophied ligaments, facet arthropathy, and bulging annulus or herniated disc. CT is poor for demonstrating spondylolisthesis although the pars defect may be seen.

Myelogram: lateral films often show "washboard pattern" (multiple anterior defects), AP films often show "wasp-waisting" (narrowing of dye column), may also show partial or complete (especially in prone position) block. May be difficult to perform LP if stenosis is severe (poor CSF flow and difficulty avoiding nerve roots).

MRI: demonstrates impingement on neural structures and loss of CSF signal on T2WI at severely stenotic levels. MRI is poor for visualizing bone which contributes significantly to the pathology (may be helpful for surgical planning). Good for evaluating nerve impingement due to spondylolisthesis (possibly better

than myelogram/CT) and juxtafacet cysts. Asymptomatic abnormalities are demonstrated in up to 33% of asymptomatic patients 50-70 years old[306].

Table 18-25 Normal AP diameter on lateral plain film

(from spinolaminar line to posterior vertebral body)[317]

average (normal)	22-25 mm
lower limits of normal	15 mm
severe lumbar stenosis	< 11 mm

Table 18-26 Normal measurements on CT[318]

AP diameter	≥ 11.5 mm
interpediculate distance (IPD)	≥ 16 mm
canal cross-sectional area	≥ 1.45 cm^2
ligamentum flavum thickness[319]	≤ 4-5 mm
height of lateral recess (*see below*)	≥ 3 mm

Normal LS spine measurements

Normal dimensions of the lumbar spine are shown in *Table 18-25* for plain film and *Table 18-26* for CT.

Interpediculate distance (IPD): The transverse diameter of the spinal canal. On plain AP x-ray of lumbar spine, an IPD < 25 mm suggests stenosis. Average normal IPDs in the lumbar and lower thoracic spine appears in *Table 18-27*. An approximation for the lumbar spine is given in *Eq 18-1*.

$$\boxed{\text{IPD (mm)} = (\text{lumbar level} + 12) \times 1.5} \qquad \textbf{Eq 18-1}$$

Adjuncts to radiographic evaluation

"Bicycle test": patients with NC can usually tolerate longer periods of exercise on a bicycle than patients with intermittent (vascular) claudication because the position in bicycling flexes the waist.

Ratio of ankle to brachial blood pressure **(A:B ratio)**: > 1.0 is normal; mean of 0.59 in patients with intermittent claudication; 0.26 in patients with rest pain; < 0.05 indicates impending gangrene.

Vascular lab studies (e.g. Doppler) may assist in identifying vascular insufficiency.

EMG with NCV may show multiple nerve-root abnormalities bilaterally.

Table 18-27 Normal interpediculate distance (IPD) on AP LS film[320]

Level	IPD (mm)*
T10	16-22
T11	17-24
T12	19-27
L1	21-29
L2	21-30
L3	21-31
L4	21-33
L5	23-37

TREATMENT

In one study of 27 unoperated patients, 19 remain unchanged, 4 improved, and 4 worsened (mean follow-up: 49 months; range: 10-103 months)[321]. NSAIDs (recent evidence suggests acetaminophen may be as effective) and physical therapy are the mainstays of nonsurgical management.

Surgical decompression is undertaken when symptoms become severe in spite of medical management. The goals of surgery are pain relief, halting progression of symptoms, and possibly reversal of some existing neurologic deficit. Most authors do not consider surgery unless the symptoms have been present > 3 months, and most patients who have surgery for this have symptoms of > 1 year duration.

SURGERY

Surgical options

1. laminectomy: posterior (direct) decompression of central canal and neural foramina without or with fusion. Fusion options:
   A. posterolateral fusion ± pedicle screw/rod fixation
   B. interbody fusion: generally not done as a “stand-alone” (i.e. usually requires additional stabilization, options here include: pedicle screws, facet screws, facet dowels, spinous process clamp…)
      1. posterior lumbar interbody fusion (PLIF): usually bilateral graft placement (*see page 193*)
      2. transforaminal lumbar interbody fusion (TLIF): unilateral graft

placement though a facet take-down on that side (*see page 193*)

2. procedures to increase disc space height and thereby <u>indirectly</u> decompress neural foramina without direct decompression
   A. anterior lumbar interbody fusion (ALIF): through laparotomy (*see page 195*)
   B. lateral lumbar interbody fusion: some techniques trademarked as extreme lateral interbody fusion (XLIF™) or direct-lateral (DLIF™): *see page 194*
   C. axial lumbar interbody fusion (Ax-LIF): L5-S1 only (*see page 195*)
3. limitation of extension by interspinous spacer: e.g. X-Stop® (*see below*)

BOOKING THE CASE - LUMBAR LAMI ± FUSION FOR STENOSIS

Also see defaults & disclaimers (*page v*).

1. position: prone
2. implants: for fusions, schedule with the vendor for the desired implants and associated instrumentation
3. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: through the back to remove bone, ligament and any other tissue that is pressing on the nerve(s). If a fusion is to be done, then typically this will be accomplished using screws, rods and small cages, as required
   B. alternatives: nonsurgical management
   C. complications: (usual spine surgery complications - *see page v*) *plus* there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain). If implants are used, then there can be problems with them including breakage, migration (slippage), or undesirable positioning which may require further surgery

Choosing which procedure to use

Although beyond the scope of this book, items that factor into consideration when choosing which procedure to use include:

1. consider indirect decompression (lateral interbody fusion (e.g. XLIF® or DLIF®), interspinous decompression (e.g. X-Stop):
   A. when foraminal stenosis appears to be the dominant problem (e.g.

with loss of disc space height, facet hypertrophy, on the concave side of a scoliotic curve)
  - B. previous spine surgery that might make exposure of the nerves more difficult or risky
2. consider direct decompression (e.g. laminectomy)
  - A. “pinpoint” central canal stenosis especially when disc height and neural foramina are well preserved
  - B. where the majority of the compression is due to a focal, correctable lesion, such as a herniated disc, synovial cyst, intraspinal tumor
3. consider motion-preservation surgery
  - A. when a fusion is undertaken at a level and the adjacent level is already starting to show some degenerative changes that have not yet reached a surgical magnitude. Motion preservation at this adjacent segment theoretically shield it from some of the transmitted stresses from the fused level
4. situations where a fusion should be considered in addition to direct or indirect decompression of the nerves:
  - A. spondylolisthesis (especially > Grade I)
  - B. dynamic instability on flexion/extension lateral lumbar spine x-rays
  - C. expectation that the decompression will destabilize the spine (e.g. facet takedown for a TLIF)
  - D. multiply recurrent herniated disc (when this is the third or more operation for the same disc
  - E. controversial situations:
    1. e.g. a “black disc” on MRI with positive concordant discogram at this level: fusion without decompression has been advocated when there is no neural compression

Laminectomy/laminotomy - surgical technique

Posterior approach with removal of the spines and lamina of affected levels (surgical “unroofing”), along with the associated ligamentum flavum. Individual nerve roots are palpated for compression within their neural foramen, with foraminotomies performed at appropriate levels. Doing a total L4 laminectomy for stenosis allows access to the L4-5 foramen, and the upper part of the L5-S1 foramen. If, in addition, the lower part of L3 is also removed, access is gained to the inferior pedicle of L3 and thus the L3-4 neural foramen. Undercutting the superior articular facet is often necessary to decompress the nerves in the

foramen (see *Lateral recess syndrome*, page 484). Treatment of moderate stenosis at adjacent levels appears warranted as these levels have been shown to have a significant likelihood of becoming symptomatic later[221].

Alternatively, laminotomies (as opposed to laminectomies) may be performed in cases where the central canal has a normal AP diameter, but the lateral canal gutter is stenotic[322, 323]. Multilevel subarticular fenestrations are another slight variation on this theme[324].

Position: either of the following is acceptable

1. prone: on a frame or chest rolls or knee-chest position to decompress the abdomen to decrease venous pressure and thus reduce bleeding
2. lateral decubitus position: if there is no laterality to symptoms, right lateral decubitus (left-side-up) is easier for most right-handed surgeons to use angled Kerrison rongeur parallel to nerve roots

Minimally invasive spine surgery (MISS) decompression

Usually a "mini-open" technique using ≈ 1" incisions and expandable retractors.

1. options include bilateral laminotomies (*see above*)
2. bilateral decompression through a unilateral laminotomy
   A. entry site: 3.5-4 cm off the midline to permit the needed angle
   B. when using a retractor with an "open side" orient the retractor with the open side facing laterally (e.g. with the Nuvasive Maxcess® place the handles medially) to permit the angle needed for contralateral decompression
   C. the laminectomy and facet takedown (usually for a TLIF) are done
   D. open the ligamentum flavum on the side you're working on, to visualize the posterior extent of the spinal canal, to permit finding the plane between the posterior part of the ligamentum flavum and the undersurface of the bone
   E. the ligamentum flavum is left in place on the contralateral side to protect the dura during drilling
   F. complete the decompression and disc removal on the side you're working on
   G. the undersurface of the bone (spinous process and contralateral lamina) are then drilled to decompress the contralateral side
   H. once the undersurface of the contralateral posterior canal has been

drilled, the ligamentum flavum is removed with pituitary rongeurs. It is possible to even do a contralateral foraminotomy at this point (curved Kerrison rongeurs are very helpful for this)

I. pedicle screws are placed through the open side, and then percutaneously through the contralateral side

Interspinous process decompression/stabilization/fusion

Interspinous spacers (e.g. X-Stop™ (Medtronic)) limit extension at 1 or 2 levels (without fusion), preventing narrowing of the associated neural foramen, and may also off-load the facet joints and even the disc. “Success rate”: 63% at 2 years. This device may be used as a standalone.

Interspinous plates (e.g. Aspen® (Lanx), Affix™ (Nuvasive), Spire® (Medtronic)) clamp across two spinous processes to fixate them (unlike X-Stop™ which just limits extension). The Aspen® clamps have a space for a graft which may optionally be used to promote fusion between the spinous processes. Interspinous plates may be used to augment other constructs e.g. lateral interbody fusion[325], but are <u>not</u> intended for standalone use. Biomechanical stability is reported to be similar to bilateral pedicle screws in flexion, and unilateral pedicle screws in lateral bending[326].

Contraindications (includes exclusionary criteria from the IDE study):

1. instability at level considered for procedure: spondylolisthesis > Grade 1 or scoliosis with Cobb angle ≥ 25° (*see page 430*)
2. cauda equina syndrome
3. acute fracture of the spinous process
4. bilateral pars defects (disconnects spinous process from the anterior elements)
5. osteoporosis. Contraindications per the IDE: DEXA scan (*see page 992*) with spine or hip T-score < –2.5 (i.e. more than 2.5 SD below the mean for normal adults) in the presence of ≥ 1 fragility fractures. Concerns: spinous process fracture at the time of insertion, or late subsidence due to microfractures. However, Kondrashov[327] interprets a T-score < –2.5 anywhere as indicative of osteoporosis (even without fragility fractures). Options here include:
   A. augmenting the spinous processes by injecting ≈ 0.5-1 cc of PMMA into each spinous process **(SP)** with a 13 Ga needle inserted ≈ halfway

into the SP on lateral fluoro[327] prior to dilating the interspace or placing the X-Stop. Verify central position within SP on AP fluoro, and monitor injection on fluoro

B. use of an X-Stop made of PEEK (modulus of elasticity of PEEK is closer to bone than titanium) - available now in Europe, soon in the U.S.

6. ankylosed level (i.e. already fused)
7. L5-S1 level: the spinous process of S1 is usually too small (not usually an issue since symptomatic stenosis at L5-S1 is rare)
8. age < 50 years: not studied in IDE investigation

Surgical pointers:

1. it is critical that the spacer sit in the anterior third of the spinous process
2. results may be better with the patient awake, under local anesthesia, lying on their side in a position that they feel is relieving their pain (thus opening up the critical levels). This may reduce the risk of undersizing the prosthesis

Post-op (based on manufacturer's recommendations):

1. to avoid spinous process stress fracture: build-up physical activity gradually
2. 1st 6 weeks post-op: no spine hyperextension, no heavy lifting. Minimize stair climbing
3. initially, walking (for < 1 hour) is recommended as long as it is comfortable
4. at 2 weeks post-op: cycling (stationary or bicycle) may be added
5. 6 months post-op: may add sports such as swimming, golf, racquetball, tennis, running or jogging

Progression of spondylolisthesis

May occur without decompression, but is more common following surgery[328]. However, lumbar instability following decompressive laminectomy is rare (only ≈ 1% of all laminectomies for stenosis will develop progressive subluxation). Fusion is rarely required to prevent progression of subluxation with degenerative stenosis[329].

Stability (without need for instrumentation) is thought to be maintained if > 50-66% of the facets are preserved during surgery and the disc space is not violated (maintains integrity of anterior and middle column). Younger or more

active patients are at higher risk of subluxing.

One approach is to obtain flexion/extension x-rays pre-op, and follow patients after decompression. Those who develop symptomatic slippage post-op are treated by fusion, possibly in conjunction with spinal instrumentation.

Instrumentation and/or fusion

PRACTICE GUIDELINE 18-13 FUSION IN PATIENTS WITH LUMBAR STENOSIS *WITHOUT* SPONDYLOLISTHESIS

Level III[330]:

- in situ posterolateral fusion is not recommended following decompression in patients with lumbar stenosis in whom there is no evidence of preexisting spinal instability or likely iatrogenic instability due to facetectomy
- in situ posterolateral fusion is recommended in patients with lumbar stenosis in whom there is evidence of spinal instability
- the addition of pedicle-screw instrumentation is not recommended in conjunction with posterolateral fusion following decompression

PRACTICE GUIDELINE 18-14 FUSION IN PATIENTS WITH LUMBAR STENOSIS AND SPONDYLOLISTHESIS

Level II[331]: posterolateral fusion is recommended for patients with stenosis and associated degenerative spondylolisthesis who require decompression

Level III[331]: pedicle screw fixation as an adjunct to posterolateral fusion should be considered in patients with stenosis and spondylolisthesis in cases where there is pre-op evidence of spinal instability* or kyphosis* at the level of the spondylolisthesis or when iatrogenic instability is anticipated

* the definition of "instability" and "kyphosis" varies, and has not been standardized

Fusion may accelerate degenerative changes at adjacent levels. Some surgeons recommend fusion at levels of spondylolisthestic stenosis[221, 309]. Patients with combined degenerative spondylolisthesis, stenosis, and radiculopathy may be reasonable candidates for fusion[1].

Brace therapy

PRACTICE GUIDELINE 18-15 BRACE THERAPY AS AN ADJUNCT TO OR INSTEAD OF LUMBAR FUSION
Level II[332]: • short-term use (1-3 weeks) of a rigid lumbar support is recommended for treatment of LBP of relatively short duration (< 6 months) • bracing in patients with LBP > 6 months duration is <u>not</u> recommended because it has not been shown to have long-term benefit

PRACTICE GUIDELINE 18-15 BRACE THERAPY AS AN ADJUNCT TO OR INSTEAD OF LUMBAR FUSION
Level III[332]: • lumbar braces may reduce the number of sick days due to LBP among workers with a previous lumbar injury. Braces are <u>not</u> recommended for LBP in the general working population • the use of pre-op bracing or transpedicular external fixation as tools to predict outcome for lumbar fusion is not recommended

OUTCOME

Morbidity/mortality

Risk of in-hospital mortality is 0.32%[311]. Other risks include: unintended durotomy (*see page 450*) (0.32%[311] to ≈ 13%[329, 333]), deep infection (5.9%), superficial infection (2.3%), and DVT (2.8%) (see also *Risks of lumbar laminectomy* on page 449).

Nonunion

Risk factors for nonunion (does not necessarily correlate with success of operation):

1. cigarette smoking delays bone healing and increases the risk of pseudoarthrosis following spinal fusion procedures, especially in the lumbar spine[295]
2. number of levels: in lumbar fusions, fusing 2 levels resulted in increased non-union rates compared to fusing 1 level[334]
3. NSAIDs: controversial

A. short-term (≤ 5 days) post-op use: high-dose ketorolac (120-240 mg/d) was associated with increased risk of nonunion, but low-dose ketorolac (≤ 110 mg/d), and celecoxib (200–600 mg/d) or rofecoxib (50 mg/d) were not[334]

B. some feel that long-term NSAID use does lower fusion rate[335]

Success of operation

No randomized study exists comparing surgery to "conservative" treatment. Patients with a postural component to their pain had much better results (96% good result) than those without a postural component (50% good results), and the relief of leg pain was much more successful than relief of back pain[336]. Surgery is most likely to reduce LE pain and improve walking tolerance[1].

Surgical failure may be divided into two groups:

1. patients with initial improvement who develop recurrent difficulties. Although short-term improvement after surgery is common, many patients progressively deteriorate over time[337]. One study found a 27% recurrence of symptoms after 5 years follow-up[221] (30% due to restenosis at the operated level, 30% due to stenosis at a new level; 75% of these patients respond to further surgery). Other etiologies include: development of herniated lumbar disc, development of late instability, coexisting medical conditions
2. patients who fail to have any post-op pain relief (early treatment failures). In one series of 45 such patients[338]:
   A. the most common finding was a lack of solid clinical and radiographic indications for surgery (e.g. non-radicular LBP coupled with modest stenosis)
   B. technical factors of surgery had less influence on outcome, with the most common finding being failure to decompress the lateral recess (which requires judicious medial facet resection or undercutting the superior articular facet)
   C. other diagnoses (e.g. arachnoiditis), missed diagnosis (e.g. spinal AVM)

Long term outcome: Literature review[311] with long-term follow-up found good or excellent outcome after surgery with a mean of 64% (range: 26-100%). A patient satisfaction survey indicated that 37% were much improved and 29% somewhat improved (total: 66%) post-op[339]. A prospective study found a

success rate of 78-88% at 6 wks and 6 months, which dropped to ≈ 70% at 1 year and 5 yrs[340]. Success rates were slightly lower for lateral recess syndrome (*see below*).

LATERAL RECESS SYNDROME

A variant of lumbar stenosis[341]. **Lateral recess**: the “gutter” alongside the pedicle which the nerve root enters just proximal to its exit through the neural foramen (*see Figure 18-4*). It is bordered anteriorly by the vertebral body, laterally by the pedicle, and posteriorly by the superior articular facet of the inferior vertebral body. Hypertrophy of this superior articular facet compresses the nerve root. L4-5 is the most commonly involved facet.

PRESENTATION

Patients develop unilateral or bilateral leg pain predominantly when walking or standing, and usually obtain relief by squatting, sitting with the waist flexed, or lying in the fetal position. Painful burning paresthesias of the lower extremities are also described. Valsalva maneuvers usually do not exacerbate the pain. The time course is usually gradually progressive over many months to years.

In comparison, a HLD usually causes increased pain on sitting, has a more abrupt onset, has pain on straight leg raising, and is worsened by Valsalva maneuvers.

The neurologic exam may be normal (including straight leg raising). Achilles reflexes may be absent.

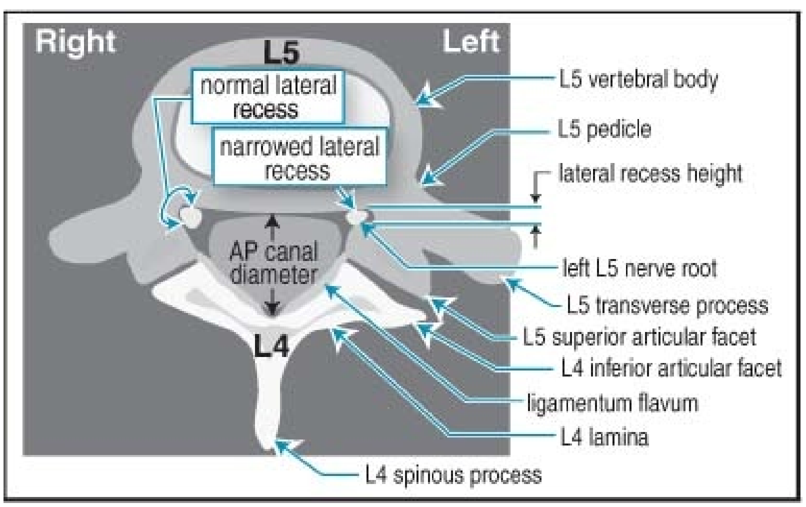

Figure 18-4 Schematic axial CT through the L4-5 facet joint showing the lateral recesses (normal on

patient's right, stenotic on left)

Evaluation

High resolution CT scan best defines the bony anatomy of the lateral recess (*see Figure 18-4* and *Table 18-28*).

MRI or water soluble contrast myelography is recommended when surgery is contemplated. Characteristic finding: flattening of nerve root as it passes beneath the hypertrophied facet joint.

Table 18-28 Dimensions of lateral recess on CT (bone windows)

Lateral recess height	Degree of lateral recess stenosis
3-4 mm	borderline (symptomatic if other lesion co-exists, e.g. disc bulging)
< 3 mm	suggestive of lateral recess syndrome
< 2 mm	diagnostic of lateral recess syndrome

Treatment

Conservative treatment with lumbosacral brace may be attempted.

Surgical therapy

Indicated for unresponsive cases. Consists of laminectomy and partial (typically medial one third) facetectomy. Requires removal of the hypertrophied portion of the facet dorsal to the involved nerve root, either by undercutting, or by reducing overhanging hypertrophied facet elements until they are flush with the pedicle.

18.4.1.2. Cervical spinal stenosis

"**Cervical spondylosis**" is occasionally used synonymously with cervical spinal stenosis. However, spondylosis usually implies a more widespread age-related degenerative condition of the cervical spine including various combinations of the following:

1. congenital spinal stenosis (the "shallow cervical canal"[342])
2. degeneration of the intervertebral disc producing a focal stenosis due to a "**cervical bar**" which is usually a combination of:
   A. osteophytic spurs ("**hard disc**" in neurosurgical jargon)
   B. and/or protrusion of intervertebral disc material ("**soft disc**")
3. hypertrophy of any of the following (which also contributes to canal

stenosis):

  A. lamina
  B. dura
  C. articular facets
  D. ligaments, including
     1. increased stenosis in extension is more common than with flexion (based on MRI studies[343] and cadaver studies), largely due to posterior inbuckling of ligamentum flavum[344]
     2. posterior longitudinal ligament: may include ossification of the posterior longitudinal ligament **(OPLL)**[345] (*see* *page 504*). May be segmental or diffuse. Often adherent to dura
     3. ossification of the ligamentum flavum[316] (yellow ligament)

4. subluxation: due to disc and facet joint degeneration
5. altered mobility: severely spondylotic levels may be fused and are usually stable, however there is often hypermobility at adjacent or other segments
6. telescoping of the spine due to loss of height of VBs → "shingling" of laminae
7. alteration of the normal lordotic curvature[346] (NB: the amount of abnormal curvature did not correlate with the degree of myelopathy)
   A. reduction of lordosis: including
      1. straightening
      2. reversal of the curvature (kyphosis): may cause "bowstringing" of the spinal cord across osteophytes
   B. exaggerated lordosis (hyperlordosis): the least common variant (may also cause bowstringing)

Although the majority of individuals > 50 yrs old have radiologic evidence of significant degenerative disease of the cervical spine, only a small percentage will experience neurologic symptoms[347].

EVALUATION

Cervical spinal stenosis is suggested on plain films when the spinolaminar line is close to the posterior margin of the lateral masses.

CLINICAL

The condition generally tends to produce three types of clinical problems[244]:

1. nerve root compression may cause radicular complaints
2. spinal cord compression may cause myelopathy. Some stereotypical syndromes are presented below (see *Cervical spondylotic myelopathy (CSM)* below)
3. pain and paresthesias in the head, neck and shoulders with little or no suggestion of radiculopathy nor abnormal physical findings. This group is the most difficult to treat, and often requires a good physician-patient relationship to decide if surgical treatment should be undertaken in an attempt to provide relief

CERVICAL SPONDYLOTIC MYELOPATHY (CSM)

Cervical spondylosis is the most common cause of myelopathy in patients > 55 yrs of age[348]. Cervical spondylotic myelopathy (CSM) develops in almost all patients with ≥ 30% narrowing of the cross-sectional area of the cervical spinal canal[349] (although some patients with severe cord compression do not have myelopathy[350, 351]).

PATHOPHYSIOLOGY

Pathogenesis is controversial. Theories include the following alone or in combination:

1. direct cord compression between osteophytic bars and hypertrophy or infolding of the ligamentum flavum, especially if superimposed on congenital narrowing or cervical subluxations
2. ischemia due to compression of vascular structures[352] (arterial deprivation[353] and/or venous stasis[354])
3. repeated local cord trauma by normal movements in the presence of protruded discs and/or osteophytic (spondylotic) bars (cord and root injuries[355])
   A. cephalad/caudad movement with flexion extension[356]
   B. anterior/posterior traction on the cord by dentate ligaments[357] & nerve roots
   C. diameter of spinal canal varies during flexion and extension
      1. increased stenosis is more common in extension (*see above*)
      2. unstable segments may sublux (so-called pincer mechanism)[358]

Histologically[359], there is degeneration of the central grey matter at the level of compression, degeneration of the posterior columns above the lesion

(particularly in the anteromedial portion), and demyelination in the lateral columns (especially the corticospinal tracts) below the lesion. Anterior spinal tracts are relatively spared. There may be atrophic changes in the ventral and dorsal roots and neurophagia of anterior horn cells.

Clinical

Gait disturbance, often with LE weakness or stiffness, is a common early finding in CSM[361]. Cervical pain and mechanical signs are uncommon in cases of pure myelopathy. See *Table 18-29* for the frequency of symptoms in CSM in one series. In most cases the disability is mild, and the prognosis for these is good. CSM is rare in age < 40 years.

Table 18-29 Frequency of symptoms in CSM (37 cases[360])

Finding	%
pure myelopathy	59%
myelopathy + radiculopathy	41%
reflexes	
hyperreflexia	87%
Babinski	54%
Hoffman	13%
sensory deficits	
sensory level	41%
posterior column	39%
dermatomal arm	33%
paresthesias	21%
positive Romberg	15%
motor deficits	
arm weakness	31%
paraparesis	21%
hemiparesis	18%
quadriparesis	10%
Brown-Séquard	10%
muscle atrophy	13%

fasciculations	13%
pain	
radicular arm	41%
radicular leg	13%
cervical	8%
spasticity	54%
sphincter disturbance	49%
cervical mechanical signs	26%

Table 18-30 Modified JOA score for cervical myelopathy[362]*

Score	Description	
Upper extremity (UE) motor dysfunction		
0	unable to feed self	
1	unable to use knife & fork; can eat with spoon	
2	can use knife & fork with much difficulty	
3	can use knife & fork with slight difficulty	
4	none (normal)	
Lower extremity (LE) motor dysfunction		
0	unable to walk	
1	can walk on flat surface with walking aid	
2	can walk up and/or down stairs with handrail	
3	lack of smooth and stable gait	
4	none (normal)	
Sensory deficit		
0	UE	severe sensory loss or pain
1		mild sensory loss
2		none (normal)
0	LE	severe sensory loss or pain
1		mild sensory loss
2		none (normal)
0	trunk	severe sensory loss or pain
1		mild sensory loss
2		none (normal)
Sphincter dysfunction		

0	unable to void
1	marked voiding difficulty (retention)
2	some voiding difficulty (urgency or hesitation)
3	none (normal)

* total score ranges from 0 to 17 (normal)

Grading

1. the modified Japanese Orthopaedic Association scale **(mJOA)** (*Table 18-30*) is a valid and reliable grading system, although it is non-specific
2. **Neck Disability Index** 535: a 10 question survey similar to the Oswestry Disability Index for the lumbar spine (*see page 430*). Mild disability is defined as a score of 10-28%, moderate = 30-48%, severe = 50-68%, complete ≥ 72%
3. other commonly used scales (not tested for validity or reliability):
   A. Nurick[363] (*see page 505*)
   B. Harsh

Natural history

The time course of symptoms is highly variable and unpredictable. In ≈ 75% of cases of CSM, there is progression either in a stepwise fashion (in one third) or gradually progressive (two thirds)[364]. In some series, the most common pattern was that of an initial phase of deterioration followed by a stabilization that typically lasts for years and may not change thereafter[365, 366]. In these cases, the degree of disability may be established early in the course of CSM. Others disagree with such a "benign" outlook and cite that over 50% of cases continue to deteriorate with conservative treatment[347]. Sustained spontaneous improvement is probably rare[348].

In patients < 75 years age and mJOA score > 12 (mild myelopathy), the clinical condition remains stable in 3-years of follow-up (Class I)[367] (however, these patients can still have significant disability that can respond to surgery). Patients with stenosis without myelopathy who have electrodiagnostic abnormalities or clinical radiculopathy are at risk of developing myelopathy (Class I)[367]. Longstanding severe stenosis over many years may cause irreversible deficit due to necrosis in gray and white matter (Class III)[367].

Motor

Findings can be due to cord (UMN) and/or root (LMN) compression. The earliest motor findings are typically weakness in the triceps and hand intrinsics[362]. There may be wasting of the hand muscles[368]. Slow, stiff opening and closing of the fists may occur[369]. Clumsiness with fine motor skills (writing, buttoning buttons…) is common.

There is often proximal weakness of the lower extremities (mild to moderate iliopsoas weakness occurs in 54%) and spasticity of the LEs.

Sensory

Sensory disturbance may be minimal, and when present are often not radicular in distribution. There may be a glove-distribution sensory loss in the hands[370]. A sensory level may occur a number of levels below the area of cord compression.

LEs often exhibit loss of vibratory sense (in as many as 82%), and occasionally have reduced pinprick sensation (9%) (almost always restricted to below the ankle). Compression of the spinocerebellar tract may cause difficulty running. Lhermitte's sign was present in only 2 of 37 cases. Some patients may present with a prominence of posterior column dysfunction (impaired joint position sense and 2 point discrimination)[371].

Reflexes

In 72-87%, reflexes are hyperactive at a varying distance below the level of stenosis. Clonus, Babinski's sign (*see page 116*) or Hoffman's sign (*see page 116*) may also be present. **Dynamic Hoffman's sign**[372] may be more sensitive: test for Hoffman's sign during multiple cervical flexion and extension movements as tolerated by the patient. 94% of asymptomatic individuals with Hoffman's reflex will have significant spinal cord compression on MRI[373]. **Inverted radial reflex**: flexion of the fingers in response to eliciting the brachioradialis reflex, said to be pathognomonic of CSM[374].

A hyperactive **jaw jerk** indicates upper motor neuron lesion above the midpons, and distinguishes long tract findings due to pathology above the foramen magnum from those below (e.g. cervical myelopathy): not helpful if absent (a normal variant). Primitive reflexes (grasp, snout, rooting) are not reliable localizing signs (except perhaps the grasp reflex) of frontal lobe pathology.

Sphincter

Urinary urgency and frequency are common in CSM as well as in the aging population. Urinary incontinence is rare. Anal sphincter disturbances are uncommon.

Syndromes

Clustering of CSM into these 5 clinical syndromes has been described[369]:

1. transverse lesion syndrome: involvement of corticospinal and spinothalamic tracts and posterior columns, with anterior horn cells segmentally involved. Most frequent syndrome, possibly an "end-stage" of the disease process
2. motor system syndrome: primarily corticospinal tract and anterior horn involvement with minimal or no sensory deficit. This creates a mixture of lower motor neuron findings in the upper extremities and upper motor neuron findings (myelopathy) in the lower extremities which can mimic ALS (*see below*). Reflexes may be hyperactive below the area of maximal stenosis (including the upper extremities), occasionally beginning several levels below the stenosis
3. central cord syndrome: motor and sensory deficit affecting the UEs more than the LEs. This syndrome is characterized by dysfunction of the watershed areas located centrally within the cord, which may be responsible for prominence of hand symptoms[375] (results in "**numb-clumsy hands**"[376]). Lhermitte's sign may be more common in this group
4. Brown-Séquard syndrome: often with asymmetric narrowing of the canal with the side of greater narrowing producing ipsilateral corticospinal tract (upper motor neuron weakness) and posterior column dysfunction with contralateral loss of pain and temperature sensation
5. brachialgia and cord syndrome: radicular UE pain with lower motor neuron weakness, and some associated long tract involvement (motor and/or sensory)

Differential diagnosis

See *Myelopathy* on page 1185 for other possible causes. Some of these (e.g. spinal cord tumor, OPLL) may be demonstrated radiographically. Asymptomatic cervical spondylosis is very common, and ≈ 12% of cases of cervical myelopathy attributed to spondylosis are later found to be due to another disease process including:

1. ALS: *see below*
2. multiple sclerosis **(MS)**: spinal cord demyelination may mimic CSM. With MS, remissions and exacerbations are common, and patients tend to be younger
3. herniated cervical disc (soft disc): patients tend to be younger than with CSM. Course is more rapid
4. subacute combined system disease: abnormal vitamin B_{12} level and possibly macrocytic anemia (*see page 1187*)
5. hereditary spastic paraplegia: family history is key. Diagnosis of exclusion[377]
6. (spontaneous) intracranial hypotension (*see page 305*)

Amyotrophic lateral sclerosis (ALS)

AKA (anterior horn) motor neuron disease (also see *Amyotrophic lateral sclerosis*, page 65). Can mimic the motor system syndrome of CSM (*see above*), and spinal cord compression may be seen on MRI in > 60% of patients with ALS[378].

"Triad" of ALS: atrophic weakness of hands and forearms (early), mild LE spasticity, diffuse hyperreflexia. Inevitably, some cases of demyelinating disease will be misdiagnosed initially as CSM until some features suggestive of ALS occur (in one series of 1500 ALS patients, 4% underwent spine surgery (56% cervical, 42% lumbar, 2% thoracic)[378] before ALS was correctly diagnosed).

Features that may help differentiate ALS from CSM:

1. ALS: sensory changes are conspicuously absent
2. ALS: bulbar symptoms (dysarthria, hyperactive jaw-jerk…)[379]
3. ALS: extensive weakness/muscle atrophy of hands, usually with fasciculations[380]
4. ALS: lower-motor neuron **(LMN)** findings in the tongue (visible fasciculations, or positive sharp waves on EMG) or in the LEs (e.g. fasciculations and atrophy) favors the diagnosis of ALS over CSM (however, LMN findings in the LEs may occur in CSM if there is coincidental lumbar radiculopathy)
5. CSM or herniated cervical disc: usually includes neck and shoulder pain, limitation of neck movement, sensory changes, and LMN findings restricted to 1 or 2 spinal cord segments

EVALUATION

Plain x-rays

Plain cervical spine x-rays demonstrates osteophytic spurs, and malalignment if any. See *Canal diameter* on page 136 for normal dimensions and measurement techniques. Patients with CSM have an average minimal AP canal diameter of 11.8 mm[381], and values ≤ 10 mm were likely to be associated with myelopathy[382]. Patients with an AP diameter < 14 mm may be at increased risk[383], and CSM is rare in patients with a diameter > 16 mm, even with significant spurs[348].

Pavlov ratio (AKA Torg ratio[384, 385]): the ratio of the AP diameter of the spinal canal at the mid VB level to the VB at the same location. A ratio < 0.8 is sensitive for transient neuropraxia, but has been shown to have poor positive predictive value for CSM.

MRI

MRI provides information about the spinal canal, and can also show intrinsic cord abnormalities (demyelination, syringomyelia, spinal cord atrophy, edema…). MRI also rules out other diagnostic possibilities (Chiari malformation, spinal cord tumor…). Bony structures and calcified ligaments are poorly imaged. This shortcoming and the difficulties in differentiating osteophytes from herniated discs on MRI are overcome with the addition of plain cervical spine films[386] or thin-section CT bone windows.

Findings that correlate with poor outcome (Class III)[387]:

1. <u>multilevel</u> T2WI hyperintensity within the spinal cord parenchyma
2. <u>single</u> level T2WI hyperintensity with corresponding T1WI hypointensity[A]
3. spinal cord atrophy (transverse area < 45 mm^2)

A. single level T2WI hyperintensity without T1WI changes are of uncertain prognostic significance

Other MRI findings seen with CSM:

1. reduced transverse area of the spinal cord **(TASC)** at the level of maximum compression. A “banana” shaped cord on axial images has a

high correlation with the presence of CSM[383]. There is conflicting evidence whether the *degree* of canal stenosis predicts *outcome*[387]. Sagittal T2WIs tend to exaggerate the magnitude of spinal cord compression by osteophytes and/or discs, and therefore axial images and T1WIs also need to be considered in the evaluation. Narrowing is not specific for CSM: ≈ 26% of asymptomatic individuals > 64 years of age have spinal cord compression on MRI[388]

2. "snake eyes" (AKA "owl's eyes") within the spinal cord on axial T2WI (*see Figure 18-5*) may be related to cystic necrosis of the cord[389] and may correlate with poor outcome (Class III)[387]

CT/myelogram

Plain CT scans may demonstrate a narrow canal, but do not provide adequate information regarding soft tissues (discs, ligaments, spinal cord and nerve roots). Cervical myelography followed by high-resolution CT scanning provides sagittal and axial information (including spinal cord atrophy), and delineates bony detail better than MRI[386]. Unlike MRI, CT/myelogram involves ionizing radiation and does not provide information about changes within the spinal cord parenchyma.

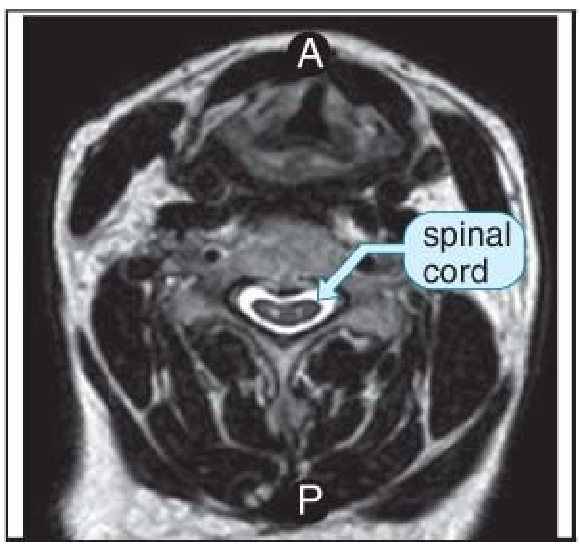

Figure 18-5 Snake eyes (two foci of high signal) within a slightly flattened and mildly atrophic spinal cord on axial T2WI MRI

Sensory evoked potentials (SEPs) - pre-op

Normal pre-op SEPs or normalization of SEPs in the early post-op period are

associated with better outcome[390].

PRACTICE GUIDELINE 18-16 PRE-OP SEPS IN CSM

Pre-op SEPs should be considered if the additional prognostic information would help treatment decisions (**Level B** Class II)[390]

EMG

Not routinely useful in CSM. EMG has poor sensitivity in cervical radiculopathy and is not reliable in predicting outcome from surgery for CSM (Class III)[387]. EMG is most helpful in suspicious cases to eliminate etiologies such as peripheral neuropathy or ALS.

TREATMENT

Indications for surgery

See *PRACTICE GUIDELINE 18-17*.

PRACTICE GUIDELINE 18-17 SURGICAL VS. NONSURGICAL MANAGEMENT

<u>Mild</u> myelopathy (mJOA score > 12)*: in the short-term (3 years) patients may be offered the option of surgical decompression or nonoperative management (prolonged immobilization in a rigid cervical collar, anti-inflammatory medications, and "low-risk" activities or bed rest (**Level C** Class II)[391]

More severe myelopathy: should be treated with surgical decompression with benefits maintained at 5 and 15 years post-op (Level D Class III)[391]

Level B Class I392 Degenerative cervical <u>radiculopathy</u>: patients do better with anterior decompression ± fusion (compared to conservative management) for

- rapid relief (within 3-4 months) of arm & neck pain and sensory loss
- relief of longer term (≥ 12 months) symptoms of weakness of wrist extension, elbow extension, shoulder abduction and internal rotation

* patients with mJOA scores > 12 (see page 487) may not always be mildly impaired, they may derive significant improvement from surgery, and deterioration from this point may be ominous

NONOPERATIVE MANAGEMENT

Measures include: prolonged immobilization with rigid cervical bracing in an attempt to reduce motion and hence the cumulative effects of trauma on the spinal cord, modified activity to eliminate "high-risk" activities or bed rest, and anti-inflammatory medications[393].

SURGICAL TREATMENT

Intraoperative electrophysiologic monitoring

PRACTICE GUIDELINE 18-18 INTRA-OPERATIVE ELECTROPHYSIOLOGIC MONITORING DURING SURGERY FOR CSM OR RADICULOPATHY

Use of intra-op EP monitoring during routine surgery for CSM or cervical radiculopathy is not recommended as an indication to alter the surgical plan or administer steroids since this paradigm has not been observed to reduce the incidence of neurologic injury (**Level D** Class III)[394]

Choice of approach

The debate between anterior approaches (anterior cervical discectomy or corpectomy) and posterior approaches (decompressive cervical laminectomy) dates back to the time that both became widely practiced[244]. General sentiment is to treat anterior disease at the disc level (e.g. osteophytic bar, herniated disc…) usually limited to ≤ 3 levels (or occasionally 4) with an anterior approach, and to use a posterior approach as the initial procedure in the situations outlined below. Considerations of spinal curvature may need to enter into the decision process.

PRACTICE GUIDELINE 18-19 CHOICE OF SURGICAL APPROACH FOR CSM

There was not enough evidence to recommend any of the following techniques over the other (in terms of <u>short-term</u> success in treating CSM): ACDF, anterior corpectomy and fusion, laminectomy (with or without fusion) and laminoplasty ((**Level D** Class III)[395]

Laminectomy without fusion, however, is associated with a higher incidence of late kyphotic deformity* (**Level D** Class III)[395]

* incidence 14-47%, not all cases are symptomatic, not all cases need treatment (see text)

Posterior approach: Options include:

1. laminectomy alone
2. laminectomy/arthrodesis (i.e. laminectomy + lateral mass fusion) (Class III[A 396])
3. laminoplasty (Class III[A 397]): methods include unilateral ("open door") and midline enlargement ("French door")
4. multilevel foraminotomies: usually not adequate for central canal stenosis

A. this procedure was found to be effective, the class shows the strength of the evidence

Situations where a posterior approach would generally be the initial approach:

1. congenital cervical stenosis where removing osteophytes will still not provide at least ≈ 12 mm of AP canal diameter
2. disease over ≥ 3 levels (although up to 4 may occasionally be dealt with anteriorly)
3. primary posterior pathology (e.g. infolding of ligamentum flavum)
4. some cases of OPLL (anterior approach has higher risk of dural tear)

Disadvantages of the posterior approach:

1. laminectomy <u>without</u> fusion
   A. degeneration and osteophytes continue to progress following surgery
   B. risk of subsequent subluxation or progressive kyphotic angulation ("swan neck" deformity)
      1. quoted incidence: 14-47%[398-400] (risk may be minimized by careful preservation of facet joints)
      2. not all cases need to be treated: in one series, 31% (18/58) developed post-op kyphosis, and 16% of these (3/18) required surgical stabilization[401]
      3. the development of kyphotic deformity does not appear to diminish the clinical outcome[400] and does not correlate with neurologic deterioration when deterioration occurs[402].
2. more painful initially post-op and sometimes more prolonged rehabilitation
3. long-term complaints of a heaviness of the head possibly associated with

atrophy of the paraspinal muscles

4. ✖ contraindicated with pre-existing swan neck deformity, and not recommended in the presence of reversal of the normal cervical lordosis (i.e. kyphotic curve)[403] where the spinal cord won't tend to move away from the anterior compression or in the presence of ≥ 3.5 mm subluxation or > 20° rotation in the sagittal plane[383] and caution must be exercised in *hyper* lordosis (*see below*)

Anterior approach: Also shown to be effective (Class III391).

Instrumentation options: in terms of <u>fusion rates</u> for 2-level anterior operations (i.e. 2 disc spaces) (Class III)[395]:

2-level ACDF with anterior plate = 1-level corpectomy with plate > 1-level corpectomy without plate* > 2-level ACDF without plate

* however, the graft extrusion rate is higher for corpectomy than ACDF

Worsening of myelopathy has been reported in 2-5% of patients after anterior decompression[404, 405] (intraoperative SSEP monitoring may reduce this rate[405]) and C5 radiculopathy may occur (*see below*).

Anterior cervical plating:

Many systems are available, with more similarities than differences. All include some method of preventing screw back out. Some general pointers:

1. for single level fusion, typical plate length is 22-24 mm
2. screw length: rule of thumb is 12 mm for females, 14 mm for males
3. do not completely tighten a single screw (to avoid kicking up plate) until the diagonally opposite screws are placed and loosely tightened
4. most systems have fixed and variable angle screws. Variable angle screws allow for load sharing with the graft (here is where a derivative of Wolff's law is often invoked: the weight sharing helps stimulate fusion). Avoid over-angling screws which may prevent the locking mechanism from properly engaging
5. optimal plate placement allows for contact of the plate with the VB at the screw location. This may require
   A. contouring of plate to follow the lordosis of the c-spine
   B. reduction of anterior osteophytes

Posterior approach: For decompression, some recommend cervical laminectomy extending one or <u>two</u> levels beyond the stenosis above and below[406, 407].

Curvature considerations: extending the laminectomy to include C2 and some-times C1 has been recommended for patients with straightening of the cervical curvature[346]. In cases of hyperlordosis, posterior migration of the spinal cord following an extensive laminectomy may put increased tension on the nerve roots and blood vessels (with possible neurologic worsening), and a limited laminectomy just where the cord is compressed is recommended (see *Post-op C5 palsy* below).

"Keyhole foraminotomies" or medial facetectomy with undercutting of the facets may be performed at levels involved with radiculopathy.

Position: choices are primarily: prone, lateral oblique, or sitting. The prone position has a major disadvantage of difficulty elevating the head above the heart, resulting in venous engorgement with significant operative bleeding. The sitting position has a number of inherent risks (see *Sitting position*, page 153) including cord hypoperfusion[405]. The lateral oblique position may introduce some distortion to the anatomy due to asym-metrical positioning.

The rate of post-op spinal deformity is 25-42%. Neurologic worsening has been reported in 2% in some series, higher in others. C5 radiculopathy may occur (*see below*).

To avoid significant destabilization of the cervical spine:

1. during the dissection, do not remove soft tissue overlying the facet joints (to preserve their blood supply)
2. take the laminectomy only as far lateral as the extent of the spinal canal, carefully preserving the facet joints[347] (use keyhole laminotomies where necessary)
3. avoid removing a total of one facet at any given level

OUTCOME

Even excluding cases that are later proven to have demyelinating disease, the outcome from surgery for CSM is often disappointing. Once CSM is clinically apparent, complete remission almost never occurs. The prognosis with surgery is worse with increasing severity of involvement at the time of presentation[406] and with longer duration of symptoms (48% showed clinical improvement or cure if operated within 1 yr of onset, whereas only 16% responded after 1 yr[347]). The success of surgery is also lower in patients with other degenerative diseases of the CNS (ALS, MS…).

Progression of myelopathy may be arrested by surgical decompression. This is not always borne out, and some early series[363, 366] showed similar results with

conservative treatment as with laminectomy which yielded improvement in 56%, no change in 25%, and worsening in 19%. Also as discussed earlier (see *Natural history*, page 487) some cases of CSM develop most of the deficit early and then stabilize.

Some series show good results, with ≈ 64-75% patients having improvement in CSM post-op[360]. However, other authors remain less enthusiastic. Utilizing a questionnaire in 32 post-op patients operated anteriorly, 66% had relief from radicular pain, while only 33% had improvement in sensory or motor complaints[360]. In one series, half the patients had improvement in fine motor function of the hands, but the other half worsened postoperatively[408]. Spinal cord atrophy as a result of continued pressure or ischemia may be partly responsible for poor recovery. Bedridden patients with severe myelopathy rarely recover useful function.

Post-op C5 palsy: Criteria: weakness of deltoid and/or biceps with no worsening of myelopathy. Follows ≈ 3-5% of extensive anterior or posterior decompression (including laminoplasty)[404, 409]. 50% have motor involvement only (deltoid > biceps), 50% also have C5 dermatomal sensory loss and/or C5 dermatomal pain (shoulder). Most occur < 1 week post-op[409]. 92% are unilateral[409]. No pre-op risk factors have been identified[410]. Etiology: unproven, may be related to traction on the nerve root from posterior migration of the cord after decompression or to bone graft displacement. Prognosis for spontaneous recovery is generally good; more severe deficits take longer to recover[409].

Late developments:

Some patients who show early improvement will develop late deterioration (7-12 yrs after reaching a plateau)[383], with no radiographically apparent explanation in up to 20% of these cases[411]. In others, degeneration at levels adjacent to the operated segments may be demonstrated.

Adjacent segment disease (ASD): degeneration that develops at a motion segment adjacent to a previous fusion. Findings include: disc degeneration, stenosis, facet hypertrophy, scoliosis, listhesis and instability. After ACDF, ASD occurred at a rate of 2.9% per year over 10 years observation[412]. Estimate: 25% of patients will develop symptomatic adjacent level changes within 10 years of surgery[412]. This rate was higher with single level fusion at C5-6 or C6-7 than it was with multilevel fusion, and natural progression of the disease was felt to be a significant contributor[412] (i.e. it was not all attributable to the fusion). Most cases of ASD observed radiographically are asymptomatic

18.4.1.3. Coincident cervical and lumbar spinal stenosis

Coincident symptomatic lumbar and cervical spinal stenosis is usually managed by first decompressing the cervical region, and later operating on the lumbar region (unless severe neurogenic claudication dominates the picture). It is also possible, in selected cases, to operate on both in a single sitting[304, 413].

18.5. Craniocervical junction and upper cervical spine abnormalities

Also see *Axis (C2) vertebra lesions*, page 1231.

ASSOCIATED CONDITIONS

Abnormalities in this region are seen in a number of conditions including:

1. rheumatoid arthritis: *see page 494*
2. traumatic & post-traumatic: including fractures of odontoid, occipital condyles…
3. **ankylosing spondylitis**: (*see page 502*) may result in fusion of the entire spine which spares the occipitoatlantal and/or atlantoaxial joints which can lead to instability there
4. congenital conditions:
   A. Chiari malformations: *see page 233*
   B. Klippel-Feil syndrome: *see page 253*
   C. Down syndrome
   D. atlantoaxial dislocation **(AAD)**
   E. occipitalization of the atlas: seen in 40% of congenital AAD[414]
   F. Morquio syndrome (a mucopolysaccharidosis): atlantoaxial subluxation occurs due to hypoplasia of the odontoid process and joint laxity
5. neoplasms: metastatic (*see page 743*) or primary
6. infection
7. following surgical procedures of the skull base or cervical spine: e.g. transoral resection of the odontoid

TYPES OF ABNORMALITIES

Abnormalities include:

1. basilar impression/invagination: as with Paget's disease
2. atlanto-occipital dislocation
3. atlantoaxial dislocation
4. occipitalization of the atlas, or thin or deficient posterior arch of atlas[415]

Treatment

Fractures of the occipital condyles, atlas or axis are usually adequately treated with external immobilization (also see *Occipital condyle fractures*, page 954). Because traumatic occipitocervical dislocations are usually fatal, optimal treatment is not well defined. Occipitalization of the atlas may be treated by creating an "artificial atlas" from the base of the occiput and wiring to that[415].

Indications and techniques are outlined in *Atlantoaxial fusion (C1-2 arthrodesis)* on page 183.

18.6. Rheumatoid arthritis

More than 85% of patients with moderate or severe rheumatoid arthritis **(RA)** have radiographic evidence of C-spine involvement[416].

The grading system of Ranawat et al.[416] for myelopathy is shown in *Table 18-31* is used in RA as well as other etiologies of myelopathy.

Table 18-31 Ranawat classification of myelopathy

Class	Description
I	no neural deficit
II	subjective weakness + hyperreflexia + dysesthesia
III	objective weakness + long tract signs III A = ambulatory III B = quadriparetic & non ambulatory

Common cervical spine involvement in RA:

1. upper cervical spine: involved in 44-88% of RA cases[417] (often found together):
   A. anterior **atlantoaxial subluxation**: the most common manifestation of RA in the cervical spine, found in up to 25% of patients with RA (*see below*)

B. **basilar impression (BI)**: upward translocation of the odontoid process, found in ≈ 8% of patients with RA (*see page 497*)
C. pannus of granulation tissue: forms around the odontoid
2. subaxial C-spine (i.e. below C2): subluxation (*see page 498*)

Less common involvement of the cervical spine in RA:

1. posterior subluxation of the atlantoaxial joint: must have either associated fracture of or near total arthritic erosion of odontoid
2. vertebral artery insufficiency secondary to changes at cranio-cervical junction[418]

18.6.1. Atlantoaxial subluxation (AAS) in RA

Inflammatory involvement of the atlantoaxial synovial joints causes erosive changes in the odontoid process (anteriorly at the synovial joint with the C1 arch, and posteriorly at the synovial joint with the transverse ligament) and decalcification and loosening of the insertion of the transverse ligament on the atlas. These changes lead to instability allowing a scissoring effect with anterior subluxation of C1 on C2. AAS occurs in ≈ 25% of patients with RA[418]. Mean time between onset of RA symptoms to the diagnosis of AAS in 15 patients: 14 years[419].

CLINICAL

Signs and symptoms of AAS are shown in *Table 18-32*.

AAS is usually slowly progressive. Mean age at onset of AAS symptoms: 57 years.

Pain is experienced locally (upper cervical and suboccipital regions, often from compression of C2 nerve root) or is referred (to mastoid, occipital, temporal, or frontal regions).

VBI may occur from VA involvement (*see page 1158*).

Table 18-32 Signs and symptoms of AAS* (15 patients with AAS[419])

Finding	%
pain	
local	67%
referred	27%

hyperreflexia	67%
spasticity	27%
paresis	27%
sensory disturbance	20%

* other possible findings not reported in this series: clumsiness, neurogenic bladder, Babinski sign

Radiographic evaluation

The magnitude of AAS is usually increased with neck flexion.

Lateral C-spine x-ray

Anterior atlantodental interval (ADI)

The ADI (*see page 957* for details) only gives information about the *stability* of the C1-2 joint. The normal ADI in adults is < 3-4 mm[420, 421]. Widening of the ADI suggests possible incompetence of the transverse ligament. However, the ADI does not correlate with the risk of neurologic injury[422, 423] and is not predictive of progression from asymptomatic AAS to symptomatic AAS.

Posterior atlantodental interval (PADI)

The amount of room available for the spinal cord can vary for any given ADI depending on the AP diameter of the spinal canal and the thickness of any pannus. The PADI (*see page 136*) and the AP diameter of the *subaxial* canal measured on a lateral C-spine x-ray correlates with the presence and severity of paralysis[422].

The PADI also predicts neurologic recovery following surgery. Patients with paralysis from AAS showed no recovery if the pre-op PADI was < 10 mm[422].

PADI ≤ 14 mm has been proposed as an indication for surgical stabilization.

MRI

The optimal test to evaluate the source and magnitude of upper cord or medulla compression. Demonstrates location of odontoid process, extent of pannus, and effects of subluxation (may need to be performed with head flexed to evaluate this).

Treatment

Requires knowledge of the following information:

- natural history: AAS in most patients progresses, with a small percentage either stabilizing or fusing spontaneously. In one series[424] with 4.5 years mean followup, 45% of patients with 3.5-5 mm subluxation progressed to 5-8 mm, and 10% of these progressed to > 8 mm
- once myelopathy occurs, it may be irreversible
- the worse the myelopathy, the higher the risk for sudden death
- the chances of finding myelopathy are significantly increased once the subluxation reaches ≥ 9 mm[425]
- associated cranial settling further decreases the tolerance for AAS
- life expectancy of patients with RA is 10 years less than the general population[424]
- the morbidity and mortality of surgical treatment (*see below*)
- pannus may regress some after medical treatment

When to treat?

- symptomatic patients with AAS: almost all require surgical treatment (C1-2 fusion in most cases). For management, *see below*
  A. some surgeons do not operate if the maximal dens-C1 distance is < 6 mm
- asymptomatic patients: controversial
  A. some authors feel surgical fusion is not necessary in asymptomatic patient if the dens-C1 distance is below a certain cutoff. Recommendations for this cutoff have ranged from 6 to 10 mm[426], with **8 mm** commonly cited (an un-validated delineation)
  B. these patients are often placed in a rigid cervical collar, e.g. while outside the home, even though it is generally acknowledged that a collar probably does not provide significant support or protection
  C. NB: some cases of sudden death in previously asymptomatic RA patients may be due to AAS and may then be erroneously attributed to cardiac arrhythmias, etc.[427]

Surgical management

It is necessary to either reduce the subluxation or to decompress the upper cord before doing a C1-C2 or occipital-C1-C2 fusion.

Menezes assesses all subluxed patients for reducibility using MRI

compatible Halo cervical traction as follows: start with 5 lbs, and gradually increase over a period of a week. Most cases reduce within 2-3 days. If not reduced after 7 days then it is probably not reducible. Only ≈ 20% of cases are not reducible (most of these have odontoid > 15 mm above foramen magnum).

Most require stabilization via posterior wiring and fusion, either of C1 to C2, or of occiput to C2. The latter is used when fusion is combined with decompression (posterior laminectomy of C1 with posterior enlargement of the foramen magnum). See *Atlantoaxial fusion (C1-2 arthrodesis)* on page 183.

Posterior fusion alone does not provide adequate relief if the subluxation is irreducible, or if pannus causes significant compression (however, there may be some reduction of pannus after fusion). In these cases, transoral odontoidectomy may be indicated. Performing the posterior stabilization and decompression first allows some patients to avoid a second operation, and permits the remainder to undergo the anterior approach without becoming destabilized. Still, some surgeons do the odontoidectomy first[426] (requires the patient to remain in traction until the fusion).

Reminder: the patient must be able to open the mouth greater than ≈ 25 mm in order to perform transoral odontoidectomy without splitting the mandible.

Posterior fusion

See *Atlantoaxial fusion (C1-2 arthrodesis)* on page 183 for technique. In RA, erosion and osteoporosis weakens the C1 arch, and extra care is needed to avoid fracturing it.

Morbidity and mortality

Because of the frequency of simultaneous involvement of other systems in RA including pulmonary, cardiac, and endocrine, operative mortality ranges from 5-15%[426].

The non-fusion rate for C1-2 wiring and fusion has been reported as high as 50%[428], typical rates are lower (with 18% of patients in one series developing a fibrous union[426]). The most common site of failure of osseous fusion is the interface between the bone graft and the posterior arch of C1429.

Post-operative care

The patient is usually mobilized almost immediately post-op in halo vest traction (some use an optional period of maintained traction before mobilization). Impaired healing in RA dictates that the Halo be worn until fusion

is well established, as seen on x-ray (usually 8-12 weeks). Sonntag evaluates the patient with flexion-extension lateral C-spine x-rays by disconnecting the halo ring from the vest.

18.6.2. Basilar impression in rheumatoid arthritis

AKA atlantoaxial impaction. Erosive changes in the lateral masses of C1 → telescoping of the atlas onto the body of C2 causing ventral migration of C1 with resultant ↓ in AP diameter of the spinal canal. There is concomitant upward displacement of the dens. The posterior arch of C1 often protrudes superiorly through the foramen magnum. All of these factors lead to compression of the pons and medulla. Rheumatoid granulation tissue behind the odontoid also contributes. Vertebral artery and/or anterior spinal artery compression may also cause neurologic dysfunction.

The degree of erosion of C1 correlates with the extent of odontoid invagination.

CLINICAL

See Table 18-33 for signs & symptoms.

Pain may occur as a result of compression of the C1 and/or C2 nerve roots. Compression of the medulla can cause cranial nerve dysfunction.

Motor exam usually difficult because of severe polyarticular degeneration and associated pain. Sensory findings (all non-localizing): diminished vibratory, position, and light touch.

Table 18-33 Symptoms and signs of BI (45 patients with RA[417])

Finding	%
headache	100%
progressive difficulty ambulating	80%
hyperreflexia + Babinski	80%
limb paresthesias	71%
neurogenic bladder	31%
cranial nerve dysfunction	22%
trigeminal nerve anesthesia	20%
glossopharyngeal	
vagus	

hypoglossal	
miscellaneous findings	
internuclear ophthalmoplegia	
vertigo	
diplopia	
downbeat nystagmus	
sleep apnea	
spastic quadriparesis	

RADIOGRAPHIC EVALUATION

See *Basilar invagination & basilar impression (BI)* on page 138 for radiographic criteria of BI. Erosion of the tip of the odontoid, commonly seen in RA, obviates use of any measurement that is based on the location of the tip of the odontoid[430]. For this reason, other measures have been developed, including the Clark station[429], Redlund-Johnell criteria[431], and Ranawat criteria[416]. Since even these methods will miss up to 6% of cases of BI in RA[430], it is recommended that suspicious cases be investigated further (e.g. with CT and/or MRI).

MRI: optimal for demonstrating brain stem impingement, poor for showing bone. **Cervicomedullary angle**: the angle between a line drawn through the long axis of the medulla on a sagittal MRI and a line drawn through the cervical spinal cord. The normal CMA is 135-170°. A CMA < 135° correlates with signs of cervicomedullary compression, myelopathy or C2 radiculopathy[432].

CT: primarily done to assess bony anatomy (erosion, fractures…).

CTA should be performed when surgery is contemplated, to show VA anatomy.

Myelography (water soluble) with CT: also good for delineating bony pathology.

TREATMENT

See also *Craniocervical junction and upper cervical spine abnormalities* on page 494.

CERVICAL TRACTION

May attempt with Gardner-Wells tongs. Begin with ≈ 7 lbs, and slowly increase up to 15 lbs. Some may require several weeks of traction to reduce.

SURGERY

Reducible cases: posterior occipitocervical fusion ± C1 decompressive laminectomy. Irreducible cases: requires transoral resection of odontoid. May perform before posterior fusion (but then must be kept in traction while waiting for posterior fusion).

18.6.3. Subaxial subluxation in rheumatoid arthritis

The direct effects of RA on the subaxial spine involves the facet joints posteriorly. Degenerative disc disease, which is generally a late manifestation in RA, is not the result of synovitis[433]. Involvement is most common at C2-3 and C3-4.

18.7. Atlantoaxial subluxation (AAS) in Down syndrome

No all cases of AAS are *unstable* (which, by definition, needs treatment).

Incidence of AAS in Down syndrome **(DS)** is 20% 434, but only 1-2% of DS patients have symptomatic AAS[435]. AAS in DS appears to be due to laxity of the transverse atlantal ligament **(TAL)**. This laxity may decrease with age as the TAL stiffens.

Management

Controversial. There have been position statements[436] and rebuttals[435, 437].

Recommendations (modified[438]):

1. children who have been screened and do not have AAS: no further screening after age 10 years (since AAS does not develop later; the cutoff age is controversial)
2. **os odontoideum**: surgical fusion
3. **symptomatic AAS**
   A. symptoms may include: gait difficulties, neck pain, limited neck motion, torticollis, clumsiness, sensory deficits, and other symptoms of myelopathy
   B. for ADI[A] > 4.5 mm or PADIA < 14 mm or spinal cord damage on cervical MRI: surgical fusion

4. **asymptomatic AAS** seen on lateral C-spine x-ray:
   A. for ADI ≤ 4.5 mm <u>and</u> PADI ≥ 14 mm: no need for further testing
   B. for ADI > 4.5 mm or PADI < 14 mm: cervical MRI
      1. if the MRI shows spinal cord damage: surgical fusion
      2. if MRI shows no spinal cord damage: surgical fusion is optional. If fusion is not done, prohibit high-risk activities and restudy in 1 year

---

A. **ADI** = atlantodental interval (*see page 136*), **PADI** = posterior atlantodental interval (*see page 136*)

18.8. Paget's disease

PATHOPHYSIOLOGY

Paget's disease **(PD)** (AKA osteitis deformans) is a disorder of osteoclasts (possibly virally induced) causing increased rate of bone resorption with reactive osteoblastic overproduction of new, weaker, woven bone, producing characteristic "**mosaic pattern**".

Initially there is a "hot" phase with elevated osteoclastic activity and increased intraosseous vascularity. Osteoblasts lay down a soft, nonlamellar bone. Later a "cool" phase occurs with disappearance of the vascular stroma and osteoblastic activity leaving sclerotic, radiodense, brittle bone[439] ("**ivory bone**").

Malignant degeneration

A misnomer, since the malignant changes actually occur in the reactive osteoblastic cells. About 1% (reported range: 1-14%) degenerate into sarcoma (osteogenic sarcoma, fibrous sarcoma, or chondrosarcoma)[440 (p 2642)], with the possibility of systemic (e.g. pulmonary) metastases. Malignant degeneration is much less common in the spine than in the skull or femur.

EPIDEMIOLOGY

Prevalence: ≈ 3% of population > 55 years old in the U.S. and Europe[441]. Slight male predominance. Family history of Paget's disease is found in 15-30% of cases (accuracy is poor since most are asymptomatic).

Common sites of involvement

Affinity for axial skeleton, long bones and skull. In approximate descending order of frequency: pelvis, thoracic and lumbar spine, skull, femur, tibia, fibula, and clavicles.

PRESENTATION

Only ≈ 30% of pagetic sites are symptomatic[442], the rest are discovered incidentally. The overproduction of weak bone may produce bone pain (the most common symptom), predilection for fractures and compressive syndromes (cranial nerve (*see page 1204*), spinal nerve root…). Painless bowing of a long bone may be the first manifestation. A number of patients present due to pain from joint dysfunction related to PD.

NEUROSURGICAL INVOLVEMENT

PD may present to the neurosurgeon as a result of:

- back pain: usually not as a direct result of vertebral bone involvement (*see below*)
- spinal cord and/or nerve root symptoms
  - compression of the spinal cord or cauda equina (relatively rare)
  - spinal nerve-root compression
  - vascular steal due to reactive vasodilatation adjacent to involved areas
- with skull involvement:
  - compression of cranial nerves as they exit through bony foramina (8th nerve is most common, producing deafness or ataxia): *see page 1204*
  - skull base involvement → basilar invagination
- to ascertain diagnosis in unclear bone lesions of the spine or skull

EVALUATION

1. lab work (markers may be normal in monostotic involvement):
   A. serum alkaline phosphatase: usually elevated (this enzyme is involved in bone synthesis and so may not be elevated in purely lytic Paget's disease[100 (p 1416)]); mean 380 ± 318 IU/L (normal range: 9-44)[443]. Bone-specific alkaline phosphatase may be more sensitive and may be useful in monostotic involvement[441]
   B. calcium: usually normal (if elevated, one should R/O hyperparathyroidism)

   C. urinary hydroxyproline: found almost exclusively in cartilage. Due to the high turnover of bone, urinary hydroxyproline is often increased in PD with a mean of 280 ± 262 mg/24 hrs (normal range 18-38)[443]
2. bone scan: lights up in areas of involvement in most, but not all[443] cases
3. plain x-rays:
   A. localized enlargement of bone: a finding unique to PD (not seen in other osteoclastic diseases, such as prostatic bone mets)
   B. cortical thickening
   C. sclerotic changes
   D. osteolytic areas (in skull → osteoporosis circumscripta; in long bones → “V” shaped lesions)
   E. spinal Paget’s disease often involves <u>several contiguous levels</u>. Pedicles and lamina are thickened, vertebral bodies are usually dense and compressed with increased width. Intervening discs are replaced by bone
4. CT: hypertrophic changes at the facet joints with coarse trabeculations

---

18.8.1. Paget’s disease of the spine

PRESENTATION

The overwhelming majority of pagetic lesions are asymptomatic[100] (p 1413) with lesions detected on radiographs or bone scan obtained for other reasons or as part of a work-up for an elevated alkaline phosphatase. Although the most common complaint in patients with Paget’s disease is of back pain, this is attributable to pagetic involvement alone in only ≈ 12%[443], in the remainder it is secondary to other factors, some of which are described below.

Symptoms that may be related to the Paget’s disease itself:

1. symptoms from the following are slowly progressive (usually present for > 12 months; rarely < 6 mos)
   A. neural compression
      1. causes of compression
         a. due to expansion of woven bone
         b. due to osteoid tissue
         c. pagetic extension into ligamentum flavum and epidural fat[444]
      2. sites of compression
         a. spinal cord (*see below*)

b. nerve root in neural foramen

B. osteoarthritis of facet joints (Paget's disease may precipitate osteoarthritis[443])

2. symptoms from the following tend to progress more rapidly

A. malignant (sarcomatous) change of involved bone (rare, *see above*)

B. pathologic fracture (pain usually sudden in onset)

C. neurovascular (compromise of vascular supply to nerves or spinal cord) by

1. compression of blood vessels (arterial or venous)

2. pagetic vascular steal (*see below*)

Spinal cord symptoms

Myelopathy or cauda equina syndrome may be due to spinal cord compression or from vascular effects (occlusion, or "steal" due to reactive vasodilatation of nearby blood vessels[100 (p 1415)]). Only ≈ 100 cases had been described as of 1981445. Characteristically, 3-5 adjacent vertebrae are involved[446 (p 2307)], whereas monostotic involvement is usually asymptomatic[447]. In case reports in the literature, progressive quadri- or paraparesis was the most common presentation[448]. Sensory changes are usually the first manifestation, progressing to weakness and sphincter disturbance. Pain was the only symptom in a neurologically intact patient in only 5.5%.

A rapid course (averaging 6 wks) with a sudden increase in pain is more suggestive of malignant degeneration.

TREATMENT

MEDICAL TREATMENT FOR PAGET'S DISEASE

There is no cure for Paget's disease. Medical treatment is indicated for cases that are not rapidly progressive where the diagnosis is certain, for patients who are poor surgical candidates, and pre-op if excessive bleeding cannot be tolerated. Medical therapy reverses some neurologic deficit in 50% of cases[449], but generally requires prolonged treatment (≈ 6-8 months) before improvement occurs, and may need to be continued indefinitely due to propensity for relapses. Medications used include the following.

Calcitonin derivatives

Parenteral salmon **calcitonin** (Calcimar®)[449]: reduces osteoclastic activity directly, osteoblastic hyperactivity subsides secondarily. Relapse may occur even while on calcitonin. Side effects include nausea, facial flushing, and the development of antibodies to salmon calcitonin (these patients may benefit from a more expensive synthetic human preparation (Cibacalcin®) starting at 0.5 mg SQ q d[450]).

Rx 50-100 IU (medical research council units) SQ q d **x** 1 month, then 3 injections per week for several months[441]. If used pre-op to help decrease bony vascularity, ≈ 6 months of treatment is ideal. Doses as low as ≈ 50 IU units 3 **x** per week may be used indefinitely post-op or as a sole treatment (alkaline phosphatase and urinary hydroxyproline decline by 30-50% in > half of patients in 3-6 months, but they rarely normalize).

Bisphosphonates

These drugs are pyrophosphate analogues that bind to hydroxyapatite crystals and inhibit reabsorption. They also alter osteoclastic metabolism, inhibit their activity, and reduce their numbers. They are retained in bone until it is resorbed. Oral absorption of all is poor (especially in the presence of food). Bone formed during treatment is lamellar rather than woven.

Etidronate (Didronel®) (AKA EHDP): reduces normal bone mineralization (especially at doses ≥ 20 mg/kg/d) producing mineralization defects (osteomalacia) which may increase the risk of fracture but which tend to heal between courses[451]. Contraindicated in patients with renal failure, osteomalacia, or severe lytic lesions of a LE. ***Rx*** 5-10 mg/kg PO daily (average dose: 400 mg/d, or 200-300 mg/d in frail elderly patients) for 6 months, may be repeated after a 3-6 month hiatus if biochemical markers indicate relapse.

Tiludronate (Skelid®): unlike etidronate, does not appear to interfere with bone mineralization at recommended doses. Side effects: abdominal pain, diarrhea, N/V. ***Rx*** 400 mg PO qd with 6-8 ounces of plain water > 2 hrs before or after eating **x** 3 months. Available: 200 mg tablets.

Pamidronate (Aredia®): much more potent than etidronate. May cause a transient acute flu-like syndrome. Oral dosing is hindered by GI intolerance, and IV forms may be required. Mineralization defects do not occur in doses < 180 mg/course. ***Rx*** 90 mg/d IV **x** 3 days, or as weekly or monthly infusions.

Alendronate (Fosamax®): does not produce mineralization defects (*see page 994*).

Clodronate (Ostac®, Bonefos®): ***Rx*** 400-1600 mg/d PO **x** 3-6 months. 300 mg/d IV **x** 5 days.

Risedronate (Actonel®): does not interfere with bone mineralization in recommended doses[452]. ***Rx***: 30 mg PO q d with 6–8 oz. of water at least 30 minutes before the first meal of the day.

Under development: ibandronate, neridronate, and others.

Plicamycin

Formerly mithramicin. A cytotoxic antibiotic that inhibits RNA synthesis with preferential toxicity for osteoclasts. Reserved for severe and extensive involvement due to dose dependent renal and hepatic impairment and possible thrombocytopenia. Not approved for treating Paget's disease in any country.

Rx 15-25 µg/kg given IV over 8-10 hours qod **x** 10 infusions.

SURGICAL TREATMENT

In general, conservative treatment of fractures in PD have a high rate of delayed union.

Surgical indications for spinal Paget's disease

1. rapid progression: indicating possible malignant change or spinal instability
2. spinal instability: severe kyphosis or compromise of canal by bone fragments from pathologic fracture. Although the collapse is usually gradual, sudden compression may occur
3. uncertain diagnosis: especially to R/O metastatic disease (osteoblastic lesions)
4. failure to improve with medications

Surgical considerations:

1. profuse bleeding is common: if significant bleeding would present an unusual problem, treat for as long as feasible pre-op with a bisphosphonate or calcitonin (*see above*)
   A. use bone wax to help control bleeding
   B. hemostasis may be difficult
2. to treat resultant spinal stenosis: decompressive laminectomy is the standard procedure in the thoracic region[448]. However, if most of the pathology is anterior, consideration should be given to anterior approach
3. bone is often thickened, and may be fused with obliteration of interspace landmarks. A high-speed drill is usually helpful

4. post-op medical treatment may be necessary to prevent recurrences[449]
5. osteogenic sarcoma
   A. surgery and chemotherapy are used, cure is less likely than in primary osteosarcoma of non-pagetic origin
   B. biopsy proven of the scalp requires en-bloc excision of scalp and tumor

Surgical outcome[448]:

In 65 patients treated with decompressive laminectomy, 55 (85%) had definite but variable degrees of improvement. Patients who had only minimal improvement were often ones with malignant changes. One patient was worse after surgery, and the operative mortality was 7 patients (10%). Survival with malignant degeneration is < 5.5 mos after admission.

18.9. Ankylosing spondylitis

Key concepts:

> • a seronegative spondylarthropathy (enthesopathy)
> • starts in the SI joints and progresses rostrally
> • clinical: morning back stiffness, kyphoscoliosis limits chest expansion
> • x-ray findings: "bamboo spine", Andersson lesions, progressive thoracic kyphosis
> • risk of SCI due to fracture is increased, and may follow minimal trauma

AKA Marie-Strümpell disease. Ankylosing spondylitis **(AS)**: one of the so-called seronegative arthropathies (ANA and serum rheumatoid factor are negative[453], unlike rheumatoid arthritis). The spine is the primary skeletal site involved, usually starting in the sacroiliac joints and lumbar spine and progressing rostrally. **Enthesopathy**: nongranulomatous inflammatory changes at the entheses (attachment points of ligaments, tendons or capsules on bones; the locus of involvement in AS) stimulates replacement of ligaments by bone ultimately resulting in osteoporotic VBs, calcified intervertebral discs (sparing the nucleus pulposus), and ossified ligaments, producing square appearing VBs with bridging syndesmophytes, the so-called "**bamboo spine**" or "poker spine".

Differential diagnosis:

1. early on, AS may resemble rheumatoid arthritis. However, in AS nodules do not form in joints, and rheumatoid factor is absent in the serum
2. metastatic prostate Ca in elderly male patients with sacroiliac pain and blastic changes compatible with sacroiliitis
3. Forestier's disease (*see page 506*) and DISH (*see page 506*): these overlapping conditions produce exuberant bony overgrowth anterior and lateral to the disc without degeneration and ossification of the disc as in AS. Both spare the facets and SI joints, do not produce flexion deformity, and tend to occur in men > 50 yrs old (older than typical AS)[453]
4. psoriasis and Reiter's syndrome: spondylitis tends to be milder and less uniform and SI joint involvement is asymmetrical

EPIDEMIOLOGY

Incidence is ≈ 1-3 cases per 100,000. Symptoms tend to be more pronounced in males, which has resulted in an underreporting of the condition in females and an exaggeration of the estimation of the male predominance (incidence is probably ≈ equal)[454]. Peak incidence: 17-35 yrs age. Although AS is not hereditary, first degree relatives are at increased risk.

DIAGNOSTIC CRITERIA

Modified New York criteria (*see Table 18-34*) may not be helpful for diagnosis early on. SI joint involvement is the sine qua non for definite diagnosis.

CLINICAL

Typical initial presentation is with nonradiating low back pain, morning back stiffness, hip pain and swelling (due to large joint arthritis), exacerbated by inactivity and improved with exercise[455]. **Patrick's test** (*see page 444*) usually positive. Compressing the pelvis with the patient in the lateral decubitus position produces pain. **Schober test** (measure distraction between skin marks on the back with forward flexion to detect reduced mobility of the spine due to fusion[46]) is not specific for inflammatory spondylopathies[456] but may be helpful for monitoring ongoing physical therapy.

Table 18-34 Modified New York Criteria for AS

Diagnosis (see criteria below)
Definite AS: radiologic criterion + ≥ 1 clinical criteria

Probable AS: radiological criterion without clinical criteria, or 3 clinical criteria without radiological criterion
Clinical criteria
low back pain > 3 months, improved by exercise, not relieved by rest
limitation of lumbar spine motion in both sagittal and frontal planes
limitation of chest expansion relative to normal values for age and sex
Radiological criterion
sacroiliitis

Neurosurgical involvement usually results from the following:

1. cauda equina syndrome **(CES)**: etiology is frequently unclear, but is usually not due to stenosis or compressive lesion. In the absence of compression, surgical intervention is not indicated
2. rotatory subluxation: at occipito-atlantal and atlanto-axial joints. May occur as these are typically the last mobile segments of the spine. Incidence is much less than with rheumatoid arthritis. Lesions that might be stable in otherwise normal spines are often not stable in AS
3. myelopathy secondary to bow-stringing of the cord: laminectomy may aggravate
4. acute spinal cord injury **(SCI)**: risk of SCI or CES due to fracture is increased in AS, and may occur following minimal trauma. Injuries are more common in the lower cervical spine. The rigid spine of AS when fractured acts as a long lever and is extremely unstable[457]. Delayed deterioration may be due to spinal epidural hematoma[458]
5. vertebral stress fractures: most common in the lower thoracic and upper lumbar spines, usually through the ossified intervertebral disc ("**chalk-stick**" fracture)
6. painful pseudarthroses
7. spinal deformity
8. spinal stenosis: rare
9. basilar impression

Radiographic evaluation

Plain x-rays: vital for diagnosis and follow-up. Sacroiliac **(SI)** joint involvement (on AP pelvic x-rays or on oblique views through the plane of the SI joints) is one of the earliest findings, and the often symmetric osteoporosis followed by sclerosis is characteristic. "Bamboo spine" (*see above*) is also

classic. X-ray of the entire spine is recommended since multiple, non-contiguous (and often unsuspected) fractures are not unusual.

MRI: can rule out spinal epidural hematoma and the occasional herniated disc. **Andersson lesions**: pathologic changes at ligament insertion sites (MRI signal abnormalities at front and back of the endplates) are characteristic. Erosive changes due to pseudarthrosis at the disc space can mimic discitis (hi signal on T1WI & T2WI with enhancement).

Bone scan: ratio of uptake of SI joint to sacrum > 1.3:1 is suggestive of AS.

Natural history

Progression is slow, and patients usually remain functionally active. Thoracic kyphosis with compensatory increase in cervical and lumbar lordosis is common. The shift in center of gravity together with spine stiffness and fragility predisposes to frequent falls and further spine injuries.

Treatment

Management of the disease itself may involve use of immune modulators.

Surgical considerations

Aspects of AS than may increase anesthetic risk:

1. difficulty intubating due to fragile, angulated & immobile spine
2. mitral valve disease
3. myocardial conduction abnormalities
4. decreased pulmonary compliance and reduced lung volume in patients with advanced thoracic kyphoscoliosis

Spinal cord injury: Following trauma, the routine of initially securing the head to a backboard with the neck in neutral position may be deleterious in the patient with kyphotic deformity related to AS[457]. AS may be suspected when the patient spontaneously holds their head in significant flexion[459], and in these cases the neck should be immobilized in that position[460]. When traction is used, the axis of traction (not the pin sites) often needs to be ventral to neutral and the use of minimal weight is recommended[457].

Subsequent treatment for SCI in AS is controversial: halo immobilization alone has been advocated by many, citing similar outcome and fewer complications. Others advocate early internal fixation because of cases of nonunion and progression of deficit while in the halo brace[457] and risk of skin

breakdown under the vest due to severe kyphosis. Neurologic deficit related to cord or root compression is an indication for decompressive laminectomy and fusion[457].

Positioning for surgery may be difficult due to the immobile kyphotic spine. Anterior approaches are difficult due to extensive bridging osteophytes, and the screws for anterior plates may not hold well in the osteoporotic VBs. Posterior cervical lateral mass plating (*see page 179*) is advocated for most.

Kyphotic deformity: Severe flexion deformity may be treated by spinal osteotomy[453].

18.10. Ossification of the posterior longitudinal ligament (OPLL)

Key concepts:

- fibrosis followed by calcification and then ossification of the posterior longitudinal ligament. The process may involve the dura
- more common in Asian population
- most patients have only mild subjective complaints
- 50% of patients have impaired glucose tolerance, respiratory compromise may result from ossification of the costotransverse and costovertebral ligaments
- surgery is best for moderate neuro involvement (Nurick grade 3 & 4)

The age of patients with OPLL ranges from 32-81 years (mean = 53), with a slight male predominance. The prevalence increases with age. Duration of symptoms averages ≈ 13 months. It is more prevalent in the Japanese population (2-3.5%)[461, 462].

Pathophysiology

The pathologic basis of OPLL is unknown, but there is an increased incidence of ankylosing hyperostosis which suggests a hereditary basis.

OPLL begins with hypervascular fibrosis in the PLL which is followed by focal areas of calcification, proliferation of periosteal cartilaginous cells and finally ossification[463].

The process frequently extends into the dura. Eventually active bone marrow production may occur. The process progresses at varying rates among patients, with an average annual growth rate of 0.67 mm in the AP direction and 4.1 mm longitudinally[464].

When hypertrophied or ossified, the posterior longitudinal ligament may cause myelopathy (due to direct spinal cord compression, or ischemia) and/or radiculopathy (by nerve root compression or stretching).

Changes within the spinal cord involve the postero-lateral gray matter more than white matter, suggesting an ischemic basis for the neurologic involvement.

Distribution

Average involvement: 2.7-4 levels. Frequency of involvement:

1. cervical: 70-75% of cases of OPLL. Typically begins at C3-4 and proceeds distally, often involving C4-5 and C5-6 but usually sparing C6-7
2. thoracic: 15-20% (usually upper, ≈ T4-6)
3. lumbar: 10-15% (also usually upper, ≈ L1-3)

Pathologic classification[465]

1. segmental: confined to space behind vertebral bodies, does not cross disc spaces
2. continuous: extends from VB to VB, spanning disc space(s)
3. mixed: combines elements of both of the above with skip areas
4. other variants: includes a rare type of OPLL that is contiguous with the endplates and is confined to the disc space (involves focal hypertrophy of the PLL with punctate calcification)

Clinical

Most patients are asymptomatic, or have only mild subjective complaints. This is probably explained by the protective effect of the fusion resulting from OPLL and the very gradual compression.

Natural history: 17% of patients without myelopathy developed myelopathy in one study[466] over 1.6 years mean follow-up. Statistically, the myelopathy-free rate in patients without initially presenting with myelopathy was 71% after 30 years[466].

Evaluation

Plain x-rays

Often fail to demonstrate OPLL.

MRI

OPLL appears as a hypointense area and is difficult to appreciate until it reaches ≈ 5 mm thickness. On T1WI it blends in with the hypointensity of the ventral subarachnoid space; on T2WI it remains hypointense while the CSF becomes bright. Sagittal images may be very helpful in providing an overview of the extent of involvement, and T2WI may demonstrate intrinsic spinal cord abnormalities which may be associated with a worse outcome.

Myelography/CT

Myelography with post-myelographic CT (especially with 3D reconstructions) is probably best at demonstrating and accurately diagnosing OPLL.

TREATMENT

Treatment decisions

Based on clinical grade[465] as follows:

- Class I: radiographic evidence without clinical signs or symptoms. Most patients with OPLL are asymptomatic[462]. Conservative management unless severe
- Class II: patients with myelopathy or radiculopathy. Minimal or stable deficit may be followed expectantly. Significant deficit or evidence of progression warrants surgical intervention
- Class IIIA: moderate to severe myelopathy. Usually requires surgical intervention
- Class IIIB: severe to complete quadriplegia. Surgery is considered for incomplete quadriplegics showing progressive slow worsening. Rapid deterioration or complete quadriplegia, advanced age or poor medical condition are all associated with worse outcome

In moderate grade patients (Nurick grades 3 & 4363, *see Table 18-35*), surgery provided a statistically significant reduction in deterioration. There was no difference between surgery and conservative treatment in mild grade (Nurick

1 or 2), and surgery was ineffective in severe grade (Nurick 5)[466].

Pre-op assessment

Appropriate cardiorespiratory assessment should be made knowing that:

- respiratory compromise may result from ossification of the costotransverse and costovertebral ligaments
- 50% of patients have impaired glucose tolerance with the attendant risks associated with diabetes

Table 18-35 Nurick grade of disability from cervical spondylosis[363]

Grade	Description
0	signs or symptoms of root involvement without myelopathy
1	myelopathy, but no difficulty in walking
2	slight difficulty in walking, able to work
3	difficulty in walking but not needing assistance, unable to work full-time
4	able to walk only with assistance or walker
5	chairbound or bedridden

Technical considerations for surgery

Severe OPLL increases the risk of spinal cord injury during neck positioning for intubation, and strong consideration should be given to awake nasotracheal intubation.

An anterior approach is generally favored, although laminectomy may be acceptable. SSEP monitoring has been recommended by some[463]. Distraction should be avoided until the spinal cord has been decompressed from the OPLL.

Some authors advocate complete removal of bone from the dura, while others feel it is permissible to leave a thin rim of bone adherent to the dura. Care must be taken in removing bone because it tends to blend imperceptibly with dura and the next thing one may see is bare spinal cord.

Depending on the distance of vertical involvement, vertebral corpectomy with strut grafting may be required. Internal plate fixation is often used as an adjunct. Post-operative immobilization for at least 3 months is employed with rigid collars for single level ACDF or 1-2 level corpectomies, or halo-vest traction for corpectomies > 2 levels.

Results with surgery

The incidence of pseudarthrosis after vertebral corpectomy and strut graft ranges from 5-10% and increases with the number of levels fused.

In one series there was a 10% incidence of transient worsening of neurologic function following anterior surgery[464] which may have been related to distraction.

The risk of dural tear with CSF leak following an anterior approach depends on the aggressiveness with which bone is removed from the dura, and ranges ≈ 16-25%.

Other risks of anterior approaches (see *ACDF complications*, page 465) also pertain.

18.11. Ossification of the anterior longitudinal ligament (OALL)

OALL of the cervical spine and/or hypertrophic anterior cervical osteophytes may produce dramatic radiographic findings and minimal clinical symptoms. Distinct from Forestier's disease (*see below*). Cervical involvement may produce dysphagia[467].

18.12. Diffuse idiopathic skeletal hyperostosis

Key concepts:

> • usually asymptomatic, but may present with globus
> • W/U: ✔ speech therapy consult for dysphagia evaluation (usually includes ✔ modified barium swallow), ✔ CT of cervical spine, ✔ ± digital video esophagoscopy

AKA "**DISH**", AKA spondylitis ossificans ligamentosa, AKA ankylosing hyperostosis, among others. A condition characterized by flowing osteophytic formation of the spine in the absence of degenerative, traumatic, or post-infectious changes. Affects Caucasians and males more commonly, and usually seen in patients in their mid 60s.

97% of cases occur in the thoracic spine, also in the lumbar spine in 90%, cervical spine in 78%, and all three segments in 70%. Sacroiliac joints are spared (unlike anky-losing spondylitis **(AS)**, *see page 502*). As with AS, unfused levels may be very unstable.

Usually does not produce clinical symptoms. Patients may have early morning stiffness and mild limitations of activities. Cervical involvement may present with dysphagia or **globus** (globus pharyngis: a sensation of a lump in the throat) due to compression of the esophagus between the osteophytes and the rigid laryngeal structures[468] (part of Forestier's disease[469]).

Plain x-rays and CT scan demonstrates the pathology. In cases of dysphagia, evaluation should include speech therapy consult for dysphagia evaluation, modified barium swallow to help localize the site of obstruction, and DVE (digital video esophagoscopy) to rule-out intrinsic esophageal disease.

Treatment: Cases that do not respond satisfactorily to dietary modifications in patients who are losing weight or are having recurrent episodes of choking or pneumonia should be considered for surgery. An anterior cervical approach, and utilization of a high-speed drill with careful protection of soft-tissue structures (esophagus, carotid sheath) without need for discectomy nor spine stabilization has been recommended[468]. Patients need to be made aware that post-op they are likely to be worse initially (from manipulation of esophagus and possibly disruption of some of the autonomic innervation of the esophagus) and will probably need a gastrostomy feeding tube. By 1 year post-op there may be some improvement.

18.13. Scheuermann's kyphosis

AKA Scheuermann juvenile kyphosis or kyphoscoliosis AKA Scheuermann disease AKA juvenile osteochondrosis of the spine.

Definition: anterior wedging of at least 5° of ≥ 3 adjacent thoracic vertebral bodies.

Other findings include: Schmorl nodes (*see page 455*) and endplate narrowing.

Presentation

Adolescents: often present as a result of the cosmetic deformity associated

with progressive kyphosis which may be mistaken for “slouching”.

Adults: often present with pain.

Radiographic findings

Anterior wedge deformities at multiple levels. End plate irregularities and Schmorl’s nodes.

Treatment

Bracing may be used in adolescents.

Adults presenting with pain often respond to nonsurgical treatment including: physical therapy and NSAIDs.

Surgical indications: refractory pain, progressive kyphosis, or neurologic deficit.

18.14. Spinal vascular malformations

Often also referred to by the term spinal AVMs which technically refers to a subset of spinal vascular malformations **(SVMs)**. Incidence of SVM is about 4% of primary intraspinal masses. 80% occur between age 20 and 60 years[470] (p 1850-3).

Classification

Classification is evolving (see review by Black[471]). 3 current era systems:

The “American/English/French Connection[A] classification

References for classification: include[472-479]

- Type I: **dural AVM** AKA AV-fistula **(AVF)**. The most common type (80%) of SVM in the adult[480]. Fed by radicular artery which forms an AV shunt (fistula) at the dural root sleeve (located in the intervertebral foramen)[477], drains into an engorged spinal vein on posterior cord. Usually in lumbar or lower thoracic spine. Slow flow. High pressure in draining vein may cause venous congestion of the cord. Cord involvement may be distant to the

fistula. Symptoms: LBP and progressive myeloradiculopathy or cauda equina syndrome (due to venous congestion) with urinary retention usually in middle-aged patients, 90% males. Up to 35% have pain. 15-20% are associated with other AVMs (cutaneous or other). Rarely bleed

- Type IA: single arterial feeder
- Type IB: two or more arterial feeders

• intradural AVMs (high flow): 75% present with acute onset of symptoms, usually from hemorrhage (SAH or intramedullary)

- Type II: AKA **spinal glomus AVM**. Intramedullary. True AVM of the spinal cord. 15-20% of all SVMs. Compact nidus fed by medullary arteries with the AV shunt contained at least partially within the spinal cord or pia. May be associated with feeding artery aneurysms. Worse prognosis than dural AVM[477]. Fed by 1, or at most 2-3 feeders 80% of the time
- Type III: AKA **juvenile spinal AVM**. Essentially an enlarged glomus AVM which occupies the entire cross-section of the cord and invades the vertebral body which may cause scoliosis
- Type IV[476]: intradural **perimedullary AVM** (also called arteriovenous *fistulae* - **(AVF)**). Direct fistula between artery supplying spinal cord (usually anterior spinal artery, often artery of Adamkiewicz) and draining veins. Typically occur in younger patients than Type I, and may present catastrophically with hemorrhage into the subarachnoid space[481]. *Table 18-36* shows the 3 subtypes[478].

• miscellaneous spinal vascular lesions:

- spinal cord cavernomas
- spinal cord venous angiomas: extremely rare. Difficult to visualize angiographically
- vertebral body hemangiomas (*see* *page 738*)

A. this descriptive label was coined by Black[471]

Table 18-36 Merland's subclassification of Type IV (perimedullary) AV fistulas*

Sub-type	Arterial Supply	AVF	Venous Drainage
I	single (thin ASA)	single, small	slowly ascending perimedullary venous system
II	multiple (dilated ASA & PSA)	multiple, medium	
III		single, giant	giant venous ectasia, rapid metameric venous drainage

* AVF = arteriovenous fistula; ASA = anterior spinal artery; PSA = posterior spinal artery

Hôpital Bicêtre classification[482]

A. AVMs
B. fistulae: micro- or macrofistulae
C. genetic classification of spinal cord AV shunts
  a. genetic hereditary lesions: macrofistulae and hereditary hemorrhagic telangiectasias
  b. genetic nonhereditary lesions: multiple lesions with metameric or myelomeric associations
  c. single lesions: incomplete associations of categories a or b

Spetzler, et al. classification[483]

(this system reincorporated vascular spinal neoplasms)

1. neoplastic vascular lesions
   A. hemangioblastoma
   B. cavernous malformation
2. spinal aneurysms (rare)
3. arteriovenous lesions
   A. AVFs
      • extradural
      • intradural: dorsal or ventral
   B. AVMs
      • extradural-intradural
      • intradural
      • intramedullary
      • intramedullary-extramedullary
      • conus medullaris

Presentation

85% present as progressive neuro deficit (back pain associated with progressive sensory loss and LE weakness over months to years). Yet, SVMs account for < 5% of lesions presenting as spinal cord "tumors". 10-20% of SVMs present as sudden onset of myelopathy usually in patients < 30 yrs age[484, 485], secondary to hemorrhage (causing SAH, hematomyelia, epidural hematoma, or watershed infarction). **Coup de poignard of Michon** = sudden excruciating back pain with SAH (clinical evidence of SVM).

Foix-Alajouanine syndrome (subacute necrotic myelopathy): acute or subacute neurologic deterioration in a patient with a SVM without evidence of hemorrhage. Presents as spastic → flaccid paraplegia, with ascending sensory level and loss of sphincter control. Initially thought to be due to spontaneous thrombosis of the AVM causing sub-acute necrotizing myelopathy[486] which would be irreversible. However, more recent evidence suggests that the myelopathy may be due to venous hypertension with secondary ischemia, and there may be improvement with treatment[487].

Clinical

Auscultation over spine reveals a bruit in 2-3% of cases. Cutaneous angioma over back is present in 3-25%; valsalva maneuver may enhance the redness of the angioma[485].

Evaluation

Spinal angiography: necessary for treatment planning. Best performed at centers that do this study regularly. For Type I dural AVMs, angiography must encompass all dural feeders of the neuraxis, which includes:

1. ICAs: because of the artery of Bernasconi & Cassinari (*see page 99*)
2. every radicular artery including the artery of Adamkiewicz (*see page 96*)
3. internal iliac arteries: for sacral feeders

MRI: detects some SVMs with greater sensitivity and safety than angiography[488], but is inadequate for treatment planning. 82% show extramedullary flow voids. Variable degree of cord enhancement (from venous congestion or venous infarction). Negative MRI does not rule out diagnosis.

Myelography: classically shows serpiginous intradural filling defects. Generally superseded by MRI. If done, patient should be imaged prone and supine (to avoid missing a dorsal AVM) ✖ Risk of bleeding from puncture of a dilated artery/vein with myelography needle.

Treatment

Type I (dural AVMs): usually require treatment. Usually amenable to endovascular techniques using glue, in which case the proximal vein must be taken as well. If you don't completely eliminate a dural fistula (spinal or intracranial) it will come back!

Type II (spinal glomus AVMs): may be amenable to interventional neuroradiologic procedures including embolization[489], especially type IIA (single feeder). However recurrence may be higher with endovascular treatment than surgery, and surgery is often preferred for Type IIB (≥ 2 feeders).

Surgical strategy: similar to intracranial AVMs except that the parenchyma cannot be retracted, bleeding is rarely life threatening, and arteries of passage must be preserved to avoid devastating deficits. Intraoperative ICG angio is often helpful. The nidus is compact, and the hemosiderin ring around the nidus on MRI often represents a plane that can be exploited.

Type III (juvenile spinal AVMS): the natural history is probably better than the prognosis with any type of treatment.

Type IV (perimedullary fistulae): *see Table 18-37* for suggested management[479].

Table 18-37 Suggested management for Type IV arteriovenous fistulae[479]

Subtype	Diagnosis	Embolization	Surgery
Subtype I	difficult; ? reliability of MRI*; tomomyelography; angiotomomyelography	difficult	easy on filum terminale; difficult on conus medullaris
Subtype II	easy: MRI or myelography	incomplete occlusion	on posterolateral AVFs
Subtype III		effective	difficult, dangerous

* due to inaccuracy, do not delay angiogram to get MRA, etc.

18.15. Spinal meningeal cysts

Spinal meningeal cysts **(SMC)**: diverticula of the meningeal sac, nerve root sheath or arachnoid. May have familial tendency.

Terminology in literature is confusing. One classification system is shown in *Table 18-38*. Previously AKA Tarlov's perineural cysts, spinal arachnoid cysts, and extradural diverticula, pouches or cysts. Only congenital lesions are considered here.

- Type I SMCs above the sacrum usually have a pedicle adjacent to entrance

of dorsal nerve root

- Type II SMCs: formerly called Tarlov's cysts and were differentiated from nerve root diverticula because the former were defined as communicating with subarachnoid space, and the latter not. However, intrathecal contrast CT **(ICCT)** shows both communicate. Often multiple, occur on dorsal roots anywhere, but are most prominent and symptomatic in sacrum
- Type III SMCs: may also be multiple and asymptomatic. More common along posterior subarachnoid space. Attributed to proliferation of arachnoid trabeculae

Table 18-38 Types of spinal meningeal cysts[490]

Type	Description
Type I	extradural meningeal cysts without spinal nerve root fibers
IA	"extradural meningeal/arachnoid cyst"
IB	(occult) "sacral meningocele"
Type II	extradural meningeal cysts with spinal nerve root fibers ("Tarlov's perineural cyst", "spinal nerve root diverticulum")
Type III	spinal intradural meningeal cysts ("intradural arachnoid cyst")

Presentation

May be asymptomatic (i.e. incidental finding). May cause radiculopathy by pressure on adjacent nerve root (may or may not cause symptoms of nerve root from which it actually arises). Symptom complex depends on size of SMC, and proximity to spinal cord and nerve roots.

- Type I SMCs: in thoracic and cervical region, may present with acute myelopathy (spasticity and sensory level); lumbar region → LBP and radiculopathy; sacral region → sphincter disturbance
- Type II SMCs: often asymptomatic, but sacral lesions may → sciatica and/or sphincter disturbance
- Type III SMCs: may also be multiple and asymptomatic; more common along posterior subarachnoid space

Evaluation

MRI to identify the mass, then water-soluble ICCT scan to evaluate communication of cyst with subarachnoid space.

- Type II SMCs: all 18 cases had bony erosion (demonstrated by canal widening,

pedicle erosion, foraminal enlargement, or vertebral body scalloping)
- Type III SMCs: may also cause bony erosion; appear on myelogram as intradural defect, may not appear on ICCT if they communicate with subarachnoid space which causes them to blend with adjacent subarachnoid space

Treatment
- Type I SMCs: close ostium between cyst and subarachnoid space. Above sacrum, can usually be dissected from dura; occasionally fibrous adhesions prevent this
- Type II SMCs: no pedicle, thus either partially resect and oversew cyst wall, or excise cyst and involved nerve root. Simple aspiration is not recommended
- Type III SMCs: excise completely unless dense fibrous adhesions prevent this, in which case marsupialize cyst. Tend to recur if incompletely excised

18.16. Syringomyelia

Key concepts:

> - AKA syrinx. Cystic cavitation of the spinal cord
> - 70% are associated with Chiari I malformation, 10% with basilar invagination. May also be posttraumatic or associated with tumor, infection…
> - symptoms: progressive neurologic deterioration over months to years, usually affecting UE first
> - diameter > 5 mm + associated edema predict a more rapid deterioration
> - preferred treatment is directed at correcting the causative pathophysiology

AKA **syrinx**. Cystic cavitation of the spinal cord. Other terms not precisely defined include: **hydrosyringomyelia**, communicating or noncommunicating syringomyelia.

Syringobulbia: Rostral extension into brainstem (usually medulla). May present with (bilateral) peri-oral tingling and numbness, due to compression of the spinal trigeminal tracts as the fibers decussate.

DISTINGUISHING FROM SIMILAR ENTITIES

1. tumor cyst:
   A. especially with intramedullary spinal cord gliomas. Tumors may secrete fluid, or may cause microcysts that eventually coalesce. Most (but not all) intramedullary tumors will enhance with IV contrast on MRI
   B. tumor cyst fluid is usually highly proteinaceous, syrinx fluid usually has the same MRI characteristics as CSF (NB: true syrinx can occur with tumor)
2. central spinal canal
   A. residual **central spinal canal**: the central canal is present within the spinal cord at birth and normally gradually involutes with age[491]. Persistence of the canal is a normal variant. Characteristic imaging features:
      1. linear or fusiform on sagittal MRI
      2. $\leq$ 2-4 mm in maximal width
      3. may be singular, or there may be several discontinuous regions in the rostral-caudal direction
      4. perfectly round in cross-section and centrally located on axial MRI
      5. if IV contrast is given, there should be no enhancement
   B. simple dilatation of the central canal with ependymal cell lining has some-times been called **hydromyelia**, but this usage is ambiguous

ETIOLOGIES

1. primary syringomyelia: this term is used differently by different authors[492]. Herein, refers to syrinx in the absence of identifiable cause
2. secondary syringomyelia: Most cases are thought to be secondary to partial obstruction of the spinal subarachnoid space[492]. Unanswered question: Why then do patients with varying degrees of degenerative cervical spinal stenosis generally not get syringomyelia?
   A. Chiari I malformation: the most common cause of syrinx (*see page 233*)
   B. postinflammatory
      1. postinfectious
         a. granulomatous meningitides (TB and fungal)
         b. postoperative meningitis, especially after intradural procedure
      2. chemical or other sterile inflammations

a. rarely after SAH
b. after myelography: especially with older agents no longer in use (ophendylate (Pantopaque®))

C. posttraumatic: also *see below*
  1. with severe posttraumatic kyphotic deformity: e.g. with retropulsed bone, scarring…
  2. arachnoid scarring without recognized trauma
  3. severe injury to spinal cord and/or its coverings. Blood may be a contributing factor

  ✖ the older concept of syrinx developing as a coalescence of foci of traumatic hematomyelia has not been borne out

D. postsurgical: has been identified many years after uncomplicated intradural neoplasm removal (e.g. neurofibromas)

E. basilar arachnoiditis:
  1. idiopathic
  2. postinfectious: *see above*

F. basilar impression (with constriction of the foramen magnum, *page 138*)

G. associated with spinal tumors: this is distinct from a tumor cyst

H. associated with disc protrusion:

I. cerebellar ectopia

J. Dandy Walker syndrome

EPIDEMIOLOGY[493]

Prevalence of non-posttraumatic syringomyelia: 8.4 cases/100,000 population. Usually presents between ages 20-50.

Associated clinical syndromes are shown in *Table 18-39*.

Table 18-39 Conditions associated with syringomyelia

Condition	%*
Chiari type 1 malformation	70
basilar invagination	10
intramedullary spinal cord tumors	4

* percent of cases of syringomyelia

PATHOPHYSIOLOGY

Major theories of formation of the cyst:

- hydrodynamic ("water-hammer") theory of Gardner: systolic pulsations are transmitted with each heartbeat from the intracranial cavity to the central canal. Has been essentially disproven using MRI[494]
- Williams' ("craniospinal dissociation") theory: maneuvers that raise CSF pressure (valsalva, coughing…) cause "hydrodissection" through the spinal cord tissue. May be more common in noncommunicating syringomyelia
- Heiss-Oldfield theory: occlusion at the foramen magnum causes CSF pulsations during cardiac systole to be transmitted through the Virchow-Robin spaces which increases the extracellular fluid which coalesce to form a syrinx[493] (i.e. through the cord parenchyma)

CLINICAL

Presentation: highly variable. Usually progresses over months to years, with a more rapid deterioration early that gradually slows[493]. Initially, pain, weakness, atrophy and loss of pain & temperature sensation in the upper extremities (with cervical syrinx) is common. Myelopathy that progresses slowly over years ensues.

Characteristic syndrome

(nonspecific for intramedullary spinal cord pathology):

- sensory loss (similar to central cord syndrome) with a suspended ("cape") dissociated sensory loss (loss of pain and temperature sensation with preserved touch and joint position sense → painless ulcerations from unperceived injuries and/or burns)
- **pain**: commonly cervical and occipital. Dysesthetic pain often occurs in the distribution of the sensory loss[493]
- **weakness**: lower motor neuron weakness of the hand and arm
- painless (neurogenic) arthropathies (**Charcot's joints**) especially in the shoulder & neck due to loss of pain & temperature sensation: seen in < 5%

EVALUATION

Prior to the CT/MRI era, diagnosis relied on myelography or on autopsy.

MRI: defines anatomy in sagittal as well as axial plane. Test of choice. Cervical & thoracic spine and brain MRI (without & with contrast, to include craniocervical junction) should be obtained. Syringomyelic cavities may be complex, with noncommunicating channels (more common with posttraumatic

syrinx).

CT: low attenuation area within cord seen on either plain CT or myelogram/CT (with water soluble contrast).

Myelogram: rarely used alone (usually performed in conjunction with CT). When used alone: often normal (false negative), some → complete block at level of syrinx; iodine contrast studies may show fusiform widening of spinal cord, whereas air contrast studies may show collapse of the cord[495]. Dye may slowly leach into the cyst.

EMG: no characteristic findings, but may be useful to R/O other conditions that may be responsible for symptoms (e.g. peripheral neuropathy causing paresthesias).

MANAGEMENT

For an incidentally discovered syrinx (i.e. asymptomatic and no neurologic deficit) with no identified etiology, if the size remains stable over 2-3 years of observation, F/U studies at 2-3 year intervals can be done if there are no changes in symptoms.

SURGICAL TREATMENT

Intervention is considered for symptomatic lesions (not all are symptomatic). If an underlying cause cannot be determined, it may be very difficult to treat a very small syrinx directly (however, these are unlikely to be causing reversible symptoms).

Options include:

1. current philosophy is to treat the underlying pathophysiology (and to use syrinx draining procedures as second choice when this is not feasible)
   A. posterior decompression: procedure of choice when posterior anomalies (e.g. Chiari malformation) are present
   B. decompression if a different site of compression is identified
2. shunts:
   A. disadvantages:
      1. complication rate: 16%
      2. clinical stabilization rate: 54% at 10 yrs
      3. may produce traction on spinal cord with potential for further injury
      4. prone to obstruction: 50% at 4 years
      5. does not correct underlying pathophysiology and so syrinx may

recur

B. indications: cases of diffuse arachnoiditis (e.g. following tuberculous or chemical meningitis) where the obstruction extends over many levels, and syrinx diameter > 3-4 mm

C. **K** or **T** tube drainage. Choice of distal sites includes:

1. peritoneum[496] (difficult in cervical region)
2. pleural cavity
3. subarachnoid space (e.g. Heyer-Schulte-Pudenz system): requires normal CSF flow in subarachnoid space, therefore cannot use in arachnoiditis

3. percutaneous aspiration of the cyst[497] (may be used repeatedly)
4. ✖ no longer recommended:
   A. plugging the obex with muscle, teflon or other material
   B. opening the subarachnoid space & removing inferior tonsils
   C. syringostomy: usually fails to remain patent, therefore using a stent or a shunt (syringosubarachnoid or syringoperitoneal) is recommended

Technical considerations:

1. intraoperative ultrasound may be helpful for:
   A. localizing the cyst
   B. assessing for septations (to avoid shunting only part of cyst)
2. if Chiari malformation is not present, consider syringosubarachnoid shunt as the initial procedure. If this fails, then syringoperitoneal shunt may be inserted
3. Rhoton suggests performing the myelotomy in the dorsal root entry zone (DREZ), between the lateral and posterior columns (instead of the midline as with a tumor) because this is consistently the thinnest part and there is usually already an upper extremity proprioceptive deficit from the syrinx[123 (p 1317)]. There is ≈ 10% incidence of posterior column dysfunction with shunting
4. with syringosubarachnoid shunts, be sure the distal shunt tip is subarachnoid (and not just subdural) or else it will not function
5. with syringopleural shunt, the pleural opening can be made posteriorly, adjacent to one of the ribs as described for ventriculopleural shunt (*see page 210*)

OUTCOME

Assessing treatment results is difficult due to rarity of the condition, variability of natural history (which may arrest spontaneously), and too short follow-up[498]. Enthusiasm for direct treatment (shunts, fenestration…) is low among neurosurgeons because of the perceived poor response and risk of iatrogenic neurologic worsening.

18.16.1. Posttraumatic syringomyelia

Posttraumatic syringomyelia **(PTSx)** may follow significant spinal trauma (with or without clinical spinal cord injury). Includes penetrating injury or non-penetrating "violent" trauma to the spinal cord (injuries such as post-spinal anesthesia or following thoracic disc herniation are not included).

EPIDEMIOLOGY

Often a late presentation following spinal cord injury, therefore incidence is higher in series with longer follow-up. Incidence increasing with increasing survival following spinal cord injury and with increasing use of MRI. Range: ≈ 0.3-3% of cord injured patients (*see Table 18-40*).

In a large number of patients followed via multicenter cooperative data bank, there were fewer cases of syrinx following cervical injuries than following thoracic injuries[500] (may be artifactual since patients with lower lesions may be more aware of ascending levels).

Table 18-40 Incidence of posttraumatic syringomyelia

Type of injury	No./risk*	Incidence
all spinal cord injury patients	30/951	3.2%
complete quadriplegics	14/177	7.9%
incomplete quadriplegics	4/181	4.5%
complete paraplegics	4/282	1.7%
incomplete paraplegics	4/181	2.2%

* number occurring over number at risk in 951 patients followed for 11 years[499]

Latency following spinal cord injury:

- latency to symptoms: 3 mos to 34 yrs (mean 9 yrs) (earlier in complete cord lesions than incomplete: mean 7.5 vs. 9.9 yrs)
- latency to diagnosis: up to 12 yrs (mean 2.8 yrs) after onset of new symptoms

CLINICAL

The presentation of patients with PTSx is shown in *Table 18-41*. The late appearance of upper extremity symptoms in a paraplegic patient should raise a high index of suspicion of posttraumatic syringomyelia[502].

Hyperhidrosis may be the only feature of descending syringomyelia in patients with complete cord lesions[503]. For the differential diagnosis, see *Delayed deterioration following spinal cord injuries*, page 1000.

EVALUATION

One end of the cavity is often found at a site of spinal column fracture or abnormal angulation.

MANAGEMENT

Many authors advocate early surgical drainage of cyst as a means of reducing increased delayed deficit[504]. Some authors feel that aside from disturbing sensory symptoms, that motor loss was infrequent and therefore conservative management is indicated in most cases[505].

MEDICAL

Managed non-surgically: 31% stable, 68% progressed over yrs (longer F/U in latter).

SURGICAL

There is probably no benefit in operating on a patient with a small syrinx[499].

Surgical options:
As in *Communicating syringomyelia*, with the following differences:
- cord transection (cordectomy)[506]: an option in complete injuries only
- plugging the obex is probably not indicated (controversial in congenital syrinx)

Table 18-41 Presentation (in 30 SCI patients with syrinx[499])

Symptom	Initial	At time of diagnosis
pain*	57%	70%
numbness	27%	40%
increased motor deficit	23%	40%
increased spasticity	10%	23%
	3%	13%

increased sweating (hyperhidrosis)		
autonomic dysreflexia	3%	3%
no symptoms	7%	7%
Signs	**Frequency**	
ascending sensory level	93%	
depressed tendon reflexes	77%	
increased motor deficits	40%	

* pain is often quite severe, and unrelieved with analgesics[501]

OUTCOME

In 9 PTSx patients treated with syringosubarachnoid shunt[499]: pain relieved in all 9 (1 only slightly), motor recovery in 5/8, improved tendon reflex in 1/10. Some post-op complications in 9 patients included: 1 incomplete lesion became complete, 1 sensorimotor deterioration, transient pain in 3.

Most results are good for radicular symptoms, with dubious efficacy for autonomic symptoms or spasticity.

18.17. Spinal cord herniation (idiopathic)

Rare. Spinal cord herniates though a defect in the dura usually located anteriorly or anterolaterally between T2-8507. Bone erosion anterior to the dural defect may occasionally be seen. Frequently associated with a calcified disc fragment which theoretically may have gradually eroded through the dura.

Main DDx is with dorsal arachnoid cyst (*see page 1186*). Both result in increased subarachnoid space posterior to the cord, and a ventral kinking of the spinal cord. Contiguous CSF pulsation artifact on MRI can be seen with cord herniation, whereas an arachnoid cyst tends to interrupt this.

Commonly presents as an incomplete Brown-Séquard syndrome (with relative sparing of posterior columns). Symptoms may be due to distortion of the spinal cord, but vascular injury may also play a role.

Surgery

Requires a posterolateral or anterolateral approach to minimize spinal cord manipulation (*see page 471*). The dural defect is widened which usually results

in reduction of the spinal cord herniation. A sling of dural substitute can then be slid anterior to the cord to prevent reherniation.

18.18. Spinal epidural hematoma

Rare. Over 200 cases of varying etiology have been reported[508], although one third of recent cases have been associated with anticoagulation therapy[509]. NSAIDs may also be a risk factor[510]. Etiologies include:

1. traumatic: including following LP or epidural anesthesia[508, 511-513], fracture (*see below*), spinal surgery[162] or chiropractic manipulation[514]. Occurs predominantly in patient who is: anticoagulated[515], thrombocytopenic, or has bleeding diathesis or a vascular lesion
2. spontaneous[516]: rare. Etiologies: hemorrhage from spinal cord AVM (*see page 507*), from vertebral hemangioma (*see page 738*) or tumor

May occur at any level of the spine, however, thoracic is most common. Most often located posterior to spinal cord (except for hematomas following anterior cervical procedures), facilitating removal via laminectomy[509].

Traumatic spinal epidural hematoma (TSEH) associated with spine fracture:

In one series[517], among 74 trauma patients who underwent emergent spinal MRI, ≈ half of the patients with spine fractures also had TSEH. Treatment was based solely on the fracture, and the outcome in patients with neurologic deficits was no worse in the group with TSEH than in the group without.

Presentation

The clinical picture of spontaneous spinal epidural hematoma is fairly consistent but nonspecific. Usually starts with severe back pain with radicular component. It may occasionally follow minor straining, and is less commonly preceded by major straining or back trauma. Spinal neurologic deficits follow, usually progressing over hours, occasionally over days. Motor weakness may go unnoticed when patients are bedridden with pain.

Treatment

Recovery of neurologic deficit without surgery is rare[510], therefore optimal treatment is immediate decompressive laminectomy in those patients who can tolerate surgery[509]. In one series, most patients who recovered underwent decompression within 72 hrs of onset of symptoms[518]. In another, decompression within 6 hours was associated with better outcome[162].

High-risk patients: for medically high-risk patients (e.g. acute MI) on anticoagulation, surgical mortality and morbidity is extremely high, and this must be considered when making the decision of whether or not to operate. In patients not operated, anticoagulants should be stopped, and reversed if possible (see *Correction of coagulopathies or reversal of anticoagulants*, page 40). Consider use of high dose methylprednisolone to minimize cord injury (see *Methylprednisolone*, page 936 under spinal cord injury). Percutaneous needle aspiration may be a consideration in high-risk patients.

18.19. Spinal subdural hematoma

Rare. May be posttraumatic (including iatrogenic causes) or may occur spontaneously. Spinal subdural hematomas **(SSH)** that occur spontaneously or following lumbar puncture usually occur in patients with coagulopathies (primary or iatrogenic)[519].

Conservative treatment is possible in nontraumatic SSHs with minimal neurologic impairment[519].

18.20. Spinal epidural lipomatosis (SEL)

Hypertrophy of epidural fat, due to prolonged exogenous steroid therapy in most (75%) cases[520] (usually moderate to high dosage for years[521]), but may also be associated with: Cushing’s disease, Cushing’s syndrome, obesity[522], hypothyroidism or may be idiopathic[523]. Male:female = 3:1521.

Back pain usually precedes all other symptoms. Progressive LE weakness and sensory changes are common. Sphincter disturbance occurs but is rare. SEL is most common in the thoracic spine (≈ 60% of cases), the rest are in the lumbar spine (no cases reported in cervical spine).

Evaluation

CT: density of adipose tissue is extremely low (-80 to -120 Hounsfield units)[524] which distinguishes SEL from most other lesions (except lipoma).

MRI: signal follows fat (high signal on T1WI, intermediate on T2WI). Suggested diagnostic criteria: epidural adipose should be **> 7 mm** thick to be considered SEL[522, 525].

Treatment

In those patients who can be weaned off steroids and lose weight, surgery may be avoided in some cases[526]. If SEL is related to obesity, weight loss alone can be successful.

Surgery is indicated for symptomatic patients in whom the above interventions are unsuccessful or not feasible. An effort to normalize cortisol levels in those with endogenous hypercortisolism (Cushing's disease…) should be made before laminectomy is performed. Due to potential complications and slow growth of the tissue, the decision to operate surgery should made with caution.

Surgery usually consists of laminectomy with removal of adipose tissue. Occasionally repeat surgery is needed for reaccumulation of adipose tissue.

Outcome

Surgery usually results in significant improvement[525]. Idiopathic cases may fare better than those due to steroid excess. Cauda equina compression responds better than thoracic myelopathy.

Complications rates may be higher than expected in part due to medical comorbidities. Fessler et al.[527] reported 22% 1-year mortality.

18.21. Coccydynia

Pain and tenderness around the coccyx. A symptom, not a diagnosis. Typically, discomfort is experienced on sitting or on rising from sitting. More common in females, possibly due to a more prominent coccyx. The condition is unusual enough in males that in the absence of trauma, strong consideration should be given to an underlying condition.

Etiologies

For differential diagnosis, see *Acute low back pain*, page 1192. Better accepted etiologies include[528]:

1. local trauma (may be associated with fracture or dislocation):
   A. 25% of patients give a history of a fall
   B. 12% had repetitive trauma (rowing machine, prolonged bicycle riding…)
   C. 12% started with parturition
   D. 5% started following a surgical procedure (half of which were in the lithotomy position)
2. idiopathic: excluding traumatic cases, no etiology can be identified in most cases
3. neoplasms
   A. chordoma
   B. giant cell tumor
   C. intradural schwannoma
   D. perineural cyst
   E. intra-osseous lipoma
   F. carcinoma of the rectum
   G. sacral hemangioma[529]
   H. pelvic metastases (e.g. from prostate cancer)
4. prostatitis

Controversial etiologies include[528, 530]:

1. local pressure over a prominent coccyx
2. referred pain:
   A. spinal disease
      1. herniated lumbosacral disc
      2. cauda equina syndrome
      3. arachnoiditis
   B. pelvic/visceral disease
      1. pelvic inflammatory disease (PID)
      2. perirectal abscess
      3. perirectal fistula
      4. pilonidal cyst
3. inflammation of the various ligaments attached to the coccyx
4. neurosis or frank hysteria

Histological evaluation of the coccyx has not helped delineate the cause, even though avascular necrosis has been suggested[531].

Evaluation

Sacrococcygeal films are often performed to rule-out a bony destructive lesion. Often, the question of a fracture will be raised, and many times cannot be definitely ruled-in or out based on this study. There may or may not be any significance of such a fracture.

Nuclear bone scans were not helpful in 50 patients with coccydynia[528].

CT scan: no consistent findings.

Treatment

Most cases resolve within ≈ 3 months of **conservative management** consisting of NSAIDs, mild analgesics, and measures to reduce pressure on the coccyx (e.g. a rubber ring ("doughnut") sitting cushion, lumbar supports to maintain sitting lumbar lordosis to shift weight from coccyx to posterior thighs)[532].

Recurrence: Occurs in ≈ 20% of conservatively treated cases, usually within the first year. Repeat therapy was often successful in providing permanent relief. More aggressive treatment may be considered for refractory cases.

Management recommendations for refractory cases[528, 532]:

1. local injection: 60% respond to corticosteroid + local anesthetic (40 mg Depo-Medrol® in 10 cc of 0.25% bipuvicaine). Recommended as initial treatment; response should be achieved by 2 injections
2. manipulation of the coccyx: usually under general anesthesia. ≈ 85% successful when combined with local injection
3. ± physiotherapy (diathermy & ultrasound): found to be of benefit only in ≈ 16%
4. caudal epidural steroid injection
5. blockade or neurolysis (with chemicals or by cryoablation[533]) of the ganglion impar (AKA ganglion of Walther, the lowest ganglion of the paired paravertebral sympathetic chain, located just anterior to the sacrococcygeal junction): some success has been described with this technique (traditionally used for intractable sympathetic perineal pain of neoplastic etiology[534])

6. neurolytic techniques directed to S4, S5 and coccygeal nerves
7. coccygectomy (surgical removal of the mobile portion of the coccyx, followed by smoothening of the residual bony prominence on the sacrum): was required in ≈ 20% of patients in one series[528], with a reported success rate of 90%. However, many practitioners do not view this as a highly effective treatment and feel that great restraint should be used in considering this form of therapy

NOTES

19. Functional neurosurgery

For functional neurosurgery related to pain, see *Pain procedures*, page 567.

19.1. Deep brain stimulation

This section covers issues related to deep brain stimulation **(DBS)** in general. For specific conditions, refer to that section. A variety of conditions may be treated including:

1. movement disorders
   A. Parkinson's disease: STN stimulation may be superior to best medical management[1, 2] because of similar efficacy to levodopa with fewer side effects (primarily dyskinesias) (*see below*)
   B. dystonia: *see page 536*
   C. tremor: *see page 545*
2. epilepsy: *see page 422*
3. pain: response is variable, typically only 25-60% respond (*see page 574*)
4. potential uses
   A. psychiatric disorders: mainly
      1. Tourette syndrome: thalamic & pallidal DBS (case reports[3, 4])
      2. obsessive compulsive disorders: anterior capsule and STN stimulation[5] and, recently, targets more posterior and rostral[6]
      3. depression: subgenual cingulate gyrus[7] and anterior capsule stimulation[8]
   B. obesity[9]
   C. drug addiction[10]
   D. hypertension (case report of lowering BP in a patient who was being treated for pain[11])

Typical targets used in functional brain surgery

Figure 19-1 depicts relationships of typical targets to other structures and

effects of DBS (or lesioning). This figure is intended for illustrative purposes only, and is not presented for purposes of performing surgical procedures.

19.2. Surgical treatment of Parkinson's disease

Historical background

An early procedure was ligation of the anterior choroidal artery. Due to variability in distribution, destruction often extended beyond the desired confines of the pallidum and the results were too unpredictable (*see page 1028*). Anterodorsal pallidotomy became an accepted procedure in the 1950's, but long-term improvement was mainly in rigidity, while tremor and bradykinesia did not improve[12]. The ventrolateral thalamus subsequently became the preferred target. Lesions there were most effective in diminishing tremor. In actuality, the tremor was often not the most debilitating symptom, particularly since it is a resting tremor at first (it may become more pervasive later). Bradykinesia and rigidity were frequently more problematic. Furthermore, the procedure only reduces tremor in the contralateral half of the body, and bilateral thalamotomies were not recommended due to an unacceptably high risk of post-op dysarthria and gait disturbance. Use of thalamotomy fell off dramatically in the late 1960's with the introduction of Ldopa[13].

However, at some point most patients will experience problematic side effects and/or resistance to treatment with antiparkinsonian drugs. Tissue transplantation (e.g. with adrenal medullary tissue) appears to have only modest benefits (*see below*). Lesioning or stimulation techniques have therefore gained in popularity with renewed interest in the posteroventral pallidum as the target.

19.2.1. Tissue transplantation

Tissue transplantation for Parkinson's disease is generally limited to research centers. The present status of implantation of fetal dopaminergic brain cells into Parkinson's disease patients is that it may reduce the severity of the illness and increase the effectiveness of levodopa[14]. For ethical reasons, this procedure is rarely performed in the U.S.

Other transplanted tissues include cells from the patients own adrenal medulla. After initial enthusiastic results[15], later studies failed to corroborate the dramatic outcomes, and benefits appear to be modest[16-18].

A double-blinded, randomized, placebo-controlled trial[19] of 34 subjects with severe PD noted initial improvement at 6 and 9 months, but found no efficacy 2 years after fetal mesencephalic cell transplantation. Of note: immunosuppression was only used for six months. Further research is ongoing[20].

19.2.2. Ablative surgery & electrical stimulation

Ablative surgery is giving way to less destructive beep brain stimulation.

PALLIDOTOMY[21,22]

Pallidotomy may work by one of the following mechanisms: directly destroying portions of the internal segment of the globus pallidus internus **(GPi)**, interrupting pallid-ofugal pathways, or diminishing inputs to the medial pallidum (especially from the subthalamic nucleus) (see *Pathophysiology*, page 59). Although early methodologies included stereotactic radiosurgery[23], modern techniques (excluding very select cases) rely primarily on radiofrequency or cryoprobe lesioning after confirming target location by electrical stimulation.

Electrical stimulation: Deep brain stimulation **(DBS)** in the area of the GPi[24] and subthalamic nucleus **(STN)** can also relieve parkinsonian symptoms[25] without irreversibly destroying tissue. A randomized study showed similar efficacy between thalamotomy and DBS, but fewer side-effects with DBS[26]. A more recent target of interest for DBS is the pedunculopontine nucleus **(PPN)**.

Indications

1. patients refractory to medical therapy (including multiple agents). However, some investigators feel the response to surgery might be better if done early
2. primary indication (based on an opinion survey[27]): patients with levodopa-induced dyskinesias (especially those with associated painful muscle spasms). Initial results indicate that these are very responsive to pallidotomy
3. gait and postural instability[28] as well as falls and freezing[A29] may respond to DBS of the pedunculopontine nucleus **(PPN)**
4. patients primarily with rigidity or bradykinesia (unilateral or bilateral), on-off fluctuations or dystonia. Tremor may be present, but if it is the predominant symptom, then using the ventralis intermedius **(VIM)** nucleus of the thalamus as the target (for ablation (thalamotomy) or stimulation)[30] is a better procedure. VIM stimulation is also used to treat essential tremor[31]

A. non-human primate data

Contraindications

1. patients with significant dementia: further cognitive impairment has been noted primarily in patients with cognitive deficits prior to treatment
2. patients with risk of intracerebral hemorrhage: those with coagulopathy, poorly controlled hypertension, those on anti-platelet drugs that cannot be withheld (may consider stereotactic radiosurgery lesions for these rare patients)
3. patients with ipsilateral hemianopsia: due to the risk of post-op contralateral hemianopsia from optic tract injury which would make the

patient blind
4. age ≥ 85 yrs
5. patients with secondary Parkinsonism (*see page 60* for more details) i.e. <u>not</u> idiopathic Parkinson's disease: respond poorly, presumably due to different patho-physiology. Look for:
   A. signs of autonomic nervous system dysfunction (suggests Shy-Drager)
   B. EOM abnormalities (may occur in progressive supranuclear palsy **(PSNP)**)
   C. long-tract signs
   D. cerebellar findings (as in olivo-ponto-cerebellar atrophy **(OPCA)**)
   E. failure to improve with levodopa
   F. MRI: lacunar infarcts in basal ganglia (as in arteriosclerotic Parkinsonism), or tumor in region of substantia nigra
   G. PET scanning (if available): decreased striatal metabolism detected by deoxyglucose PET scan (suggests striato-nigral degeneration **(SND)**)

TECHNIQUE

Antiparkinsonian medications are withheld the morning of the procedure to bring out symptoms. A stereotactic frame is applied under local anesthetic parallel to the orbitomeatal line (which aligns with the anterior-posterior commissural **(AC-PC)** line).

Radiologic target localization

May utilize: MRI, CT, and/or ventriculography. MRI is the most common imaging modality, and may best demonstrate the desired anatomy, but is susceptible to geometric distortion. Therefore many centers also utilize CT and/or ventriculography to supplement MRI. T1WI images are commonly employed, however some feel that optimal MRI imaging may be performed with gadolinium-enhanced axial and coronal projections using 1 mm slice intervals and a STIR or spoiled GRASS volume acquisition protocol.

The posterior commissure is the white-matter band at the level of the pineal that crosses at the posterior third ventricle.

The typical initial target[27] is shown in *Table 19-1*. Avoid encroachment on internal capsule (medial to GPi) and optic tract (inferior to GPi). Lesions of the subthalamic nucleus are associated with hemiballismus. An entry site is chosen from imaging studies, and is usually just anterior to the coronal suture and 15-20 mm lateral to the midline. A 4 mm twist drill hole is used. The trajectory should

avoid midline venous structures, arterioles within sulci (therefore enter through a gyrus), and passage through the lateral ventricle.

Table 19-1 Target for pallidotomy

1. 1-3 mm anterior to the mid-point of the AC-PC line	**MEDIAN**
	2 mm
2. 18-23 mm lateral*	**21 mm**
3. 2-6 mm inferior	**5 mm**

* may be decreased in women (start at ≈ 19 mm), or increased when the 3rd ventricle is dilated

Electrophysiologic target localization

Stimulation:

The patient must be awake for the procedure. For patients with dyskinesias that occur only following a dose of medication, their normal dose of medicine is given after imaging to bring out the symptoms for the procedure. Stimulation is required to verify the neurophysiologic target which varies between individuals. Macroelectrode stimulation may be done with the lesioning electrode. Impedance typically drops when a white matter tract is encountered. The impedance of the desired target is usually > 600 Ω. Stimulate with square wave at 1, 5, 50 and 100 Hz with voltage range of 0.5-3 volts (NB: above ≈ 2 V you may be seeing wide-field stimulation). Pallidum stimulation usually increases (but occasionally decreases) contralateral muscle tone. Also look for reduction of tremor or dyskinesia. Contralateral weakness or hypotonia indicates proximity to the internal capsule. Visual scotomata suggests stimulation of the optic tract.

Micro-electrode recording:

About half the institutions surveyed perform microelectrode recording, and half the remaining centers were considering starting it.

Lesioning

Kondziolka et al.[22] use a 1.1 mm diameter probe with a 3 mm exposed tip. A small lesion is made at 45°C for 30 seconds, before making the definitive lesion at 70-80°C for 60 seconds. The probe is withdrawn 3-4 mm and a second lesion is made. Lesions with cryoprobes may be associated with a higher incidence of intracerebral hemorrhage.

For the very rare patient in whom insertion of an electrode is contraindicated

(e.g. refractory coagulopathy), lesioning may be done with stereotactic radiosurgery, however, this eliminates the critical ability to verify the site of the planned lesion electrophysio-logically before a permanent lesion is made.

Unilateral pallidotomy produces primarily contralateral effects, although some ipsilateral changes occur. Bilateral procedures are usually staged separately with a 3-12 hiatus between sides. Although they can been done in one sitting, bilateral pallidotomies may carry an increased risk of speech difficulties and cognitive decline.

Results

At present, the major focus of therapy has been on improvement of *motor* symptoms. Although 97% of patients showed at least some improvement (some poor results may derive from inclusion of some patients with secondary Parkinsonism), in 17% the degree of improvement was graded as mild.

Significant reduction of levodopa induced dyskinesias occurred in 90%. Bradykinesia improved in 85%, rigidity in 75%, and tremor in 57%. Other areas of improvement include: speech, gait, posture, and reduction of on-off phenomenon and freezing. Although symptoms may be ameliorated, overall functional improvement may not be remarkable[32].

Although dosages of antiparkinsonian medication are often reduced, continued medical therapy is usually required, and no change is made for at least 2 months following pallidotomy.

Indications are that beneficial surgical effects can last ≥ 5 years, with early failures possibly due to production of too small of a lesion, and late failures possibly due to progression of the disease.

Ongoing studies are investigating longer term results, microelectrode recording, alternate lesioning targets, the role of early surgery… Until more information is available, one cannot make any statements about the optimal target, localizing method, etc.

Complications

Visual field deficit occurs in 2.5% due to proximity of the optic tract to the globus pallidus. Hemiparesis may occur due to the nearby passage of the internal capsule. Intracerebral hemorrhage may also occur. Dysarthria occurs in ≈ 8%, but is usually temporary. Speech difficulties and also cognitive decline may be more risky when bilateral pallidotomies are performed at the same sitting.

THALAMIC LESIONS

Lesioning the thalamic ventralis intermedius nucleus **(VIM)** nucleus reduces Parkinsonian tremor in > 85%. It can also be useful in the treatment of rigidity and drug induced dyskinesias by extending the lesioning anteriorly to include the ventral oralis. However thalamotomy does not improve symptoms of akinesia or bradykinesia and can result in worsening of gait symptoms or speech problems.

SUBTHALAMOTOMY

Lesioning the subthalamic nucleus **(STN)** is classically associated with intractable hemiballism. There are few studies as a result, but the limited data suggests that selective lesioning in this region provides relief on par with pallidotomy. Postoperative hemichorea is a known complication but is generally transitory and mild[33]. DBS in this region may be a better option (*see page 532*).

19.3. Dystonia

Pallidal stimulation is the primary *surgical* treatment for dystonia[34]. Response is better for primary dystonias, e.g. tardive dystonias than for secondary dystonias such as postanoxic, postencephalitic, perinatal and poststroke dystonias[34] (other targets need to be assessed).

For primary dystonias, the globus pallidus internus **(GPi)** is the most common primary target (see *Figure 19-1*, page 533). Good results have also been reported with STN DBS.

19.4. Spasticity

Results from lesions in upper motor neuron pathway, causing absence of inhibitory influence on alpha motor-neurons **(αMN)** (alpha spasticity) as well as on gamma motor neurons (intrafusal fibers) (gamma spasticity). Causes uninhibited reflex arc between αMN and Ia afferents from muscle spindles resulting in a hypertonic state of muscles with clonus, and sometimes with involuntary movements. Etiologies include: injury to cerebrum (e.g. stroke) or spinal cord (spasticity is an expected sequelae of spinal cord injury rostral to the conus medullaris), multiple sclerosis, and congenital abnormalities (e.g. cerebral palsy, spinal dysraphism).

CLINICAL

Increased resistance to passive movement, hyperactive muscle stretch reflexes, simultaneous activation of antagonistic muscle groups, may occur spontaneously or in response to minimal stimuli. Characteristic postures include scissoring of legs or hyperflexion of thighs. May be painful, or may disrupt patient's ability to sit in wheel-chair, lay in bed, drive modified vehicles, sleep, etc. May also promote development of decubitus ulcers. A spastic bladder will have low capacity and will empty spontaneously.

Spasticity is often exacerbated by same type of stimuli that aggravate autonomic hyperreflexia (see *Autonomic hyperreflexia*, page 1000).

The onset of spasticity following spinal cord injury may be delayed for several days to months (the latency period is attributed to "**spinal shock**", during which time there is decreased tone and reflexes)[35] (*see page 930*). Onset of spasticity following spinal shock starts with increasing flexor synergistic activity over 3-6 mos, with more gradual increases of extensor synergy which ultimately predominates in most cases.

Some "beneficial" aspects of mild spasticity:

1. maintains muscle tone and therefore bulk: provides support for patient when sitting in wheelchair, helps prevent decubitus ulcers over bony prominences
2. muscle contractions may help prevent DVTs
3. may be useful in bracing

Grading spasticity

Assessment should be performed with patient supine and relaxed. The Ashworth scale (*see Table 19-2*) is commonly used for the clinical grading of the severity of spasticity. Many attempts have been made to quantitate spasticity electrodiagnostically, the most reliable has been H-reflex measurement.

Table 19-2 Ashworth scores[36]

Ashworth score	Degree of muscle tone
1	no increase in tone (normal)
2	slight increase, a "catch" with flexion or extension
3	more marked increase, passive movements easy
4	considerable increase, passive movements difficult
5	affected part rigid in flexion or extension

TREATMENT

Depends on extent of useful function (or potential for same) present in areas at and below the level where spasticity starts (complete spinal cord injuries usually have little function, whereas patients with MS may have significant function).

MEDICAL TREATMENT

1. "prevention": measures to decrease inciting stimuli (physical therapy to prevent joint damage, good skin & bladder care… see *Autonomic hyperreflexia*, page 1000)
2. prolonged stretching (more than just range of motion): not only prevents joint and muscle contractures, but modulates spasticity
3. oral medications[37] (see *Surgical treatment* below for intrathecal medications): few drugs are effective without significant undesirable side effects
   A. diazepam (Valium®): activates $GABA_A$ receptors, increases pre-synaptic inhibition of αMN. Most useful in patients with complete spinal cord injuries. ***Rx*** start with 2 mg PO BID-TID, increase by 2 mg per day q 3 days up to a max of 20 mg TID.

      SIDE EFFECTS: may cause sedation, weakness, decreased stamina (most of which may be minimized by gradual increases in dosage). Abrupt discontinuation may cause depression, seizures, withdrawal syndrome

   B. baclofen (Lioresal®): activates presynaptic $GABA_B$ receptors of Ia muscle spindle afferents, causes pre-synaptic inhibition of αMN and decreases nociception. May be most useful in patients with spinal cord lesions (complete or incomplete).

      Rx start with 5 mg PO BID-TID, increase in 5 mg increments q 3 days up to max of 20 mg QID. **SIDE EFFECTS:** sedation, lowers seizure threshold. Must be tapered to discontinue (abrupt discontinuation may result in seizures, rebound hyperspasticity or hallucinations).

   C. dantrolene (Dantrium®): reduces depolarization induced Ca^{++} influx into sarcoplasmic reticulum of skeletal muscle; acts on all skeletal muscle (with no preferential effect on spasmogenic reflex arc).

      Rx start with 25 mg PO q d, increase q 4-7 days to BID, TID, then QID, then by 25 mg per day up to max of ≈ 100 mg QID (may take 1 week at new steady state to see effect); **SIDE EFFECTS:** muscle

weakness (may make ambulation impossible), sedation, idiosyncratic hepatitis (may be fatal; more common in patients on > 300 mg/d x > 2 mos) that is often preceded by anorexia, abdominal pain, N/V; D/C if no benefit is seen by ≈ 45 days; follow LFTs (SGPT or SGOT)

D. progabide: activates both $GABA_A$ and $GABA_B$ receptors. Useful for patients with severe flexor spasms

E. theoretical benefits may be derived from other agents, but they have not been used for some practical reason in each case 35 (e.g. phenothiazines reduce gamma spasticity, but only at high PO doses or parenterally; clonidine; Darvon; tetrahydrocannabinal…)

Surgical treatment

Reserved for spasticity refractory to medical treatment, or where side effects of medications are intolerable. Generally either orthopedic (e.g. tendon release operations (tenotomies) of heel cord or hamstrings, iliopsoas myotomies, etc.) or neurosurgical (e.g. nerve blocks, neurectomies, myelotomy, etc.).

1. nonablative procedures
   - A. intrathecal **(IT)** baclofen (*see below*)
   - B. intrathecal morphine (tolerance and dependence may develop)
   - C. electrical stimulation via percutaneously placed epidural electrodes[38]
2. ablative procedures, with <u>preservation</u> of potential for ambulation
   - A. motor point block[35] (intramuscular phenol neurolysis): preserves sensation and existing voluntary function. Especially useful in patients with incomplete myelopathies; time consuming
   - B. phenol nerve block: similar to motor point block, but used when spasticity more severe and complete block of muscle desired. Open phenol block used instead of percutaneous when nerve is mixed and sensory preservation is desired (also reduces post-block dysesthesias)[39]
   - C. selective neurectomies[35]
     1. sciatic neurectomy (may be done with RF lesion)[40]
     2. obturator neurectomy: useful if strong hip adductor spasticity that causes scissoring and wasted energy expenditure in ambulating
     3. pudendal neurectomy: useful if excessive detrusor dyssynergy interferes with bladder retraining
   - D. percutaneous radiofrequency foraminal rhizotomy: small unmyelinated sensory fibers are more sensitive to RF lesions than

larger myelinated A-alpha fibers of motor units.

Technique: start at S1 on one side, and work up to T12, then repeat on other side. At each level: verify needle position by stimulating with 0.1-0.5 V and watch for movement in appropriate myotome (tip should be extradural, avoid subarachnoid placement), ablate with 70-80° C **x** 2 mins for S1, and 70° C x 2 mins for L5 to T12 (to preserve motor function). If symptoms recur, may repeat with lesions at 90° C x 2 mins

E. myelotomies[41]
   1. Bischof's myelotomy: divides anterior and posterior horns via laterally placed incision, disrupts reflex arc. No effect on α–spasticity
   2. midline "T" myelotomy: interrupts reflex arc from sensory to motor units without disrupting connections from corticospinal tract to anterior motor neurons. Slightly higher risk of losing motor function. *Technique*: laminectomy from T11 to L1. Mobilize midline dorsal longitudinal vein and incise cord in midline from T12 at a depth of 3 mm to S1 at a depth of 4 mm (preserving S2-S4 maintains bladder reflex pathways. Unilateral extension up to conus medullaris reduces bladder spasticity and increases capacity before reflex emptying occurs)

F. selective dorsal rhizotomy[42, 43]: uses intraoperative EMG and electrophysio-logical stimulation to eliminate sensory rootlets involved in "handicapping spasticity" (leaves rootlets subserving "useful spasticity" intact). Interrupts the afferent limb of pathologic reflex arc. May be temporary, but seems to persist at least ≈ 5 yrs. No effect on α–spasticity. Ambulatory children with cerebral palsy have improved gait, nonambulatory children are improved but are still not able to ambulate afterwards

G. stereotactic thalamotomy or dentatotomy: may be useful in cerebral palsy[44]. Useful for unilateral dystonia, but cannot be used for bilateral dystonia as bilateral lesions would be required which jeopardizes speech. Effective only for dystonia <u>distal</u> to shoulders or hips, and should not be used if the condition is rapidly progressive

3. ablative procedures, with <u>sacrifice</u> of potential for ambulation (in complete cord injuries, nonablative procedures are not indicated because there is no motor function to recover). Used after failure of percutaneous rhizotomy (*see above*) and "T" myelotomy (*see above*)

A. intrathecal injection of 6 ml of 10% phenol (by weight) in glycerin mixed with 4 ml of iohexol (Omnipaque® 300) (*see* *page 122*) for a final concentration of 6% phenol and ≈ 120 mg iodine/ml. Administered via LP at L2-3 interspace with patient in lateral decubitus position (most symptomatic side down) under fluoro until T12-S1 nerve root sleeves are filled (sparing S2-4 for bladder function). Patient is maintained in this position **x** 20-30 mins and then kept sitting upright **x** 4 hrs[45] (absolute alcohol provides more permanent blocks, but is hypobaric and more difficult to control)
B. selective anterior rhizotomy: results in flaccid paralysis with denervation atrophy of muscles
C. neurectomies, often combined with tenotomies[40]
D. intramuscular neurolysis by phenol injection[40]
E. cordectomy 46: most drastic measure, reserved for patients who do not respond to any other measure. Results in total flaccidity with loss of benefits from mild spasticity. Converts bladder from UMN to LMN control. Works well for progressive deficit from syringomyelia and for spasticity, but poor for "phantom" leg pain[47]
F. cordotomy: rarely used

Intrathecal baclofen[48-51]

Selection criteria used in one study[50] are shown in *Table 19-3*. Other indications include: CVA[52], cerebral palsy, TBI, dystonia, stiff-man syndrome.

Test doses: Incremental test doses of 50, 75, and then 100 mcg intrathecal baclofen **(ITB)** via lumbar puncture or temporary catheter were used[50], randomly alternated with placebo, with dose escalation halted if a response to active drug occurred. The following parameters were evaluated at 0.5, 1, 2, 4, 8 & 24 hrs post injection: pulse and respiratory rate, BP, hypertonia (Ashworth score, see *Table 19-2*, page 537), reflexes, spasm score, voluntary muscle movement, and adverse effects (if any, including seizures). Pump implantation was offered if there was a 2 point reduction in the Ashworth score and muscle spasm score for ≥ 4 hrs after bolus injection of active drug without intolerable side effects. Usual daily dose for ITB is twice the test dose, typically 200 micrograms/d.

Alternatively, give 25 mcg IT in the O.R., and if the patient improves, insert subcutaneous pump[37].

Table 19-3 Selection criteria for baclofen pump

• age 18-65 yrs (older patients treated on compassionate use basis)
• able to give informed consent
• severe, chronic spasticity (≥ 12 mos duration) due to spinal cord lesion or MS
• spasticity refractory to oral drugs (including baclofen), or unacceptable side effects
• no CSF block (e.g. on myelography)
• positive response to IT baclofen at test dose ≤ 100 µg and no response to placebo
• no implanted programmable device such as cardiac pacemaker*
• females of childbearing potential: not pregnant & using adequate contraception
• no hypersensitivity (allergy) to baclofen
• no history of stroke, impaired renal function, or severe hepatic or GI disease

* this study used a programmable IT pump

Pump systems: Available programmable systems include N'Vision, manufactured by Medtronic, Inc., Minneapolis, MN.

Insertion technique: IT catheter is typically inserted ≈ L2-3, and is threaded rostrally ≈ 3 levels, but should be no higher than T10 (risk of rostral progression of hypotonia).

Post-op orders: Guidelines for post-operative orders following baclofen pump insertion

1. admit PACU, transfer to:
   A. floor if insertion follows test dosing or if patient has just been transitioned from stable PO dose
   B. ICU if there has been a hiatus in baclofen therapy
2. neuro checks q 2 hrs for 1st 24 hours
3. baclofen:
   A. for patients on oral or IV baclofen: continue baclofen at the previous dose via the same route (oral or IV) until the ITB takes effect (usually 2-4 hrs, full effect is delayed up to 24 hrs). The IV/PO drug is then tapered
   B. if there has been a hiatus in baclofen therapy: baclofen 20 mg PO QID
4. have 2 vials of IV physostigmine available and labeled "FOR EMERGENCY USE ONLY" for possible baclofen overdose

Baclofen overdose:

1. ABCs (airway/breathing/circulation). Intubate if necessary
2. empty pump reservoir to stop drug flow (record amount withdrawn)

3. administer physostigmine if not contraindicated:
   A. ***Rx*** adult: 0.5-1.0 mg IM or IV @ rate ≤ 1 mg/min (may repeat q 10-30 minutes PRN)
   B. ***Rx*** peds: 0.02 mg/kg IM or IV @ rate ≤ 0.5 mg/min (may repeat q 5-10 min up to 2 mg max)
4. withdraw 30-40 ml CSF either via LP or through catheter access port
5. notify the pump manufacturer

Complications: Device-related complications are shown in *Table 19-4*. The frequency of most is ≈ 1%, except catheter-related problems which had a rate of ≈ 30% 50.

Complications related to the drug therapy itself include: overdosage problems (rostral progression of hypotonia, respiratory depression, coma, and seizures.

Table 19-4 ITB pump complications*

• mechanical problems
• pump underinfusion
• catheter problems: occlusion, kink, dislodgment, cut, break or disconnection
• wound complications
• pocket erosion
• incisional pain
• infection
• seroma (may require aspiration)
• CSF collection

* device-related complications requiring a secondary invasive procedure

Intrathecal baclofen withdrawal: Interruption of ITB therapy may occur as a result of: empty pump reservoir, pump battery failure, catheter migration/breakage/kinking/disconnection/occlusion, programming error. Steps in assessing the infusion system are shown in *Table 19-5*.

The severity of withdrawal syndrome depends on dose of drug used (increased with higher dose) and duration of therapy (increased with longer therapy).

Syndromes: with abrupt discontinuation of ITB

- mild withdrawal symptoms: return of spasticity and rigidity, tachycardia, piloerection (goosebumps) & pruritus
- more significant withdrawal symptoms: seizures & hallucinations
- severe withdrawal symptoms (estimated incidence: 3-5%)Coffey, 2002 #5531]:

increased rebound spasticity, rigidity, fever, labile BP, and reduced level of consciousness (resembling but distinct from malignant hyperthermia (*see* *page 5*) or neuroleptic malignant syndrome). If untreated, the severe syndrome can progress over 24-72 hours to rhabdomyolysis (with elevated creatine kinase (CK) and transaminase), hepatic and renal failure, DIC, and occasionally death

Table 19-5 Assessing ITB infusion systems

• interrogate the pump (with device programmer)
• refill reservoir with drug if empty (by experienced ITB practitioner)
• obtain AP & lateral x-rays to assess location of catheter tip and to look for breaks, kinks or migration

Management of abrupt ITB withdrawal syndrome[53]:

1. ABCs (airway/breathing/circulation). Intubate if necessary
2. primary goal is to reestablish ITB therapy at the same dose as soon as possible
3. assess pump/system as outlined in *Table 19-5*
4. early use of high-dose oral/enteral baclofen: ≥ 120 mg/d in 6-8 divided doses if the patient's condition permits (NB: PO baclofen is not reliable as the lone treatment for ITB withdrawal, and safety not established for age < 12 yrs)
5. attempt to restore ITB therapy at or near pre-withdrawal dosage by experienced physician by one of the following:
   A. using a programmed bolus through the pump
   B. via the catheter access port
   C. via LP
   D. via new externalized catheter
6. if restoration of ITB therapy is delayed and if symptoms persist
   A. move pt. to ICU if not already there
   B. parenteral benzodiazepine infusion: diazepam or midazolam. Titrate dose to reduce muscle rigidity, hyperthermia, BP lability, seizures
   C. cyproheptadine[54]: a serotonin antagonist. Start with 4 mg po q 6 hrs
   D. diphenhydramine 50 mg PO or IM, may repeat q 6 hrs for pruritus
   E. dantrolene may not be as effective as it is for malignant hyperthermia

If it is necessary to electively (or semi-electively) remove a pump system, the optimal scenario is to gradually taper the drug by reprogramming the pump and/or by filling the reservoir with solution of decreased baclofen concentration.

19.5. Torticollis

AKA wry neck. A form of dystonia resulting in a failure to control head position (if shoulders or trunk are also involved, *dystonia* is a more proper label).

A symptom of diverse causes. Differential diagnosis includes:

1. congenital torticollis (may be the initial presentation of dystonia musculorum deformans)
2. **spasmodic torticollis**, AKA wry neck: a specific subtype of torticollis that is idiopathic by definition. The shortened sternocleidomastoid **(SCM)** muscle is usually in spasm
3. extrapyramidal lesions (including degenerative): often alleviated by lying down; EMG shows abnormal grouped activity
4. psychogenic (often mentioned, seldom verified)
5. torticollis from atlantoaxial rotatory subluxation: (*see page 955*) the <u>elongated</u> SCM may be in spasm (opposite of that in spasmodic torticollis)
6. neurovascular compression of the 11th nerve (*see below*)
7. hemorrhage into sternocleidomastoid muscle (with subsequent contracture)
8. infection of the cervical spine
9. cervical adenitis
10. syringomyelia
11. cerebellar tumors in children
12. bulbar palsies
13. “pseudotorticollis” may develop as an unconscious correction to reduce diplopia that occurs with imbalance of extraocular eye musculature

Non-surgical treatment of torticollis

Should be attempted first, and includes:

1. relaxation training, including biofeedback
2. thorough neuropsychiatric evaluation
3. trans-epidermal neuro-stimulation **(TENS)** to the neck

Surgical procedures

Reserved for disabling, refractory cases. Includes:

1. dorsal cord stimulation
2. local injection of botulinum toxin: may work for retrocollis, is poor for lateral torticollis (must inject posterior cervicals and both SCM, and may cause temporary pharyngeal muscle dysfunction resulting in dysphagia), and is totally ineffective for anterocollis
3. selective rhizotomy and spinal accessory nerve section

Other treatments for torticollis include

1. stereotactic electrocoagulation of Forel's H_1 field

TORTICOLLIS OF 11TH NERVE ORIGIN

1. usually a horizontal type (manifests as horizontal head movement) which may be exacerbated when supine (unlike extrapyramidal torticollis)
2. contraction of SCM is usually accompanied by activity in contralateral agonist muscles
3. may be treated surgically. Procedures include
   A. sectioning of the anastomotic branches between the 11th nerve and the upper cervical posterior root (C_1 anastomotic branch is sensory only)
   B. microvascular decompression of the 11th nerve (most cases caused by vertebral artery, but PICA compression is also described[55]). Relief takes several weeks post-op

---

19.6. Neurovascular compression syndromes

Syndromes due to compression of cranial nerves at the root entry zone **(REZ)** (or in the case of motor nerves, root *exit* zone). The REZ (AKA Obersteiner-Redlich zone) is the point where central myelin (from oligodendroglial cells) changes to peripheral myelin (from Schwann cells).

Syndromes include:

1. trigeminal neuralgia (see *Trigeminal neuralgia*, page 551)
2. hemifacial spasm: *see below*
3. disabling positional vertigo
4. some forms of torticollis of 11th nerve origin (see *Torticollis* above)

19.6.1. Hemifacial spasm

Key concepts:

- intermittent unilateral painless contractions of facial muscles
- typically caused by compression of VII nerve by AICA
- along with palatal myoclonus: the only movement disorder that persists in sleep
- responds well to microvascular decompression, but risk of hearing loss is ≈ 20%

Hemifacial spasm **(HFS)** is a condition of intermittent, painless, involuntary, spasmodic contractions of muscles innervated by the facial nerve in one side of the face only. May be limited to the upper or lower half of the face only, and excess lacrimation may be present. HFS usually begins with rare contractions of the orbicularis oculi, and slowly progresses to involve the entire half of the face and increases in frequency until the ability to see out of the affected eye is impaired.

HFS may be associated with trigeminal neuralgia, geniculate neuralgia (see *Tic convulsif* page 564), or vestibular and/or cochlear[56] nerve dysfunction.

HFS is more common in women, is seen more often on the left, and usually presents after the teenages. Auditory function testing reveals abnormal acoustic middle ear reflex in almost half of patients, indicating some degree of VIII compromise[56].

Meige's syndrome: hemifacial spasm with oral movements.

HFS and **palatal myoclonus** are the only involuntary movement disorders that persist during sleep[57].

ETIOLOGIES

1. vascular compression syndrome (*see below*): the most common etiology (much more common than with trigeminal neuralgia)
2. idiopathic
3. tumor compressing the nerve
4. can follow some cases of Bell's palsy
5. conditions that can mimic HFS
    A. **blepharospasm** (bilateral spasmodic closure of the orbicularis oculi

muscles) which is more common in the elderly, and may be associated with organic brain syndrome. Blepharospasm is notorious for disappearing when the patient presents for medical evaluation (an effect of alerting), but may be elicited by asking patient to gently close the eyes and then rapidly open them, following which a blepharospasm may occur. HFS usually involves more than the ocular muscles

B. **facial myokymia**: *continuous* facial spasm which may be a manifestation of an intrinsic brainstem glioma or of multiple sclerosis. Often associated with other findings

Vascular compression

HFS is usually caused by compression of the facial nerve at the root exit zone **(REZ)** by a vessel, which is most often an artery (most commonly AICA[58] (either pre- or postmeatal[59]), but other vascular possibilities include an elongated PICA, SCA, a tortuous VA, the cochlear artery, a dolichoectatic basilar artery, AICA branches…), aneurysm, a vascular malformation, and rarely, veins have been implicated. In typical HFS (onset in the orbicularis oculi, and progressing downward over the face), the vessel impinges on the antero-caudal aspect of the VII/VIII nerve complex, in atypical HFS (beginning in the buccal muscles and progressing upward over the face) the compression is rostral or posterior to VII[60].

Vessels contacting the REZ of the vestibular nerve may cause vertigo, whereas tinnitus or hearing loss may result from cochlear nerve REZ compression.

Infrequently, benign tumors or a cyst in the cerebellopontine angle, multiple sclerosis, adhesions, or osseous skull deformities will be the cause of HFS.

Evidence indicates that there is not cross (ephaptic) conduction at the compressed REZ, but that the facial motonucleus is involved secondarily as a result of the REZ compression, via a phenomenon similar to kindling[61]. In addition to the spasm, a 2nd electro-physiological phenomenon associated with HFS is **synkinesis**, where stimulation of one branch of the facial nerve results in delayed discharges through another branch (average latency: 11 mSec[62]).

EVALUATION

In typical cases of HFS, the diagnostic work-up is negative.

Most patients should have MRI of the posterior fossa (CT scan is less sensitive here) to R/O tumors or AVMs.

Vertebral angiography is usually not performed if imaging is normal. The neurovascular compression responsible for HFS usually cannot be identified on angiography.

TREATMENT

MEDICAL MANAGEMENT

HFS is generally a surgical condition. Early, mild cases may be managed expectantly. Carbamazepine and phenytoin are generally ineffective, unlike the situation with the causally similar condition of trigeminal neuralgia. Local injection of **botulinum toxin** (Oculinum®) may be effective in treating HFS and/or blepharospasm[63, 64]. Baclofen has been advocated but is not very effective.

SURGICAL MANAGEMENT

Many ablative procedures are effective for HFS (including sectioning of divisions of the facial nerve), however, this leaves the patient with some degree of facial paresis. The current procedure of choice for HFS is microvascular decompression **(MVD)** wherein the offending vessel is physically moved off of the nerve, and a sponge (e.g. Ivalon®, polyvinyl formyl alcohol foam) is interposed as a cushion. Other cushions may not prove to be as satisfactory (muscle may disappear, and Teflon felt may thin[65]).

Most often, the offending vessel approaches the nerve at a right angle, and causes grooving in the nerve. Compression must occur at the root exit zone; decompression of vessels impinging distal to this area is usually ineffective.

Operative risks: *see below*.

Post-operatively, there may be episodes of mild HFS, however they usually begin to diminish 2-3 days following MVD. Severe spasm that does not abate suggests failure to achieve adequate decompression, and reoperation should be considered.

Surgical results of MVD depends on the duration of symptoms (shorter duration has better prognosis) as well as on the age of the patient (elderly patients do less well). Complete resolution of HFS occurred in 44 (81%) of 54 patients undergoing MVD, however, 6 of these patients had relapse[66]. 5 patients (9%) had partial improvement, and 5 (9%) had no relief.

Technique of MVD

Intraoperative brainstem auditory evoked potential (BAER)[67], or more applicable, direct VIII nerve monitoring[68] may help prevent hearing loss during MVD for 7th or 8th nerve dysfunction. Furthermore, monitoring for the disappearance of the (delayed) syn-kinetic response may aid in determining when adequate decompression has been achieved (generally reserved for teaching institutions)[61].

For a diagram of the normal anatomy of the CPA, see *Figure 5-8*, page 90. The facial nerve should not be manipulated, and one should avoid dissection around the VII and VIII nerves near the IAC[69]. Vessels must be preserved, especially the cochlear artery and small perforators.

Place gentle medial traction on the cerebellum (< 1 cm is recommended[69]), and incise the arachnoid membrane between the flocculus and the eighth nerve (to avoid tension on nerves that could cause post-op deficit). The IX nerve may be followed medially from the jugular foramen to locate the origin of the VII nerve (the origin of VII is 4 mm cephalad and 2 mm anterior to that of the IX nerve[70]).

SURGICAL RESULTS

Complete resolution of spasm occurs in ≈ 85-93%[65, 71-74]. Spasm is diminished in 9%, and unchanged in 6%[74]. Of 29 patients with complete relief, 25 (86%) had immediate post-op resolution, and the remaining 4 patients took from 3 mos to 3 yrs to attain quiescence.

Recurrence

Return of symptoms after a period of complete resolution of HFS occurs in up to 10% of patients, 86% of recurrences happen within 2 yrs of surgery, and the risk of developing recurrence after 2 yrs of post-op relief is only ≈ 1%[74].

Surgical complications

1. ipsilateral hearing loss: may occur from traction injury or a vasospasm
   A. total hearing loss occurs in ≈ 13% (range: 1.6-15%) (2.8% in one series[56], 15% in another series[66])
   B. partial hearing loss: 6%
2. facial weakness
   A. transient: 18%
   B. permanent facial weakness: 6%[72]

3. ataxia in 1-6%
4. other complications that are minor or temporary include:
   A. aseptic meningitis (AKA hemogenic meningitis) in 8.2%
   B. hoarseness or dysphagia in 14%
   C. CSF rhinorrhea in 0.3%
   D. perioral herpes in 3%[69]

19.7. Hyperhidrosis

Either essential (primary, or idiopathic) or secondary (etiologies include: hyperthyroidism, diabetes mellitus, pheochromocytoma, acromegaly, parkinsonism, CNS trauma, syringomyelia, hypothalamic tumors, menopause)[75].

Due to overactivity of eccrine sweat glands (found over entire body, highest concentration in palms and soles of feet). They produce a hypotonic secretion with saline as the primary constituent. These glands are under control of the sympathetic nervous system, however, the neurotransmitter is paradoxically acetylcholine (i.e. they are cholinergic, unlike most sympathetic end organs which are adrenergic). Most eccrine sweat glands serve a thermoregulatory function, however, those on the palms and soles respond primarily to emotional stress[75].

Essential hyperhidrosis is a generalized condition that usually manifests mostly in the palms. The incidence is unknown, although it was ≈ 1% in an Israeli study (probably high).

Treatment

Mild cases are treated medically with:

1. topical agents: astringents (potassium permanganate, tannic acid…) or antiperspirants (contact dermatitis usually limits use of these agents)
2. or systemically with anticholinergics: including atropine, probantheline bromide… (side effects of dry mouth and blurred vision usually limits use of these)
3. tap water iontophoresis: may produce keratinization of palmar epithelium

Severe cases refractory to medical therapy may be candidates for surgical sympathectomy (*see below*).

19.8. Tremor

Thalamotomy or thalamic stimulation may be useful for tremors that are refractory to medical treatment (including parkinsonian (*see page 534*), essential[76, 77], cerebellar and post-traumatic)[30].

19.9. Sympathectomy

Cardiac sympathectomy

With the advances in percutaneous coronary artery techniques, cardiovascular surgery and drugs, cardiac sympathectomy for angina pectoris has found less application. However, it may still be useful in patients who have no further treatment options. Bilateral sympathectomy from the stellate ganglion through the T7 ganglia is required. Newer thoracoscopic techniques may revive some interest in this.

UPPER EXTREMITY SYMPATHECTOMY

Various pathologies that may be indications for upper extremity sympathectomy are shown in *Table 19-6*.

Removal of the only second thoracic ganglion is probably adequate, and avoids a Horner's syndrome in most. Techniques used include: anterior transthoracic, thoracic endoscopic[78], percutaneous radiofrequency, and supraclavicular. An approach via a midline posterior incision with a T3 costotransversectomy allows bilateral access[75, 79]. The risk of significant complications is ≈ 5% and include pneumothorax, intercostal neuralgia, spinal cord injury, and Horner's syndrome.

Table 19-6 Indications for UE sympathectomy

- essential hyperhidrosis
- primary Raynaud's disease
- shoulder-hand syndrome
- intractable angina
- ± causalgia major (*see page 576*)

UPPER THORACIC SYMPATHECTOMY

Approaches include:

1. posterior paravertebral approach
2. axillary thoracotomy with transthoracic exposure of the sympathetic chain
3. supraclavicular, retropleural exposure
4. percutaneous radiofrequency technique[80, 81]
5. video endoscopic approach[82]

LUMBAR SYMPATHECTOMY

Primary indication is for causalgia major of the lower extremity. Preoperative lumbar sympathetic blocks may be utilized to evaluate patient for response.

Removal of the L2 and L3 sympathetic ganglion is usually adequate to remove sym-pathetic tone from the lower extremities (occasionally L1 and sometimes T12 are also removed for causalgia of the thigh).

The most common approach is a retroperitoneal approach through a flank incision. The patient is placed in a lateral oblique position, and the skin incision is made from the anterior superior iliac spine to the tip of the 12th rib. The peritoneum is dissected from the muscular wall and is retracted anteriorly. The kidney and ureter are retracted anteriorly; injury to the ureter being a major risk of the operation. The sympathetic chain is identified on the lateral aspect of the vertebral bodies. The vena cava makes a right-sided approach more difficult as the aorta is easier to deal with on left-sided approaches.

20. Pain

For pain medication, see *Analgesics*, page 44.

Major types of pain:

1. nociceptive
   A. somatic: well localized. Described as sharp, stabbing, aching or cramping. Results from tissue injury or inflammation, or from nerve or plexus compression. Responds to treating the underlying pathology or by interrupting the nociceptive pathway
   B. visceral: poorly localized. Poor response to primary pain medications
2. deafferentation: poorly localized. Described as crushing, tearing, tingling or numbness. Also causes burning dysesthesia numbness often with lancinating pain, and hyperpathia. Unaffected by ablative procedures
3. "sympathetically maintained" pain and the likes (e.g. causalgia): *see page 576*

20.1. Neuropathic pain syndromes

Definition: Neuropathic pain: pain caused by a lesion of the peripheral and/or central nervous system manifesting with sensory symptoms and signs[A].

A. Backonja[1] modified from the International Association for the Study of Pain[2]

Neuropathic pain syndromes **(NPS)** are typified by painful diabetic neuropathy **(PDN)** and postherpetic neuralgia **(PHN)**. Common chronic NPSs are shown in *Table 20-1*[3], divided into central or peripheral nervous system origin of the pain. The pain of PDN and PHN is typically burning and aching, and is continuous. and is characteristically refractory to medical and surgical treatment.

Table 20-1 Common neuropathic pain syndromes

Peripheral neuropathic pain
acute & chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)
alcoholic polyneuropathy
chemotherapy induced polyneuropathy
complex regional pain syndrome (CRPS)
entrapment neuropathies
HIV sensory neuropathy
iatrogenic neuralgias (e.g. postthoracotomy pain)
idiopathic sensory neuropathy
neoplastic nerve compression or infiltration
nutritional-deficiency neuropathies
painful diabetic neuropathy (PDN)
phantom limb pain
postherpetic neuralgia (PHN)
postradiation plexopathy
radiculopathy toxic exposure-related neuropathies
trigeminal neuralgia
posttraumatic neuralgias
Central neuropathic pain
cervical spondylotic myelopathy
HIV myelopathy
multiple sclerosis-related pain
Parkinson disease-related pain
postischemic myelopathy
postradiation myelopathy
poststroke pain
posttraumatic spinal cord injury pain
syringomyelia

MEDICAL TREATMENT OF NEUROPATHIC PAIN

Treatment traditionally includes narcotic analgesics[4], and tricyclic antidepressants (*see below*). For further details and other treatment measures, *see page 796* for PDN, and *page 565* for PHN.

Tricyclic antidepressants: Use is often limited by anticholinergic and central effects and by limited pain relief[5, 6]. Possibly because serotonin potentiates the analgesic effect of endorphins and elevates pain thresholds, serotonin re-uptake blockers are more effective than norepinephrine re-uptake blockers, e.g. tranzodone (Desyrel®) blocks only serotonin. Also useful: amitriptyline (Elavil®) 75 mg daily; desipramine (Norpramin®) 10-25 mg/d; doxepin (Sinequan®) 75-150 mg/d. Some benefit may also derive from the fact that many patients with chronic pain are depressed. **SIDE EFFECTS:** anticholinergic effects and orthostatic hypotension, especially in the elderly. ✖ Not recommended for use in patients with ischemic heart disease.

Gabapentin: Effective in postherpetic neuralgia **(PHN)** (*see page 566*) and

painful diabetic neuropathy. Benefit also reported in pain associated with: trigeminal neuralgia, cancer[7], multiples sclerosis, HIV-related sensory neuropathy, CRPS, spinal cord injury, post-operative state[8], migraine[9] (a number of these studies may have been sponsored by the manufacturer[10]). See *page 416* for side effects, dosing & availability…

Lidocaine patch (Lidoderm®): may be effective[3]. ***Rx***: apply patch for up to 12 hrs/day up to a maximum of 3 patches at a time to the intact skin over the most painful area (may trim patch to appropriate size). **SUPPLIED**: 5% lidocaine (*see page 566*).

Tramadol (Ultram®): A centrally acting analgesic[3] (*see page 47*).

20.2. Craniofacial pain syndromes

Possible pathways for facial pain include: trigeminal nerve (portio major as well as portio minor (motor root)), facial nerve (usually deep facial pain), and eighth nerve[11]. Etiologies (adapted[12 (p 2328), 13]).

1. cephalic neuralgias
    A. trigeminal neuralgia (*see below*)
        1. vascular compression of V at root entry zone: the most common cause
        2. MS: plaque within V nerve
    B. glossopharyngeal neuralgia: pain usually in base of tongue and adjacent pharynx (*see page 563*)
    C. geniculate neuralgia: otalgia and deep prosopalgia (*see page 563*)
    D. **tic convulsif**: geniculate neuralgia with hemifacial spasm (*see page 564*)
    E. occipital neuralgia: *see page 804*
    F. superior laryngeal neuralgia: a branch of the vagus, results primarily in laryngeal pain and occasionally pain on the auricle
    G. sphenopalatine neuralgia
    H. herpes zoster: pain is continuous (not paroxysmal). Characteristic vesicles and crusting usually follow pain, most often in distribution of V_1 (isolated V_1 TGN is rare). In rare cases without vesicles, diagnosis may be difficult

I. postherpetic neuralgia (Ramsay-Hunt syndrome): *see page 564*
J. supraorbital neuralgia (SON) (*see page 562*)
K. trigeminal neuropathic pain (AKA trigeminal deafferentation pain)[13]: may follow injuries from sinus or dental surgery, head trauma
L. trigeminal deafferentation pain: follows trigeminal denervation including therapeutic measures to treat trigeminal neuralgia[13]
M. short-lasting unilateral neuralgiform headache with conjunctival injection and tearing **(SUNCT)**[14]: rare. Usually affects males 23-77 years old. Brief (< 2 minutes) pain (burning, stabbing or shock-like) usually near the eye, occurring multiple times per day. Associated autonomic findings (the "hallmark of SUNCT"): ptosis, conjunctival injection, lacrimation[A], rhinorrhea, hyperemia. May be due to CPA AVM. Microvascular decompression or trigeminal rhizotomy may be effective in some cases refractory to medical treatment with AEDs or corticosteroids

2. ophthalmic pain
   A. Tolosa-Hunt syndrome (*page 837*): painful ophthalmoplegia
   B. (Raeder's) paratrigeminal neuralgia (*page 838*): unilateral Horner's syndrome + trigeminal neuralgia
   C. orbital pseudotumor (*page 837*): proptosis, pain, and EOM dysfunction
   D. diabetic (oculomotor) neuritis
   E. optic neuritis
   F. iritis
   G. glaucoma
   H. anterior uveitis
3. otalgia (*see below*)
4. masticatory disorders
   A. dental or periodontal disease
   B. nerve injury (inferior and/or superior alveolar nerves)
   C. temporo-mandibular joint **(TMJ)** dysfunction
   D. elongated styloid process
   E. temporal & masseter myositis
5. vascular pain syndromes
   A. migraine headaches: see *Migraine*, page 57
      1. simple migraine

a. classic
b. common
2. complicated migraine
a. hemiplegic
b. ophthalmoplegic
B. cluster H/A (subtypes: episodic, chronic, chronic paroxysmal hemicrania) (*see page 58*)
C. giant cell arteritis (temporal arteritis): *see page 74*. Tenderness over STA
D. toxic or metabolic vascular H/A (fever, hypercapnia, EtOH, nitrites, hypoxia, hypoglycemia, caffeine withdrawal)
E. hypertensive H/A
F. aneurysm or AVM (due either to mass effect or hemorrhage)
G. carotidynia: e.g. with carotid dissection (*see page 1162*)
H. basilar dolichoectasia with fifth n. compression or indentation of the pons
6. sinusitis (maximally, frontal, ethmoidal, sphenoidal)
7. dental disease
8. neoplasm: may cause referred pain or fifth nerve compression
A. extracranial
B. intracranial tumor: primarily posterior fossa lesions, neoplastic compression of trigeminal nerve usually causes sensory deficit (see *Tumors and trigeminal neuralgia*, page 552)
9. atypical facial pain **(AFP)** (prosopalgia): traditionally a "wastebasket" category used for many things. It has been proposed[13] to reserve this term for a psychogenic disorder. May be suspected by
10. primary (nonvascular) H/A: including
A. tension (muscle contraction) H/A
B. post-traumatic H/A

A. lacrimation (the most common) or other autonomic signs may occur in V1 trigeminal neuralgia but are usually mild, and appear only in the later stages of the condition and with long lasting attacks[15]. Dramatic lacrimation and conjunctival injection from the onset of symptoms with SUNCT are the best characteristics to distinguish this from trigeminal neuralgia[16]. May also occur in cluster headache (*see page 58*)

Otalgia

Because of redundant innervation of the region of the ear, primary otalgia may have its source in the 5th, 7th, 9th, or 10th cranial nerves or the occipital nerves[17]. As a result, sectioning of the 5th, 9th or 10th nerve or a component of the 7th (nervus intermedius, chorda tympani, geniculate ganglion) has been performed with varying results[18]. Also, microvascular decompression **(MVD)** of the corresponding nerve may also be done[19].

Work-up includes: neurotologic evaluation to rule out causes of secondary otalgia (otitis media or externa, temporal bone neoplasms…). CT or MRI should be done in any case where no cause is found.

Primary otalgia

Primary otalgia is unilateral in most (≈ 80%). Trigger mechanisms are identified in slightly more than half, with cold air or water being the most common[18]. About 75% have associated aural symptoms: hearing loss, tinnitus, vertigo. Pain relief upon cocainization or nerve block of the pharyngeal tonsils suggests glossopharyngeal neuralgia (*see page 563*), however, the overlap of innervation limits the certainty.

An initial trial with medications used in trigeminal neuralgia (carbamazepine, phenytoin, baclofen…, *see page 552*) is the first line of defense. In intractable cases not responding to pharyngeal anesthesia, suboccipital exploration of the 7th (nervus intermedius) and lower cranial nerves may be indicated. If significant vascular compression is found, one may consider MVD alone. If MVD fails, or if no significant vessels are found, Rupa et al. recommend sectioning the nervus intermedius, the 9th and upper 2 fibers of 10th nerve, and a geniculate ganglionectomy (or, if glossopharyngeal neuralgia is strongly suspected, just 9th and upper 2 fibers of 10th)[18].

20.2.1. Trigeminal neuralgia

Key concepts:

- sharp. electric shock-like paroxysmal lancinating pain in the distribution of one or more branches of the trigeminal nerve on <u>one side</u>
- characterized by periods of remission and initial response to carbamazepine
- neurologic exam must be intact (only exception: mild sensory loss)
- 80-90% of cases are caused by compression of the trigeminal nerve at the

root entry zone by the superior cerebellar artery (SCA). In MS patients, may be due to MS plaque (MS patients are usually less responsive to procedures)
- 75% will ultimately fail medical therapy and require a procedure (main options: microvascular decompression, percutaneous rhizotomy or radiosurgery). Choice of modality depends on patient age, location of symptoms, prior treatment…

Trigeminal neuralgia **(TGN)** (AKA **tic douloureux**): paroxysmal lancinating electric-like pain lasting a few seconds, often triggered by sensory stimuli, confined to the distribution of one or more branches of the trigeminal nerve (*see Figure 20-1*) on one side of the face, with no neurologic deficit. The term "**atypical facial pain**" **(AFP)** is sometimes used to describe any other type of facial pain.

Rarely, TGN manifests as **status trigeminus**, a rapid succession of tic-like spasms triggered by seemingly any stimulus. IV carbamazepine (where available) or phenytoin may be effective for this.

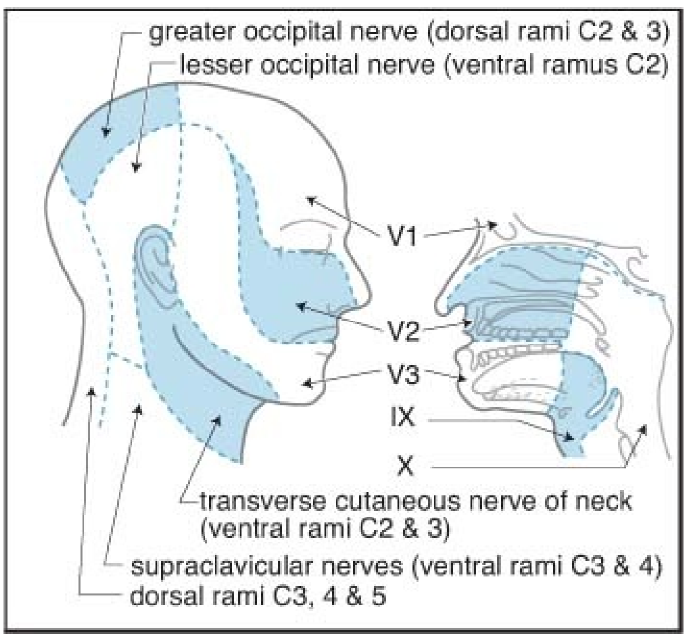

Figure 20-1 Pain/temperature innervation of the head*

* **KEY: V1** = ophthalmic nerve; V2 = maxillary nerve; V3 = mandibular nerve; IX = glossopharyngeal nerve; X = vagus

Epidemiology

See *Table 20-2*. Annual incidence 4/100,000. There is no correlation with herpes simplex infection[20]. There is a tendency for spontaneous remission with

pain free intervals of weeks or months being characteristic, regardless of treatment. 2% of patients with MS have TGN[21], whereas ≈ 18% of patients with bilateral trigeminal neuralgia have MS[22].

Pathophysiology

Probably due to ephaptic transmission in trigeminal nerve from large-diameter partially demyelinated A fibers to thinly myelinated A-delta and C (nociceptive) fibers. Pathogenesis may be due to:

1. vascular compression of the trigeminal nerve at the root entry zone (NB: compression may be seen in up to 50% of autopsies in patients without TGN[25]):
   A. most commonly (80%) by the SCA (see *Neurovascular compression syndromes*, page 542 for more details)
   B. persistent primitive trigeminal artery[26] (*see page 107*)
   C. dolichoectatic basilar artery[27 (p 1108)]
2. posterior fossa tumor (see *Tumors and trigeminal neuralgia* below)
3. in MS, plaque within brainstem may cause TGN that is often poorly responsive to microvascular decompression

In addition to the sensory division of the trigeminal nerve, other possible pain path-ways include[11]: the motor branch of the 5th nerve (portio minor), or the 7th or 8th nerve.

Evaluation

MRI is often used to evaluate these patients for possible intracranial tumors or MS plaques, especially in cases with atypical features. The yield in typical cases is low.

Table 20-2 Epidemiology of trigeminal neuralgia[23, 24]

age (years)	typically > 50 (average 63)
female:male	1.8:1
Laterality	
right	60%
left	39%
both	1%
Division involved	
V1 only	2%

V2 only	20%
V3 only	17%
V1 & V2	14%
V2 & V3	42%
all three	5%

Differential diagnosis

See *Craniofacial pain syndromes* on page 549.

History and physical (in addition to routine)

- history
  A. accurate description of pain localization to determine which divisions of trigeminal nerve need to be treated
  B. determine time of onset of TGN, trigger mechanisms
  C. ascertain presence and length of pain-free intervals (lack of any pain-free interval is atypical for TGN)
  D. determine duration, side-effects, dosages, and responses to medications tried
  E. inquire about symptoms that may indicate the presence of conditions other than TGN: e.g. history of herpetic vesicles, excessive tearing of the eye (may indicate SUNCT (*page 549*)), facial twitching (tic convulsif), tongue pain (glossopharyngeal neuralgia), sensory loss (tumor…), progressive relentless pain (tumor, herpes…), symptoms that suggest MS
- physical exam: the exam should be normal in TGN, any neurologic deficit (except very mild sensory loss) in previously unoperated patient should prompt search for structural cause, e.g. tumor (*see below*). This exam also serves as a baseline for post-op comparison
  A. assess sensation in all 3 divisions of trigeminal nerve bilaterally (include corneal reflexes)
  B. assess masseter function (bite) and pterygoid function (on opening mouth, chin deviates to weak side)
  C. assess EOM function

Tumors and trigeminal neuralgia

In > 2000 patients with facial pain seen over 10 yrs, only 16 harbored tumor

(< 0.8% incidence)[28]. 3 tumors outside cranial vault included nasal carcinoma and skull base mets; all had hypalgesia and AFP. 6 middle fossa tumors included 2 meningiomas, 2 schwannomas (1 primary tumor of Gasserian ganglion), and 1 pituitary adenoma. Posterior fossa tumors are the most likely to cause symptoms that most closely resemble true TGN; of these, vestibular schwannoma **(VS)** is most common. 2 of 7 VSs had tumors contralateral to the neuralgia (presumably due to brainstem shift). Patients with true TGN initially responded to carbamazepine, none with AFP did.

When facial pain is caused by tumor, especially with peripheral tumors, the pain is frequently atypical (usually constant), neurologic abnormalities are often present (usually sensory loss, although some are neurologically normal at first), and the age is often younger than typical TGN.

MEDICAL THERAPY FOR TRIGEMINAL NEURALGIA

carbamazepine (Tegretol®) DRUG INFO

Complete or acceptable relief in 69% (if 600-800 mg/d are tolerated and give no relief, diagnosis of TGN is suspect[21]). **SIDE EFFECTS:** Drowsiness. Rash in 5-10%. Possible Stevens-Johnson syndrome. Relative leukopenia is common (usually does not require discontinuing drug). See precautions under *carbamazepine (CBZ) (Tegretol®)* on page 411.

Rx 100 mg PO BID, increase by 200 mg/d up to maximum of 1200 mg/d divided TID. **SUPPLIED**: *see page 411*.

oxcarbazepine (Trileptal®) DRUG INFO

Rapidly metabolized to carbamazepine, similar efficacy, often tolerated at higher doses than carbamazepine. **SIDE EFFECTS:** symptomatic hyponatremia.

Rx for trigeminal neuralgia: 300 mg PO BID, increase by 600 mg/d q week. Usual dose: 450-1200 mg. Maximum of 2400 mg/d. **SUPPLIED**: 150, 300, 600 mg tablets; 500 mg/5-ml suspension.

baclofen (Lioresal®) DRUG INFO

2nd DOC (not as effective as carbamazepine, but fewer side-effects).

Caution: teratogenic in rats. Avoid abrupt withdrawal (can cause hallucinations and seizures). May be more effective if used in conjunction with low dose carbamazepine.

Rx Start low, 5 mg PO TID, increase q 3 d by 5 mg/dose; not to exceed 20 mg QID (80 mg/d); use smallest effective dose.

gabapentin (Neurontin®) **DRUG INFO**

An anticonvulsant (*see page 416*), may act synergistically with carbamazepine and baclofen. **SIDE EFFECTS:** include ataxia, sedation and rash.

Rx start with 100mg po BID, titrate to 5-7mg/kg/day (3600 mg/d max).

MISCELLANEOUS DRUGS

Also possibly effective:

1. phenytoin (Dilantin®): may be useful IV in patients in too much pain to open their mouths to take carbamazepine orally (*see page 409* for dosages)
2. capsaicin (Zostrix®): 1 gm applied TID for several days resulted in remission of symptoms in 10 of 12 patients (4 relapsed in < 4 mos, but remained pain free for 1 yr after 2nd course)[29]
3. clonazepam (Klonopin®): works in 25% (*see page 415*)
4. lamotrigine (Lamictal®)
5. amitriptyline (Elavil®): more commonly used for atypical facial pain
6. **botulinum toxin** (Botox®): reduces transmission of CGRP producing a direct effect on the sensory nerve fibers

SURGICAL THERAPY FOR TRIGEMINAL NEURALGIA

Reserved for cases refractory to medical management, or when side effects of medications exceed risks and drawbacks of surgery.

SURGICAL OPTIONS

1. peripheral trigeminal nerve branch procedures to block or ablate the division involved with pain, or can be used to block the trigger[30]:
   A. means of blocking
      1. local blocks (phenol, alcohol) s
      2. neurectomy of trigeminal branch involved

B. nerve branches:
   1. V1 (ophthalmic division) at the supraorbital, supratrochlear, or infraorbital nerves
   2. V2 (maxillary division) at the foramen rotundum
   3. V3 (mandibular division) block at the foramen ovale, or neurectomy of inferior dental nerve
2. blocking the trigger: either via percutaneous rhizotomy or alcohol block
3. **percutaneous trigeminal rhizotomy (PTR)**: AKA percutaneous (stereotactic) rhizotomy **(PSR)** of trigeminal (Gasserian) ganglion (*see below*) (not truly a stereotactic procedure in the current sense of the word, therefore the term *percutaneous trigeminal rhizotomy* is preferred). Objective is to selectively destroy A-delta and C fibers (nociceptive) while preserving A-alpha and beta fibers (touch). Ideally, a retrogasserian lesion (not a ganglionic lesion). May also be used to block trigger. Lesioning techniques include (*see below* for comparison of techniques):
   A. radiofrequency rhizotomy **(RFR)** (originated by Sweet and Wespic[31]). Uses radiofrequency energy to thermocoagulate the pain fibers. Requires the patient to be awake at intervals during the procedure
   B. glycerol injection into Meckel's cave[32, 33]: possibly lower incidence of sensory loss and anesthesia dolorosa than with radiofrequency lesion[34]. Water soluble contrast cisternography was recommended in original description, may not be essential[35]
   C. mechanotrauma (percutaneous microcompression **(PMC)** rhizolysis): via inflation of No. 4 Fogarty catheter balloon[36-38]. Does not require the patient to be awake
   D. injection of sterile boiling water
4. intradural retrogasserian trigeminal nerve section (sensory portion ± motor root, *see below*): may be performed during MVD if no vascular compression is identified
5. cutting descending trigeminal tract in lower medulla (99.5% success): rarely used
6. microvascular decompression **(MVD)**[39]: (*see below*) microsurgical exploration of root entry zone, usually via posterior fossa craniectomy, and displacement of vessel impinging on nerve (if such a vessel is found). Usually with the placement of a non-absorbable "insulator" (Ivalon® sponge or shredded Teflon felt - see *page 543* for relative merits of Ivalon® vs. Teflon felt)

7. complete section of the nerve proximal to the ganglion via a p-fossa crani
8. stereotactic radiosurgery: *see below*
9. motor cortex stimulation[40]: (somewhat analogous to spinal cord stimulation for spinal or extremity pain). Better for neuropathic trigeminal pain (as distinct from trigeminal neuralgia)

SELECTION OF SURGICAL OPTION

Some pearls that influence treatment option choices (expert opinion[41]):

1. V3 neuralgia: RF. Can selectively treat V3 without involving other divisions
2. V1 or V2: balloon compression. Causes numbness in all 3 divisions, but unlike RF the corneal numbness is better tolerated and the corneal reflex is often preserved
3. bilateral pain: glycerol. It has the shortest duration of effect, which is an advantage if you think you may need to treat the other side at some point
4. SRS: due to latency until pain relief, suboptimal for patients who need immediate pain relief

Peripheral nerve ablation and neurectomies

Limited to pain or trigger points in territory of supraorbital/supratrochlear, infraorbital, or inferior dental nerves. Neurectomy may be a consideration especially for elderly patients who are not candidates for MVD (neurectomy may be done under local anesthesia) with pain in the forehead (to avoid anesthesia of the eye, as could occur with RFR). Disadvantages include sensory loss in the distribution of the nerve and a high rate of pain recurrence due to nerve regeneration (usually in 18-36 months) which often responds to repeat neurectomy[42]. May also be used following PTR.

Supraorbital and supratrochlear nerve: For information on supraorbital neuralgia (SON) or supratrochelar neuralgia (STN), *see page 562*. SON may be treated with rhizotomy (e.g. with alcohol or radiofrequency) or with neurectomy. Alcohol injection is used with caution for STN because of risk of injury to the superior oblique muscle. For neurectomy, these nerves are exposed through a 2 cm incision parallel to and just above the medial portion of the eyebrow (never through the eyebrow as this can create an unsightly “bi-brow”; shaving the eyebrow is also discouraged since it occasionally does not grow back). The incision is carried down to the bone and the periosteum is elevated caudally towards the supraorbital foramen or notch. The nerves will be visible on the

undersurface of the periosteal flap. The supraorbital nerve is freed in its foramen/notch, and is then avulsed by grasping it with a mosquito hemostat and twisting the clamp. The nerve avulses "like pulling a worm out of a hole". The distal portion of the nerve should be located at the site were the periosteum was incised and it, too, should be avulsed. The process can be repeated for the more medially situated supratrochlear nerve.

Other nerves: Not covered here, other nerve branches that may be cut or avulsed include: infratrochlear, lacrimal (the branch of V_1 at the lateral edge of the orbit), infraorbital nerve, inferior alveolar, lingual and mental nerves[43] (p 290).

Percutaneous trigeminal rhizotomy (PTR)

Recommended for patients who: are poor risk for general anesthesia (elderly or those with increased risk for general anesthesia), wish to avoid "major" surgery, have unresectable intracranial tumors, have MS, have impaired hearing on the other side, or have limited life expectancy (< 5 yrs)[34]. For "atypical facial pain", denervating the painful region of the face benefits < 20% of patients, and worsens 20%[44]. Recurrences are easily treated by repeat procedures. May be used to treat failures of peripheral nerve ablation.

Choice of lesion technique:

Recurrence rates and incidence of dysesthesias are comparable among the various lesioning techniques. Incidence of intraoperative hypertension is less with PMC than with radiofrequency rhizotomy **(RFR)** lesion[38] (no reports of intracerebral hemorrhage). Bradycardia occurs regularly with PMC which may not be harmful (some prophylax with atropine[45]). RFR requires a patient who is able to cooperate; PMC can be done with the patient asleep. Paralysis of ipsilateral trigeminal motor root (e.g. pterygoids) is more common after PMC (usually temporary) than RFR, and so PMC should not be done if there is already contralateral paralysis from a previous procedure. See *page 556* for technique.

Microvascular decompression (MVD)

(For more details, *see page 559*).

Recommended for patients with inadequate medical control of pain with > 5 years anticipated survival and able to tolerate a small craniotomy[34] (surgical morbidity increases with age). Relief is often long lived, persevering 10 yrs in 70%. Incidence of facial anesthesia is much less than with PTR, and anesthesia

dolorosa does not occur. Mortality: < 1%. Incidence of aseptic meningitis (AKA hemogenic meningitis): 20%. 1-10% major neurologic morbidity. Failure rate: 20-25%.

1-2% of patients with MS will have a demyelinating plaque at the root entry zone, this usually does not respond to MVD, and one should attempt a PTR.

Stereotactic radiosurgery (SRS)

The first use of SRS by Leksell was for the treatment of TGN. Initially, this was reserved for refractory cases following multiple operations[46], now becoming more widely practiced. The least invasive procedure. Generally recommended for patients with comorbidities, high-risk medical illness, pain refractory to prior surgical procedures, or those on anticoagulants (anticoagulation does not have to be reversed to have SRS).

Treatment plan: 4 -5 mm isocenter in the trigeminal nerve root entry zone identified on MRI. Use 70-80 Gy at the center, keeping the 80% isodose curve outside of the brainstem.

Results: Significant pain reduction after initial SRS: 80-96%[47-50], but only ≈ 65% become pain free. Median latency to pain relief: 3 months (range: 1 d-13 months)[51]. Recurrent pain occurs within three years in 10-25%. Patients with TN and multiple sclerosis are less likely to respond to SRS than those without MS. SRS can be repeated, but only after four months following the original procedure.

Favorable prognosticators: higher radiation doses, previously unoperated patient, absence of atypical pain component, normal pretreatment sensory function[52].

Side effects: Hypesthesia occurred in 20% after initial SRS, and in 32% of those requiring repeat treatment[51] (higher rates associated with higher radiation doses[48]).

MANAGEMENT OF TREATMENT FAILURES

90% of recurrences are in distribution of previously involved divisions; 10% are in new division and may represent progression of the underlying process. Some treatment failures are not persistent TN, but rather represent trigeminal neuropathic pain (AKA trigeminal deafferentation pain).

PTR may be repeated in patients who have a recurrence with some preservation of facial sensation. Attempted repeat PTR is often productive, and failures can be managed as below.

MVD may be performed in patients failing PTR, but the success rate may be reduced[53] (91% for patients undergoing MVD first, vs. 43% for those having MVD following PTR[A]). Repeat MVD may also be performed, with attention given to possible slippage of the insulating sponge, or the fact that the true offending vessel may be “artificially” moved away from the nerve secondary to the surgical positioning.

A. 91% may be an unrealistically high success rate, and taking patients that fail PTR may select for a more difficult subgroup

SRS can be repeated, using the same dose, with reported significant reduction in pain in 89%, and complete relief in 58%[51].

Intradural retrogasserian trigeminal nerve section

May be used as a measure of last resort in patients who have recurrent TGN following one or more PTRs in the presence of total facial anesthesia, or in patients undergoing posterior-fossa craniectomy for the purpose of MVD when no impinging vessel can be identified. In the latter case, a partial rhizotomy is performed by sectioning 2/3 of nerve, with resulting partial anesthesia. In the case of patients with facial anesthesia pre-op, consideration should be given to sectioning the motor division (portio minor) as an alternate pain pathway[11].

PERCUTANEOUS TRIGEMINAL RHIZOTOMY (PTR)

Due to concerns about hemorrhage, check coagulation profile (PT/PTT, consider bleeding time), and discontinue ASA and NSAIDs, preferably 10 days pre-op. Procedure may be performed in OR with fluoro, or in angiography suite in x-ray department.

BOOKING THE CASE - PERCUTANEOUS TRIGEMINAL RHIZOTOMY

BOOKING

(For any of the percutaneous methods: balloon, glycerol, RFR)
Also see defaults & disclaimers (*page v*) and pre-op orders (*see below*).

1. position: supine
2. anesthesia: MAC with sedation
3. equipment:

A. lesion generator and needle kit for radiofrequency rhizotomy
B. C-arm fluoroscopy (2 C-arms for balloon compression)
C. calibrated inflatable balloons (as in kyphoplasty) for balloon rhizotomy

4. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: put a needle into the cheek to numb the nerve to the face
   B. alternatives: medical treatment, surgery through the back of the skull (microvascular decompression), radiation (stereotactic radiosurgery)
   C. complications: facial numbness is anticipated, rarely: stroke, bleeding, blindness

PRE-OP ORDERS (RFR)

1. NPO after MN except meds
2. continue Tegretol® & other meds PO with sips of water
3. AM of procedure: IV NS @ KVO in arm contralateral to neuralgia
4. atropine 0.4 mg IM PRN (✖ contraindications include rapid a-fib)
5. non-disposable LP tray to accompany patient

TECHNIQUE PERCUTANEOUS TRIGEMINAL RADIOFREQUENCY RHIZOTOMY ***(RFR)***

Adapted technique[54]. NB: needle insertion and/or lesioning may cause HTN, consider monitoring BP. Use either a straight electrode (bare 5 mm for 1 division, 7.5 mm for 2 divisions, or 10 mm for total lesions) or a curved electrode[55].

Electrode insertion

1. attach ground electrode to patient's upper arm
2. prep the cheek on the involved side with Betadine
3. entry point: under short-acting anesthetic agent (e.g. propofol (Diprivan® - *see page 24*) or methohexital (Brevitol® - *see page 24*), insert electrode-needle **2.5-3 cm lateral to oral commissure**
4. trajectory:
   A. palpate the buccal mucosa with a gloved finger inside the mouth (lateral to the teeth) and with the other hand pass the electrode medial to the coronoid process of the mandible (keeping the needle deep to the oral mucosa, i.e. outside the oral cavity) initially aiming towards the plane intersecting a point **3 cm anterior to EAM** and the **medial**

aspect of the pupil when the eye is directed forward. Be careful not to contaminate the field with the hand that was in the patient's mouth

B. as insertion progresses, use fluoroscopy to direct the tip towards the intersection of the top of the petrous bone with the clivus (5-10 mm below floor of sella along clivus)

C. upon entering foramen ovale the masseter often contracts, causing the jaw to briefly close. Remove the stylet, look for CSF to verify location (may not occur in re-do cases), and insert electrode through needle

In difficult cases, intraoperative fluoroscopy may assist in localizing the needle to Meckel's cave and to R/O e.g. entry into superior orbital fissure (which can cause blindness after lesioning), or entry into foramen spinosum (middle meningeal artery). If necessary to visualize (e.g. when there is difficulty entering), the foramen ovale is optimally seen on a submental x-ray by hyperextending neck 20° and rotating head 15-20° away from side of pain[56].

Impedance measurements: from the tip of the electrode when available may help indicate location of needle tip. Impedance: CSF (or any fluid) low (≈ 40-120 Ω); connective tissue, muscle, or nerve is usually 200-300 Ω (may be up to 400 Ω); if > 400 Ω this likely indicates electrode is contacting periosteum or bone. After starting the lesion, impedance often goes down by 30 Ω transiently, and then as the lesioning continues it gradually returns to baseline or ≈ 20 Ω above it. If char develops on the electrode tip, the impedance will read higher than where it started.

Stimulation and repositioning

Once the foramen ovale is entered, the needle is positioned with the following guidelines: for V3 division lesion the curved electrode should be just short of the clivus and pointing down, for V2 it is at the clivus and directed up, for V1 it is 5 mm beyond clivus and pointing up. ✖ At no time should the needle tip extend > 8 mm beyond clival line (to avoid Cr. N. III or VI complications).

The patient is allowed to wake up and is stimulated through the electrode with the following settings: frequency = 50-75 Hz, 1 mS duration, start at 0.1 V amplitude and slowly increase (usually 0.2-0.5 V is adequate, higher voltages may indicate that the needle is not near the target and that stimulation is due to far-field currents, however, in previously lesioned patients up to 4 V may sometimes be necessary). If stimulation does not reproduce pain in the distribution of the patient's TGN, then the amplitude is returned to 0, the electrode is repositioned (straight electrode: advance needle < 5 mm at a time,

until the tip is in the vicinity of the clival line; curved tip electrode: advance and/or rotate) and then slowly elevate the voltage again from 0 and repeat the repositioning-stimulating process until stimulation reproduces the distribution of tic pain. If previous lesions have produced analgesia and the patient cannot feel the stimulating current, one may stimulate at 2 Hz. and watch for masseter twitch (requires preserved motor root).

Lesioning

When stimulation produces pain in the involved distribution of the TGN, perform the first lesion under short-acting anesthesia at 60-70° C **x** 90 sec. A facial flush may be noted[56]. After every lesion, perform a post-lesion assessment (*see below*). The goal is analgesia (but not anesthesia) in the areas of tic pain and hypalgesia in areas of trigger points. An average of three lesions are necessary at the first sitting, each ≈ 5° C higher than the previous for 90 seconds. Anesthetic may not be needed after the first lesion if moderate analgesia has been produced by previous lesions.

Post-lesion assessment

After each lesion and at completion of procedure, assess:

1. sensitivity to pinprick and light touch in all three divisions of trigeminal nerve (grading: normal, hypalgesic, analgesic, anesthetic)
2. corneal reflex bilaterally
3. EOM function
4. masseter muscle strength (patient clenches teeth, palpate cheeks for contraction)
5. pterygoid muscle strength (ask patient to open mouth, chin deviates towards side of pterygoid weakness)

Post-op care (PTR)

Include in post-op orders:

1. ice pack to face on side of procedure for 4 hrs
2. soft diet
3. routine activity when alert
4. avoid narcotics (usually not necessary)
5. if corneal reflex impaired: risk of neuroparalytic keratitis. Natural tears 2 gtt q 2 hrs while awake to eye on affected side. Lacrilube® to eye & tape

eye shut q hs

Prior to discharge from hospital, repeat post-lesion assessment (*see above*). Patients are then weaned off of carbamazepine as tolerated.

PERCUTANEOUS MICROCOMPRESSION RHIZOLYSIS BALLOON (PMC)

Via inflation of No. 4 Fogarty catheter balloon.

Technique

1. the needle is placed as with RFR (*see page 556*).
2. aim for balloon placement in the medial foramen ovale (to avoid entering the middle fossa). After placing the balloon, insert the stylet to visualize where the balloon will go. Use Omnipaque 240 to fill the balloon
3. inflate to 1.4 atmospheres of pressure

COMPLICATIONS[A]

1. mortality: only 17 deaths in over 22,000 procedures (includes lesser experienced neurosurgeons and patients often considered poor surgical risks)[21]
2. dysesthesias[24] (sometimes called "annoying paresthesias"): higher rate in more complete lesions
   A. minor: 9%
   B. major (requiring medical treatment): 2%
   C. **anesthesia dolorosa** (severe, constant, burning aching pain that is refractory to all treatment): 0.2-4%
3. meningitis[23]: 0.3%
4. alterations in salivation[57]: 20% (increased in 17%, decreased in 3%)

	------850 cases[55]------		315 cases[57]
	straight electrode (N = 700)	curved electrode (N = 150)	
5. partial masseter weakness (usually not perceived by patient)	15-24%	7%	50%
6. oculomotor paresis (usually temporary)	2%	0	
7. reduced hearing (secondary to paresis of tensor tympani)	0	0	27%
8. **neuroparalytic keratitis** (keratitis due to fifth nerve deficit which impairs sensation)	4%	2%	0

9. intracranial hemorrhage: personal report of 7 cases (6 fatal) in > 14,000 procedures, probably due to transient HTN (SBP up to 300 torr)
10. alterations in lacrimation[57]: 20% (increased in 17%, decreased in 3%)
11. herpes simplex eruption: prescribe antiherpetic drug if patient develops symptoms (e.g. Acyclovir® - *see page 360*)
12. bradycardia and hypotension: 1% with RFR, up to 15% with glycerol injection
13. rare[58, 59]:
    A. temporal lobe abscess
    B. intracerebral abscess: 0.1%
    C. aseptic meningitis
    D. trigeminal trophic syndrome **(TTS)**[60]: triad of unilateral crescentic nasal alar ulceration with anesthesia and paresthesia of the trigeminal dermatome (may present with severe pruritus and self-induced skin lesions from scratching). A result of trigeminal nerve injury. Treatment has included: carbamazepine, diazepam, amitriptyline, chlorpromazine, clonazepam or pimozide[61]
    E. complications related to needle placement[62]:
        1. carotid cavernous fistula **(CCF)**: may occur with any percutaneous technique[63] (including balloon microcompression[64])
        2. injury to other cranial nerves: II, III, IV, VI[65]
        3. blindness: from penetration of inferior orbital fissure[66]
    F. subarachnoid hemorrhage
    G. seizures

A. NB: some “numbness” is actually expected in most successful PTRs and occurs in 98% of cases[24], and is not considered a complication here

Table 20-3 Comparison of outcomes of percutaneous techniques to MVD

Parameter	Percutaneous techniques (PTR)			MVD
	RFR*	Glycerol	Balloon	
initial success rate[11, 24]	91-99%	91%	93%	85-98%
medium-term recurrence rate	19% at 6 yrs[23]	54% at 4 yrs	21% at 2 yrs	15% in 5 yrs
long-term recurrence rate	80% at 12 yrs[57] †			30% at 10 yrs
facial numbness[24]	98%	60%	72%	2%

* abbreviations: RFR = radiofrequency rhizotomy; MVD = microvascular decompression; balloon = balloon microcompression

† this author included initial failures to PTR requiring repeat procedures during same hospitalization

Results (PTR)

Results of various PTR techniques compared to microvascular decompression **(MVD)** are shown in *Table 20-3*. Recurrence rate is higher in patients with multiple sclerosis (50% at 3 yrs mean F/U)[67].

MICROVASCULAR DECOMPRESSION (MVD) FOR TRIGEMINAL NEURALGIA

Indications:

1. patients unable to achieve adequate medical control of trigeminal neuralgia with ≥ 5 yrs anticipated survival, without significant medical or surgical risk factors[34] (although a small p-fossa exploration is usually well tolerated, surgical morbidity increases with age)
2. may be used in patients who do not fit the above criteria, but have intractable pain and fail PTR
3. patient with tic involving V1 for whom the risk of exposure keratitis due to corneal anesthesia would be unacceptable (e.g. already blind in contralateral eye) or patient wishing to avoid facial anesthesia for any reason

✖ patients with MS are usually not considered candidates for MVD due to low response rate

Booking the case - microvascular decompression

Also see defaults & disclaimers (*page v*) and pre-op preparation (*see below*).

1. position: park bench
2. equipment: microscope
3. implants: Ivalon sponge or shredded Teflon
4. intra-op monitoring: (optional) BAER, possible nervus intermedius
5. consent (in lay terms for the patient - not all-inclusive):
   A. procedure: surgery behind the ear to move a blood vessel from the sensory nerve of the face, if no offending vessel can be identified then possible partial sectioning of the appropriate part of the trigeminal nerve with associated numbness)
   B. alternatives: needle procedures through the cheek (percutaneous rhizotomy), radiation (stereotactic radiosurgery)
   C. complications: (in addition to usual craniotomy complications), CSF leak, hearing loss, facial numbness, pain near incision (occipital neuralgia or lesser occipital neuralgia), rarely: diplopia, facial paralysis, failure of the procedure

Technique

Also see *Paramedian suboccipital craniectomy*, page 154 for important pointers, including use of armored endotracheal tube.

Preoperative preparation

An MRI is recommended to rule-out mass lesion or vascular abnormality. Baseline BAER are performed by some[68] (*see below* for intra-op monitoring).

O.R. setup

Setup for lateral oblique suboccipital (posterior-fossa) craniotomy (*see page 154*). Microscope: observer's eyepiece is placed on the side opposite to that of the tic.

Positioning[69]

- lateral oblique position (*see page 154*), symptomatic side up, axillary roll
- thorax elevated 10-15° to reduce venous pressure

- 3-pin skull fixation. Head position:
  - ♦ head rotation: head rotated just slightly away from the affected side
  - ♦ lateral head tilt
    - for trigeminal neuralgia or VIII nerve approach: the head is parallel to the floor (if it is lower, nerves VII & VIII will obscure view of V)
    - for VII nerve or lower, the vertex is tilted 15° <u>down</u> from the horizontal
  - ♦ flex neck: leave 2 fingerbreadths room between the chin and the sternum
- upper shoulder retracted caudally with adhesive tape
- option: lumbar spinal drain. Drain 20-30 cc during craniotomy, then drain off small amounts from time-to-time during the case to keep the field mostly dry, but occasionally letting CSF build up to bathe cranial nerves

Intra-operative monitoring

Option: intraoperative monitoring of facial EMG and BAER (assesses acoustic nerve)[68].

Approach

1. skin incision[69]: vertical incision 3-5 cm in length, 5 mm medial to mastoid notch (a small "5-6-4" incision - *see page 155*) (in thick or short-necked patients, a slightly longer incision that angles inferomedially is used). 75% of the incision is inferior to the transverse sinus, 25% superior
2. burr hole:
   A. 1 cm inferior and 1 cm medial to the asterion[70] pp 60
   B. if the asterion is not easily identified or if there are concerns about the reliability of the asterion as a landmark for the junction of the transverse and sigmoid sinuses[71], place the burr hole directly over the mastoid emissary vein which drains superolaterally into the sigmoid sinus
3. craniotomy: top of bone opening as close as possible to transverse sinus. The position of the **transverse sinus** can be approximated by a line drawn from the posterior base of the zygomatic process to the inion, or roughly ≈ 2 finger-breadths above the upper end of the mastoid notch. Lateral limit of bone opening is sigmoid sinus. A triangular bony opening with a leg along each sinus works well. Craniectomy diameter needs to be only ≈ 3

cm. Apply bone wax liberally (blocks off any possible opening into the mastoid air cells)

4. dural opening: either a curvilinear with each end at a sinus and the convexity away from the junction (Jannetta) or an inverted "T" (with one incision towards each sinus and the third towards junction of sinuses)

Technique

- minimal or no retraction of cerebellum is usually required
- allow CSF to drain before proceeding: this may require gentle advancement of a cottonoid in the CPA. A lumbar drain should be placed if CSF cannot be drained
- follow the junction of tentorium with temporal bone deep. Place a retractor that both medially displaces the cerebellum and slightly "lifts" the cerebellum towards the surgeon (medial displacement alone is not as effective)
- petrosal vein: coagulate and divide the petrosal vein complex (usually 2-3 veins connecting to the tentorial dura). If the vein is torn, the dural side is tamponaded (sometimes up to 30 minutes is needed) while the free end is coagulated
- V is deeper than the VII/VIII complex, which should not even be seen with this approach. If VII/VIII are seen, move the retractor superiorly as even gentle traction may cause hearing loss (see *Figure 5-8*, page 90). There is often a hillock of bone just posterior to Meckel's cave obscuring the site where the fifth nerve enters the cave
